Background: Toxins such as LvIA can help elucidate the physiological roles of nAChR subtypes.

Results: Three residues in the $\beta 2$ subunit were identified as critical to LvIA binding.

Conclusion: The β complementary subunit plays a crucial role in the subtype selectivity of α -conotoxin LvIA.

Significance: This study provides new insights into the unique selectivity of LvIA and more broadly into toxin-receptor interactions.

α -Conotoxin LvIA (α -CTx LvIA) is a small peptide from the venom of the carnivorous marine gastropod *Conus lividus* and is the most selective inhibitor of $\alpha 3\beta 2$ nicotinic acetylcholine receptors (nAChRs) known to date. It can distinguish the $\alpha 3\beta 2$ nAChR subtype from the $\alpha 6\beta 2^*$ (* indicates the other subunit) and $\alpha 3\beta 4$ nAChR subtypes. In this study, we performed mutational studies to assess the influence of residues of the $\beta 2$ subunit versus those of the $\beta 4$ subunit on the binding of α -CTx LvIA. Although two $\beta 2$ mutations, $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K], strongly enhanced the affinity of LvIA, the $\beta 2$ mutation $\alpha 3\beta 2$ [V111I] substantially reduced the binding of LvIA. Increased activity of LvIA was also observed when the $\beta 2$ -T59L mutant was combined with the $\alpha 3$ subunit. There were no significant difference in inhibition of $\alpha 3\beta 2$ [T59I], $\alpha 3\beta 2$ [Q34A], and $\alpha 3\beta 2$ [K79A] nAChRs when compared with wild-type $\alpha 3\beta 2$ nAChR. α -CTx LvIA displayed slower off-rate kinetics at $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K] than at the wild-type receptor, with the latter mutant having the most pronounced effect. Taken together, these data provide evidence that the $\beta 2$ subunit contributes to α -CTx LvIA binding and selectivity. The results demonstrate that Val¹¹¹ is critical and facilitates LvIA binding; this position has not previously been identified as important to binding of other 4/7 framework α -conotoxins. Thr⁵⁹ and Phe¹¹⁹ of the $\beta 2$ subunit appear to interfere with LvIA binding, and their replacement by the corresponding residues of the $\beta 4$ subunit leads to increased affinity.

Nicotinic acetylcholine receptors (nAChRs),³ which comprise many different molecular subtypes, are ligand-gated ion channels that are activated by the endogenous neurotransmitter acetylcholine (ACh) or exogenous nicotine (1, 2). nAChRs are found in the neuromuscular junction, and in peripheral and central nervous systems throughout the animal kingdom, and play important roles in regulating synaptic transmission (3–9). Neuronal nAChRs are pentameric membrane-bound proteins, which are made up of α ($\alpha 2$ – $\alpha 10$) and β ($\beta 2$ – $\beta 4$) subunits (10). Pharmacological properties of the heteromeric nAChRs are influenced by the presence of $\beta 2$ and/or $\beta 4$ subunits (11). This study is part of an ongoing effort to elucidate the physiological role of each subtype of nAChR and the key binding residue determinants for selective ligands (12).

α -Conotoxins (α -CTxs) are a rich source of highly selective ligands that discriminate among different nAChR subtypes (13–15). α -CTxs contain two conserved disulfide bridges and are classified into several structural subfamilies according to the number of residues in the two backbone loops bracketed by cysteine residues, the largest subfamilies being the 4/7, 4/6, 4/5, 4/4, 4/3, and 3/5 α -CTxs. The 4/7 α -CTxs are able to discriminate between diverse neuronal α - β nAChR subunit combinations and stoichiometries (16, 17).

Previous research revealed that some of the 4/7 α -CTxs, such as α -CTx MII, PnIA, and BuIA, bind to a small conserved cleft of the $\alpha 3\beta 2$ nAChR, and the $\beta 2$ subunit contributes to binding and selectivity (18, 19). This cleft contains the ligand-accessible residues $\beta 2$ Leu¹²¹, Val¹¹¹, Phe¹¹⁹, and Thr⁵⁹, which act as a common binding site/pocket for 4/7 α -CTxs (18, 19). α -CTx MII from *Conus magus* is a potent antagonist of $\alpha 3\beta 2$ and $\alpha 6\beta 2^*$ (* indicates the other subunit) nAChRs (20). The α -CTx PnIA is selective on the $\alpha 3\beta 2$ and $\alpha 7$ nAChRs (21). α -CTx BuIA from *Conus bullatus* blocks both $\beta 2^*$ (* indicates the other subunit) and $\beta 4^*$ (* indicates the other subunit) nAChRs, and kinetically distinguishes between them with long and short off-times

$\beta 2$ Subunit Contribution to α -CTx LvIA Binding of $\alpha 3\beta 2$ nAChR

(22). The 4/7 α -CTx LtIA targets a novel microsite and has a shallow binding site on the $\alpha 3\beta 2$ nAChR that includes $\beta 2$ Lys⁷⁹ outside of the cleft (23). This indicates that different key residues of the $\beta 2$ subunit are targeted by different α -CTxs to block the $\alpha 3\beta 2$ nAChR (19, 24).

