Trace Inclusion for One-Counter Nets Revisited

Piotr Hofman¹ and Patrick Totzke²

¹ University of Bayreuth, Germany

² LaBRI, Univ. Bordeaux & CNRS, France

Abstract. One-counter nets (OCN) consist of a nondeterministic finite control and a single integer counter that cannot be fully tested for zero. They form a natural subclass of both One-Counter Automata, which allow zero-tests and Petri Nets/VASS, which allow multiple such weak counters. The trace inclusion problem has recently been shown to be undecidable for OCN. In this paper, we contrast the complexity of two natural restrictions which imply decidability.

We show that trace inclusion between a OCN and a *deterministic* OCN is NL-complete, even with arbitrary binary-encoded initial counter-values as part of the input. Secondly, we show that the trace *universality* problem of nondeterministic OCN, which is equivalent to checking trace inclusion between a finite and a OCN-process, is Ackermann-complete.

1 Introduction

A fundamental question in formal verification is if the behaviour of one process can be reproduced by – or equals that of – another given process. These inclusion and equivalence problems, respectively have been studied for various notions of behavioural preorders and equivalences and for many computational models. Trace inclusion/equivalence asks if the set of *traces*, all emittable sequences of actions, of one process is contained in/equal to that of another. Other than for instance Simulation preorder, trace inclusion lacks a strong locality of failures, which makes this problem intractable or even undecidable already for very limited models of computation.

We consider one-counter nets, which consist of a finite control and a single integer counter that cannot be fully tested for zero, in the sense that an empty counter can only restrict possible moves. They are subsumed by One-counter automata (OCA) and thus Pushdown Systems, which allow explicit zero-tests by reading a bottom marker on the stack. At the same time, OCN are a subclass of Petri Nets or Vector Addition Systems with states (VASS): they are exactly the one-dimensional VASS and thus equivalent to Petri Nets with at most one unbounded place.

Related work. Valiant and Paterson [16] show the decidability of the trace equivalence problem for *deterministic* one-counter automata (DOCA). This problem has recently been shown to be NL-complete by Böhm, Göller, and Jančar [2], assuming fixed initial counter-values. The equivalence of deterministic pushdown automata is known to be decidable [12] and primitive recursive [13, 8], but the exact complexity is still open.

Valiant [15] proves the undecidability of both trace inclusion for DOCA and universality for nondeterministic OCA. Jančar, Esparza, and Moller [10] consider trace inclusion between Petri Nets and finite systems and prove decidability in both directions. Jančar [9] showed that trace inclusion becomes undecidable if one compares processes of Petri Nets with at least two unbounded places. In [7], the authors show that trace inclusion is undecidable already for (nondeterministic) one-counter nets. Simulation preorder however, is known to be decidable and PSPACE-complete for this model [1, 11, 6], which implies a PSPACE upper bound for trace inclusion on DOCN as trace inclusion and simulation coincide for deterministic systems.

Higuchi, Wakatsuki, and Tomita [5] compare the classes of *languages* defined by DOCN with various acceptance modes and consider the respective inclusion problems. They derive procedures that exhaustively search for a bounded witness that work in time and space polynomial in the size of the automata if the initial counter-values are fixed. We show that for monotone relations like trace inclusion or the inclusion of languages defined by acceptance with final states, it suffices to search for witnesses in a particular compact representation.

Our contribution. We fix the complexity of two well-known decidable decision problems regarding the traces of one-counter processes. We show that trace inclusion between *deterministic* OCNs is NL-complete. Our upper bound holds even if only the supposedly larger process is deterministic and if (binary encoded) initial counter-values are part of the input. We use short certificates for the existence of (possibly long) distinguishing traces. The sizes of certificates are polynomial in the number of states of the finite control and they can be verified in space logarithmic in the binary representation of the initial counter-values.

Our second result is that trace universality of *nondeterministic* OCN is Ackermann-complete. This problem is (logspace) inter-reducible with checking trace inclusion between a finite process and a process of a OCN.

2 Background

We write \mathbb{N} for the set of non-negative integers. For any set A , let A^* denote the set of finite strings over A and $\varepsilon \in A^*$ the empty string.

Definition 1 (One-Counter Nets). *A one-counter net (OCN) is given as triple $\mathcal{N} = (Q, Act, \delta)$ where Q is a finite set of control states, Act is a finite set of action labels and $\delta \subseteq Q \times Act \times \{-1, 0, 1\} \times Q$ is a set of transitions, each written as $p \xrightarrow{a,d} p'$. A process of \mathcal{N} consists of a state $p \in Q$ and a counter-value $m \in \mathbb{N}$. We will simply write pm for such a pair. Processes can evolve according to the transition rules of the net: For any $a \in Act$, $p, q \in Q$ and $m, n \in \mathbb{N}$ there is a step $pm \xrightarrow{a} qn$ iff there exists $(p \xrightarrow{a,d} q) \in \delta$ such that*

$$n = m + d \geq 0. \tag{1}$$

The net \mathcal{N} is deterministic (a DOCN) if for every $p \in Q$ and $a \in Act$, there is at most one transition $(p, a, d, q) \in \delta$. It is complete if for every $p \in Q$ and $a \in Act$ at least one transition $(p, a, d, q) \in \delta$ exists.

Definition 2 (Traces). Let pm be a process of the OCN \mathcal{N} . The traces of pm are the elements of the set

$$T_{\mathcal{N}}(pm) = \{a_1 a_2 \dots a_k \in \text{Act}^* \mid \exists qn \ pm \xrightarrow{a_0} \circ \xrightarrow{a_1} \circ \dots \circ \xrightarrow{a_k} qn\}.$$

We will omit the index \mathcal{N} if it is clear from the context. Trace inclusion is the decision problem that asks if $T_{\mathcal{A}}(pm) \subseteq T_{\mathcal{B}}(p'm')$ holds for given processes pm and $p'm'$ of nets \mathcal{A} and \mathcal{B} , respectively. Trace universality asks if $\text{Act}^* \subseteq T(pm)$ holds for a given process pm .