α -CTx LvIA from *Conus lividus* was recently characterized and has high affinity for $\alpha 3\beta 2$ nAChRs, with an IC_{50} of 8.7 nM (25). LvIA is notable for its ability to selectively block $\alpha 3\beta 2$ versus $\alpha 6/\alpha 3\beta 2\beta 3$ or $\alpha 3\beta 4$ nAChRs. The residues in the $\beta 2$ subunit that contribute to α -CTx LvIA binding to the $\alpha 3\beta 2$ nAChR remain unknown. We therefore performed a mutational study of the $\alpha 3\beta 2$ nAChR in which we assessed the influence of residues that line the $\beta 2$ subunit on the binding of α -CTx LvIA.

EXPERIMENTAL PROCEDURES

Materials—Reagents for peptide synthesis were from GL Biochem (Shanghai, China). Reversed-phase HPLC analytical Vydac C18 column (5 μ m, 4.6 \times 250 mm) and preparative C18 Vydac column (10 μ m, 22 \times 250 mm) were from Grace Vydac (Hesperia, CA). Clones of rat $\alpha 3$, $\beta 2$, and $\beta 4$ cDNAs were kindly provided by S. Heinemann (Salk Institute, San Diego, CA).

Peptide Synthesis—A two-step oxidation protocol was used to synthesize α -CTx LvIA as described previously (25). Because this protocol worked well, we did not attempt a simpler one-step oxidation approach. In this protocol, linear (see Fig. 1A) and folded (see Fig. 1B) peptides were purified by HPLC on a reversed-phase C18 Vydac column. HPLC elution conditions included a linear gradient of 0–40% solvent B over 40 min. Solvent A was 0.075% trifluoroacetic acid in H₂O. Solvent B was 0.05% TFA, 90% acetonitrile in H₂O. Absorbance was monitored at 214 nm.

Mutagenesis and Construction of Chimeric $\beta 2$ Point Mutation Receptors—Point mutants of nAChR $\beta 2$ subunit cDNA (see Table 1) were created using PCR and the QuikChange site-directed mutagenesis kit (Stratagene) according to the manufacturer's instructions. Primers that contained the desired point mutation as well as at least 15 bases on either side of the mutation were synthesized. The mutagenic primers were extended and incorporated by PCR. DpnI was then used to digest the methylated, non-mutated parental cDNA. The point mutated DNA was inserted in the pSP65 or pGEMHE vector, which was transformed into DH5 α -competent cells. All the PCR mutations were sequenced to confirm incorporation of the desired mutation (19). The nomenclature for the point mutants lists the naturally occurring residue position followed by the change made, e.g. $\alpha 3\beta 2$ [V111I] is a $\beta 2$ subunit with the valine residue at position 111 replaced by an isoleucine residue.

cRNA Preparation and Injection into *Xenopus laevis* Oocytes—Capped cRNA was synthesized *in vitro* following linearization of the plasmid containing template DNA encoding the rat $\alpha 3$, $\beta 2$, and $\beta 4$ subunits, as well as the various mutant subunits using the mMESSAGING mMACHINE *in vitro* transcription kit (Applied Biosystems/Ambion, Austin, TX), as described previously (20). The cRNA was purified using the Qiagen RNeasy kit (Qiagen). Their concentration was determined by absorbance at 260 nm. Mature *X. laevis* frogs were anesthetized by submersion in 0.1% 3-aminobenzoic acid ethyl ester, and oocytes were surgically removed. Two collagenase treatments lasting 1 h

were performed at room temperature to remove follicle cells. RNA transcripts of wild-type $\alpha 3$ subunit with either wild-type $\beta 2$ or mutant $\beta 2$ subunit were mixed at a molar ratio of 1:1. Fifty nl of this mixture with ~ 10 ng of each cRNA was injected into each *Xenopus* oocyte and incubated at 17 °C. Oocytes were injected within 1 day of harvesting.

Voltage-clamp Recording—Voltage-clamp recordings were performed 1–4 days after cRNA injection. All recordings were done at ~ 22 °C room temperature. Briefly, oocytes were voltage-clamped at -70 mV and exposed to ACh and peptide in a 30- μ l cylindrical oocyte recording chamber, which was gravity-perfused at a rate of 2 ml/min with ND-96 buffer. The ND-96 buffer consisted of 96.0 mM NaCl, 2.0 mM KCl, 1.8 mM CaCl₂, 1.0 mM MgCl₂, 1 μ M atropine, 5 mM HEPES, 0.1 mg/ml bovine serum albumin, pH 7.1–7.5. The oocyte was subjected once a minute to a 1-s pulse of 100 μ M ACh. Once a stable baseline was achieved, either ND-96 alone or ND-96 containing varying concentrations of the α -CTx LvIA was manually pre-applied in a static bath for 5 min prior to the addition of the agonist ACh pulse.

Data Analysis—Three to five ACh responses were averaged for the baseline responses of ND-96 after a 5-min incubation just preceding a test response, which was used to normalize evoked responses as a percentage of control response. The percentage of response of the toxin was divided by the pre-toxin baseline value to yield a percentage of response. The dose-response data were fitted to the equation: % of response = 100 / (1 + ([toxin]/ IC_{50})^{*nH*}), where *nH* is the Hill coefficient, using GraphPad Prism (GraphPad Software, San Diego, CA). Each data point of a dose-response curve is the average \pm S.E. from at least three oocytes. IC_{50} values were determined by nonlinear regression analysis using Graph-Pad Prism.

Molecular Modeling—A molecular model of the interaction between LvIA and the ligand-binding domain of $\alpha 3\beta 2$ nAChR was built by homology using the NMR solution structure of LvIA (Protein Data Bank (PDB) identifier 2mdq) and the crystal structure of the complex between acetylcholine-binding protein (AChBP) and conotoxin PnIA variant (PDB identifier 2br8) as templates, as described previously (25). The molecular model was refined by a 30-ns explicit water molecular dynamics simulation carried out with the GROMACS 4.6.5 (26) package and the ff03 force field (27), using a procedure described previously (28, 29). All the models of complexes involving $\beta 2$ subunit mutants were generated by substituting residue side chains using Modeler 9v14 (30). This procedure refines the positions of the substituted side chain atoms as well as of those of the neighbor residues using a conjugate gradient minimization followed by a short molecular dynamics simulation. The molecular models were refined by a 2-ns explicit water molecular dynamics simulation, and the simulations of the T59K, V111I, and F119Q mutants were extended to 10 ns.

RESULTS

Chemical Synthesis of α -CTx LvIA— α -CTx LvIA linear peptide (Fig. 1A) was successfully synthesized with Fmoc (*N*-(9-fluorenyl)methoxycarbonyl) chemistry, in which Cys residues were orthogonally protected using acid-labile *S*-trityl and acid-stable *S*-acetamidomethyl groups. The acid-labile groups (tri-

D, HPLC chromatograms of oxidized and folded α -CTx LvIA. Peptides were analyzed on a reversed-phase analytical Vydac C18 HPLC using a linear gradient of 0–40% Solvent B over 40 min, where Solvent A = 0.075% TFA and Solvent B = 0.05% TFA, 90% acetonitrile in H₂O. Absorbance was monitored at 214 nm. Flow rate was 0.75 ml/min. AU, absorbance units.

FIGURE 2. Amino acid sequence alignment of rat $\beta 2$ and $\beta 4$ nAChR subunits, which have 68.4% sequence identity in their ligand-binding domains. The positions that were mutated in this study, *i.e.* positions 34, 59, 79, 111, and 119, are indicated with arrows. Rectangles indicate the agonist-binding domain loops D, E, and F (3). The subunit positions that were shown to contact LvIA according to a previous molecular modeling study (Luo *et al.* (25)) are underlined.

tyl) were first removed after cleavage of the assembled peptide chain from the resin. The linear peptide after the initial cleavage was purified by HPLC with a retention time of 27.7 min (Fig. 1C). Ferricyanide was used to close the first disulfide bridge, and iodine oxidation was used to subsequently close the second disulfide bridge. The fully folded peptide of α -CTx LvIA with Cys¹–Cys³ and Cys²–Cys⁴ disulfide bonds (Fig. 1B) was purified again by HPLC, with a retention time of 27.9 min (Fig. 1D). The mass of the α -CTx LvIA matched that of the amidated sequence (calculated average mass, 1679.9 Da; observed, 1679.7). This synthesized fully folded peptide was utilized in all subsequent experiments.

Effect of Mutations of the $\beta 2$ Subunit on Block by α -CTx LvIA—Previous studies using molecular modeling of related toxins suggested the nAChR positions that form the ligand-binding pocket of α -conotoxins (23, 31, 32). The residue positions of the $\beta 2$ and $\beta 4$ subunits that were suggested to form the LvIA-binding pocket in a previous modeling study (25) are highlighted in Fig. 2. We created point mutations of the $\beta 2$ subunit where residues in this pocket were replaced with those

TABLE 1
IC₅₀ and Hill slope values for block of nAChRs by α -CTx LvIA

Subtypes	IC ₅₀ ^a	Ratio ^b	Hill slope

found in the homologous position of the $\beta 4$ subunit. These mutant receptors were then tested to determine toxin potency differences (Table 1). Seven nAChR $\beta 2$ mutants were created, including Q34A, T59I, T59K, T59L, K79A, V111I, and F119Q. The concentration-response block by α -CTx LvIA on $\alpha 3\beta 4$ nAChR and wild-type and mutant $\alpha 3\beta 2$ nAChRs was investigated (Table 1 and Fig. 3). The potency at wild-type $\alpha 3\beta 2$

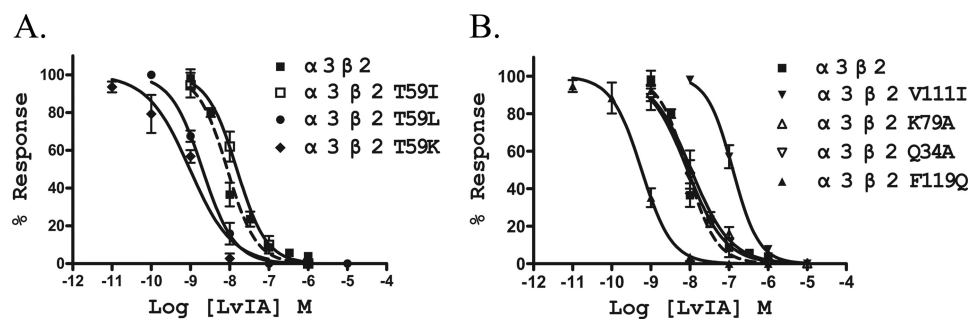

FIGURE 3. α -CTx LvIA dose-response curves for wild-type and mutant $\alpha 3\beta 2$ nAChRs. All seven mutant receptors exhibited similar sensitivity for ACh to wild-type $\alpha 3\beta 2$ nAChR. Values are mean \pm S.E. from a recording made using 5–9 separate oocytes. Results are summarized in Table 1.

TABLE 2

Recovery time after block by α -CTx LvIA

nAChR subtype	T_{95}^a	nAChR subtype	T_{95}^a
	min		min
$\alpha 3\beta 2$	<2	$\alpha 3\beta 2$ [T59L]	6–9
$\alpha 3\beta 2$ [K79A]	<1	$\alpha 3\beta 2$ [F119Q]	10–12
$\alpha 3\beta 2$ [V111I]	<1	$\alpha 3\beta 4$	20–26
$\alpha 3\beta 2$ [Q34A]	2–3	$\alpha 3\beta 2$ [T59K]	>>20 ^b
$\alpha 3\beta 2$ [T59I]	2–3		

^a Time to 95% recovery after toxin washout.

^b < 3% recovery after 20 min; concentration of α -CTx LvIA was 10 μ M.

nAChR was 17-fold greater than that at wild-type $\alpha 3\beta 4$ nAChR. Among the seven $\alpha 3\beta 2$ mutants, LvIA had the lowest activity on $\alpha 3\beta 2$ [V111I], with an IC_{50} of 126 nM, which is similar to the 148 nM IC_{50} on wild-type $\alpha 3\beta 4$. Thus, the $\beta 2$ subunit mutation V111I reduced the binding of LvIA to $\alpha 3\beta 2$ nAChR by 15-fold. There were no significant differences in LvIA potency on mutants $\alpha 3\beta 2$ Q34A, K79A, or T59I when compared with activity at wild-type $\alpha 3\beta 2$ nAChR (Table 1, Fig. 3).

Increased potency of α -CTx LvIA was observed at $\alpha 3\beta 2$ [F119Q], $\alpha 3\beta 2$ [T59K], and $\alpha 3\beta 2$ [T59L] nAChRs. LvIA potently blocked ACh-evoked currents of these nAChRs with IC_{50} values of 0.58, 0.96, and 2.03 nM, respectively (Table 1). The ratio between the IC_{50} values of wild-type and mutant $\alpha 3\beta 2$ nAChRs was 15 and 11 for $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K], respectively. The mutation T59L resulted in only a small increase (~ 4.3 -fold) of LvIA potency. The most LvIA-sensitive mutant, $\alpha 3\beta 2$ [F119Q], had a potency 2 orders of magnitude higher than that of the least sensitive mutant, $\alpha 3\beta 2$ [V111I] (Table 1, Fig. 3B).

LvIA is 255-fold less potent at $\alpha 3\beta 4$ than at $\alpha 3\beta 2$ [F119Q], and 154-fold less potent at $\alpha 3\beta 4$ than at $\alpha 3\beta 2$ [T59K]. Although introducing the $\beta 4$ residues Lys and Gln at positions 119 and 59, respectively, increased the potency of LvIA for $\alpha 3\beta 2$, this CTx is more potent at wild-type $\alpha 3\beta 2$ than $\alpha 3\beta 4$. A synergistic effect of binding site positions displaying different residues between the two subtypes might explain why LvIA is more active at $\alpha 3\beta 2$ than at $\alpha 3\beta 4$.

Mutations of the $\beta 2$ Subunit Affect Recovery Time after Block by α -CTx LvIA—The $\alpha 3\beta 2$ receptor mutants affected not only the potency of LvIA but also its recovery (Table 2, Fig. 4). α -CTx LvIA (10 nM) blocked wild-type $\alpha 3\beta 2$ nAChRs versus mutant receptors $\alpha 3\beta 2$ [F119Q], $\alpha 3\beta 2$ [T59K], and $\alpha 3\beta 2$ [V111I] to different degrees (Fig. 4). α -CTx LvIA at 10 nM blocked $\sim 55\%$ current of wild-type $\alpha 3\beta 2$ but produced little or no block of $\alpha 3\beta 2$ [V111I] (Fig. 4, A and B). In contrast, complete block of ACh-

evoked currents was obtained with 10 nM α -CTx LvIA on mutant receptors $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K] (Fig. 4, C and D).

We compared the recovery time (>95% initial current) after block by 10 μ M toxin for the wild-type and mutant receptors (Table 2). Recovery of wild-type $\alpha 3\beta 2$ nAChR was complete within 2 min after toxin washout. Thus, the $t_{1/2}$ was estimated to be <30 s, and this time scale is beyond the resolution of the experimental setup. Similarly the off-rates for $\alpha 3\beta 2$ [T59I], $\alpha 3\beta 2$ [K79A], $\alpha 3\beta 2$ [V111I], and $\alpha 3\beta 2$ [Q34A] were also rapid (full recovery in 1–3 min). The recovery time of wild-type $\alpha 3\beta 4$ nAChR was 20–26 min, which is slower than that of $\alpha 3\beta 2$ [F119Q] (10–12 min), but much faster than $\alpha 3\beta 2$ [T59K].

The three $\alpha 3\beta 2$ mutations, T59K, T59L, and F119Q, affected the off-rates of LvIA significantly, as evidenced by the corresponding receptors having much slower reversible block by LvIA than wild-type $\alpha 3\beta 2$ nAChR or mutants T59I, K79A, V111I, and Q34A. The recovery times of mutants $\alpha 3\beta 2$ [T59L] and $\alpha 3\beta 2$ [F119Q] were 6–9 and 10–12 min, respectively (Fig. 4C, Table 2), whereas $\alpha 3\beta 2$ [T59K] displayed the slowest recovery time, with less than 3% recovery 20 min after washout (Table 2). Even at low concentrations of LvIA (10–100 nM), $\alpha 3\beta 2$ [T59K] recovered very slowly from block. At 10 nM LvIA concentration, $\alpha 3\beta 2$ [T59K] recovered to $28 \pm 3.5\%$ current 20 min after washout, and at 100 nM concentration, only $13 \pm 2\%$ current was recovered 20 min after washout (Fig. 4D).

Molecular Modeling—A molecular model of the interactions between LvIA and the wild-type $\alpha 3\beta 2$ nAChR showed that the $\beta 2$ subunit positions considered for mutations are all potentially in contact with the conotoxin with the exception of position 34, as shown in Fig. 5A. LvIA had similar activity at wild-type and $\alpha 3\beta 2$ Q34A nAChR, in agreement with the absence of interaction of this position. The wild-type $\beta 2$ residue Lys⁷⁹ can form a surface salt bridge with LvIA Asp¹¹, and this interaction was found to be stable over a 30-ns molecular dynamics simulation (Fig. 5B). The three other substituted positions, *i.e.* positions 59, 111, and 119, are at least partly buried at the interface with LvIA. The change of activity of LvIA correlated with a change of buried surface solvent-accessible surface area at the interface for mutants of positions 59 and 119 (Fig. 5C). The molecular model did not provide a simple explanation for the decreased activity of LvIA at the V111I mutant, and we propose that this mutation could potentially result in conformational changes that cannot be modeled using short molecular dynamics simulations. The other mutated positions, *i.e.* 59 and 119, are located in β -strands, and the residues chosen for substitu-

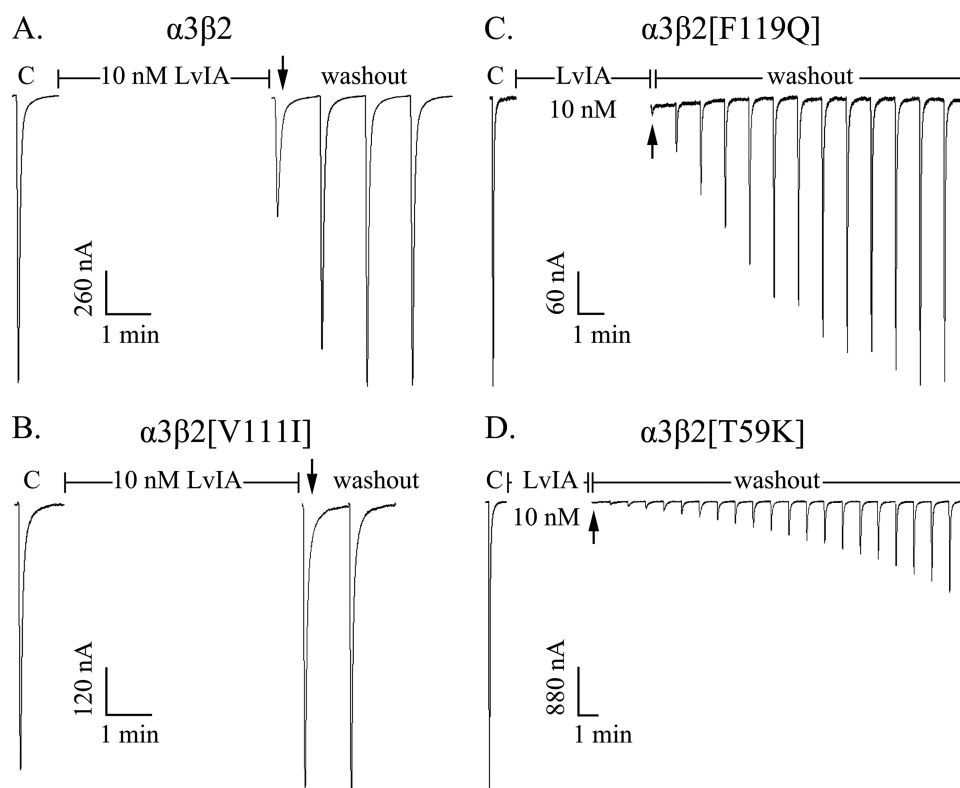

FIGURE 4. α -CTx LvIA differentially blocks wild-type $\alpha 3\beta 2$ nAChR (A) and mutant receptors $\alpha 3\beta 2$ [V111I] (B), $\alpha 3\beta 2$ [F119Q] (C), and $\alpha 3\beta 2$ [T59K] (D). The nAChRs display different reversibility kinetics after block. C indicates control responses to ACh. Oocytes were exposed to 10 nM peptide for 5 min followed by repetitive application of ACh. α -CTx LvIA at 10 nM blocked $\sim 55\%$ current of wild-type $\alpha 3\beta 2$ nAChR with rapid reversibility (A), but did not block $\alpha 3\beta 2$ [V111I] nAChR (B). LvIA at 10 nM blocked $\sim 100\%$ current of mutant receptors $\alpha 3\beta 2$ [F119Q] nAChR with slow reversibility (C) and $\alpha 3\beta 2$ [T59K] nAChR with slowest reversibility (D).

FIGURE 5. **Molecular modeling of the interaction between LvIA and $\alpha 3\beta 2$ wild-type and mutant nAChR.** A, binding of LvIA (white) into the rat wild-type $\alpha 3\beta 2$ -binding pocket, which comprises the $\alpha 3$ principal subunit (green) and the $\beta 2$ complementary subunit (blue). The conformation of the side chains of the $\beta 2$ positions that were mutated are displayed overlaid with those of the wild-type receptor. The side chains of the mutants are shown in different colors from those used for the wild-type structure. B, distance between the NZ atom of $\beta 2$ Lys⁷⁹ and the CG atom of LvIA Asp¹¹ over a 2-ns molecular dynamics simulation. C, correlation between the differences of buried solvent-accessible surface area between wild-type and mutant complexes (Δ BASA) and the IC_{50} for the $\alpha 3\beta 2$ mutants.

tions are not likely to disrupt this β -strand secondary structure. The 10-ns simulations of complexes incorporating the mutations T59K, V111I, or F1119Q resulted in similar binding modes with no change of binding site conformation (Fig. 6).

DISCUSSION

Neuronal nAChRs are widely expressed in the CNS and peripheral nervous system in adults and during development,

but the identification of which subtype is expressed in which nervous cell is challenging (33–38). LvIA is the first ligand to be highly specific for $\alpha 3\beta 2$ nAChR, and it could potentially be used in physiological studies of this receptor (25). We sought here to gain further insights into the binding interactions of LvIA at this receptor through mutations of positions that have been shown to be important for the binding of other α -CTxs and ligands (24, 39). These studies have shown that competitive nicotinic ligands of

$\beta 2$ Subunit Contribution to α -CTx LvIA Binding of $\alpha 3\beta 2$ nAChR

nAChRs generally bind to both the α subunits and the β subunits that form a ligand-binding interface (18, 32).

We investigated the influence of seven $\alpha 3\beta 2$ nAChR mutants on the binding of α -CTx LvIA. These residues were chosen

based on previous findings with the related α -CTx LtIA (23). Four mutants, $\alpha 3\beta 2$ [F119Q], $\alpha 3\beta 2$ [T59K], $\alpha 3\beta 2$ [T59L] and $\alpha 3\beta 2$ [V111I], had significantly different sensitivity than the wild-type receptor to α -CTx LvIA (Tables 1 and 2; Figs. 3 and 4). The three other mutations, Q34A, K79A and T59I, had little or no detectable effect on α -CTx LvIA activity (Tables 1 and 2; Figs. 3 and 4). α -CTx LvIA at 10 nM blocked $\sim 55\%$ of the current of wild-type $\alpha 3\beta 2$ with rapid reversibility but blocked $>95\%$ of the current of $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K]; the block of the latter two nAChRs had much slower reversibility after toxin washout when compared with that observed for the wild-type $\alpha 3\beta 2$ nAChR (Fig. 4). The substitution of Phe¹¹⁹ of the $\beta 2$ subunit by Gln, which is present in the homologous position of the $\beta 4$ subunit ($\alpha 3\beta 2$ [F119Q]), resulted in a 15-fold increase in α -CTx LvIA potency. The mutation T59K caused an 11-fold increase sensitivity for α -CTx LvIA, partly due to a decrease in off-rate (Fig. 4D). A similar finding has been reported for the 4/4 α -CTx BuIA (19). The potency of BuIA at $\alpha 3\beta 2$ [F119Q] and $\alpha 3\beta 2$ [T59K] increased 8- and 20-fold, respectively, when compared with wild-type $\alpha 3\beta 2$, with very slow off-rates. However, BuIA had a faster off-rate but similar IC_{50} at $\alpha 3\beta 2$ [V111I] versus wild-type $\alpha 3\beta 2$, in contrast to LvIA, which has a 15-fold decrease in potency at $\alpha 3\beta 2$ [V111I] when compared with wild-type $\alpha 3\beta 2$ (Table 3) (19). Thus, we suggest that BuIA and LvIA have overlapping, yet distinct binding interactions with the receptor. Overall our data suggest that the three positions on the receptor, 59, 111, and 119, are key to LvIA binding. Of course, because we examined only a finite number of mutations, we cannot exclude the possibility that other positions might also be important.

As far as ligand residues contributing to binding are concerned, the highly conserved Ser-Xaa-Pro motif in the first loop of α -CTxs contains a small α -helix important for nAChR binding. α -CTx LtIA is atypical because it lacks this Ser-Xaa-Pro motif and has been suggested to bind a novel microsite on the $\alpha 3\beta 2$ nAChR (19). α -CTx LtIA potentially interacts with $\beta 2$ Phe¹¹⁹ and $\beta 2$ Lys⁷⁹ because the Phe¹¹⁹ and Lys⁷⁹ mutants disrupted LtIA binding (19), but mutations of these positions were without effect for activity of α -CTxs MII, PnIA, and GID (18). By contrast, the mutation F119Q increased affinity of LvIA, and the mutation K79A did not affect LvIA activity. The mutation V111I in the $\beta 2$ subunit was previously reported to have only a small effect on the activity of 4/7 α -CTxs MII, PnIA, GID (18),

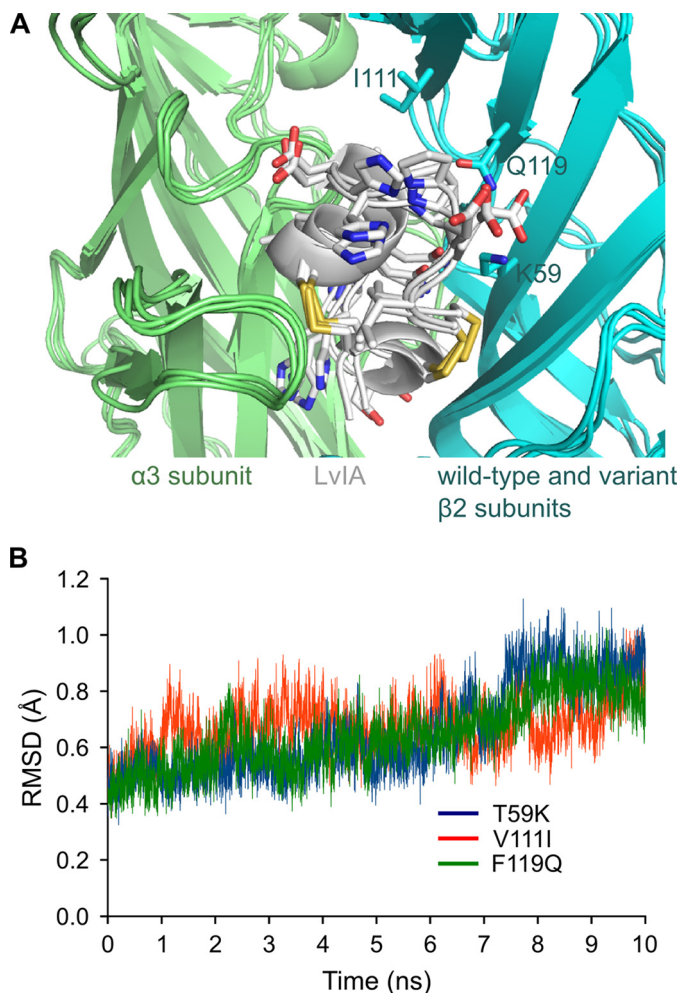

FIGURE 6. Molecular dynamics simulation of LvIA/ $\alpha 3\beta 2$ incorporating $\beta 2$ subunit mutations T59K, V111I, or F119Q. *A*, overlay of the conformation of the binding sites after 10-ns simulations, with the $\alpha 3$ subunit in green, the $\beta 2$ subunit in blue, and conotoxin LvIA in white. The side chains of LvIA as well as the mutated side chains Lys⁵⁹, Ile¹¹¹, and Gln¹¹⁹ are in stick representation. *B*, backbone root mean square deviation (RMSD) over the 10-ns simulations from the starting conformation of the $\beta 2$ subunit binding site. This binding site is defined here as including the $\beta 1$ (positions 32–40), $\beta 2$ (positions 57–63), $\beta 5'$ (positions 109–113), and $\beta 6$ (positions 116–120) strands.

and LtIA (23) (Table 3). By contrast, this mutation decreased LvIA activity by 15-fold. LvIA displays the conserved Ser-Xaa-Pro motif in its first loop, suggesting that it adopts a similar binding mode to most 4/7 α -CTxs. The sequence in the second loop of α -CTx LvIA is therefore probably a determinant of its unique selectivity and distinct binding site. Molecular models indeed suggest that this second loop, especially residues Asn⁹, Val¹⁰, Asp¹¹, and Pro¹³, interacts with the β 2 subunit. Interestingly, the 4/7 α -CTx PeIA also potentially blocks α 3 β 2 nAChRs and has similar residues in its second loop (31).

The mutant K79A does not show a significant difference in activity from the wild-type nAChR, but the molecular models suggest that the Lys⁷⁹ residue establishes a stable charge interaction with LvIA Asp¹¹ (Fig. 5B). It has been proposed that surface salt bridges can have little contribution to binding affinity because the favorable charge-charge interaction can be counterbalanced by the negative entropic effect of restraining the conformation of the side chain (40). This compensation of enthalpy for entropy components between apo and bound states is a potential explanation for the innocuous nature of the K79A substitution. Indeed, the Lys⁷⁹ side chain is highly exposed to the solvent and should therefore have considerable conformational freedom in the absence of the toxin. The side chain of Lys⁷⁹ was restrained during the molecular simulations of the bound toxin, suggesting a significant entropic cost to the immobilization of the side chain.

The molecular models suggest that substitutions at positions 119 and 59 increase the solvent-accessible surface area buried at the interface, and this increase correlates with higher affinities of LvIA observed experimentally (Fig. 5C). In particular, the three mutations, T59I, T59L, and T59K, incrementally introduce longer side chains at position 59, and they result in increasing inhibitory potency of LvIA. The introduction of a positively charged Lys at position 59 results in the burial of a positively charged group, which could be detrimental to binding, but this residue can potentially interact with the negatively charged β 2 subunit Glu⁶¹, which is proximally located (Fig. 5A). The F119Q mutation resulted in better complementarity at the interface by creating further interactions, especially with LvIA residues Val¹⁰ and Pro¹³, resulting in the largest buried surface area among all mutants in this study, in agreement with the highest inhibitory activity of LvIA among all mutants.

It is interesting to compare the trends in LvIA binding to α 3 β 2 versus α 3 β 4 relative to the individual residue substitutions at the three key positions of 59, 111, and 119. In principle, the decreases in IC₅₀ values associated with the T59K and F119Q substitutions should more than compensate for the increased IC₅₀ associated with the V111I substitution. Nevertheless LvIA is 17-fold more potent at α 3 β 2 than at α 3 β 4. The non-additivity of the single point mutant effects can probably be explained by the spatial organization of these positions because the side chain at position 119 is sandwiched by those of positions 111 and 59. The β 4 subunit, which displays bulkier side chains at these positions than the β 2 subunit, should present a different interface to LvIA than the β 2 subunit single point mutants.

In conclusion, we have identified three residues in the nAChR β 2 subunit that are key to the binding interaction of

LvIA with the α 3 β 2 nAChR. Furthermore, molecular modeling indicates that the sequence of residues in the second loop of LvIA is particularly important for high affinity for the α 3 β 2 nAChR. These findings help provide insights into the unique selectivity profile of this toxin. Understanding interactions between different α -CTxs and α 3 β 2 nAChR should further help to elucidate the molecular pharmacology of this subtype.