An important property of one-counter nets is that the step relation and therefore also trace inclusion is monotone with respect to the counter:

Lemma 1 (Monotonicity). If $pm \xrightarrow{a} p'm'$ then $p(m+1) \xrightarrow{a} p'(m'+1)$. This in particular means that $T(pm) \subseteq T(p(m+1))$ holds for any OCN-process pm .

Remark 1. In this paper we consider what are sometimes called *realtime* automata, in which no silent (ε -labelled) transitions are present. This is no restriction: the usual syntactic requirement for DPDA, that no state with outgoing ε -transition may have outgoing transitions labelled by $a \neq \varepsilon$, together with the monotonicity of steps in OCN, implies that all states on ε -cycles are essentially deadlocks. One can thus eliminate ε -labelled transitions in logarithmic space.

We will w.l.o.g. assume input nets in a certain form, justified by the next lemma. A pair \mathcal{A}, \mathcal{B} of OCNs is in *normal form* if \mathcal{A} is deterministic and \mathcal{B} is complete. The proof is a simple construction and can be found in Appendix A.

Lemma 2 (Normal Form). Given OCNs \mathcal{A} and \mathcal{B} with state sets N and M , one can in logarithmic space construct nets $\mathcal{A}', \mathcal{B}'$ in normal form, with states N and $M' \supseteq M$, respectively, such that for all $(p, n, q, m) \in N \times \mathbb{N} \times M \times \mathbb{N}$

$$T_{\mathcal{A}}(pm) \subseteq T_{\mathcal{B}}(qn) \iff T_{\mathcal{A}'}(pm) \subseteq T_{\mathcal{B}'}(qn). \quad (2)$$

Moreover, the constructed net \mathcal{B}' is deterministic if the original net \mathcal{B} is.

Due to the undecidability of trace inclusion for OCN [7], a direct consequence of Lemma 2 is that $T_{\mathcal{A}}(pm) \subseteq T_{\mathcal{B}}(qn)$ is already undecidable if we allow the net \mathcal{B} to be nondeterministic. Unless otherwise stated, we will from now on assume a DOCN $\mathcal{A} = (Q_{\mathcal{A}}, \text{Act}, \delta_{\mathcal{A}})$ and a complete DOCN $\mathcal{B} = (Q_{\mathcal{B}}, \text{Act}, \delta_{\mathcal{B}})$.

3 Trace Inclusion for Deterministic One-Counter Nets

We characterize witnesses for non-inclusion $T_{\mathcal{A}}(pm) \not\subseteq T_{\mathcal{B}}(qn)$, starting with some notation to express paths and their effects.

Definition 3 (OCN Paths). Let $\mathcal{N} = (Q, \text{Act}, \delta)$ be a OCN and $t = (p, a, d, p') \in \delta$. We write $\text{source}(t) = p$, $\text{target}(t) = p'$ and $\Delta(t) = d$ for its source and target states and effect, respectively. A path in \mathcal{N} is a sequence $\pi = t_0 t_1 \dots t_k \in \delta^*$

of transitions where $\text{target}(t_i) = \text{source}(t_{i+1})$ for every $i < k$. Let ${}^i\pi$ denote its prefix of length i . The effect $\Delta(\pi)$ and guard $\Gamma(\pi)$ of π are

$$\Delta(\pi) = \sum_{i=0}^k \Delta(t_i) \quad \text{and} \quad \Gamma(\pi) = -\min\{\Delta({}^i\pi) \mid 0 \leq i \leq k\}.$$

The path π is enabled in process pm (write $pm \xrightarrow{\pi}$) if $\Gamma(\pi) \leq m$. We write $pm \xrightarrow{\pi} p'm'$ if π takes pm to $p'm'$, i.e., if $pm \xrightarrow{\pi}$, $\text{target}(\pi) = p'$ and $m' = m + \Delta(\pi)$.

The guard $\Gamma(\pi)$ is the minimal counter-value that is sufficient to traverse the path π while maintaining a non-negative counter-value along the way. This value is always non-negative. Notice that the absolute values of the effect and guard of a path are bounded by its length. We consider the synchronous product of the control graphs of two given deterministic one-counter nets.

Definition 4 (Products). The product of nets \mathcal{A} and \mathcal{B} is the finite graph with nodes $V = Q_{\mathcal{A}} \times Q_{\mathcal{B}}$ and $(\text{Act} \times \{-1, 0, 1\} \times \{-1, 0, 1\})$ -labelled edges E , where

$$(p, q) \xrightarrow{a, d_{\mathcal{A}}, d_{\mathcal{B}}} (p', q') \in E \text{ iff } p \xrightarrow{a, d_{\mathcal{A}}} p' \in \delta_{\mathcal{A}} \text{ and } q \xrightarrow{a, d_{\mathcal{B}}} q' \in \delta_{\mathcal{B}}.$$

A path in the product is a sequence $\pi = T_0 T_1 \dots T_k \in E^*$ and defines paths $\pi_{\mathcal{A}}$ and $\pi_{\mathcal{B}}$ in nets \mathcal{A} and \mathcal{B} , respectively. It is enabled in (pm, qn) if $\pi_{\mathcal{A}}$ and $\pi_{\mathcal{B}}$ are enabled in pm and qn , respectively. In this case we write $(pm, qn) \xrightarrow{\pi} (p'm', q'n')$ to mean that $pm \xrightarrow{\pi_{\mathcal{A}}} p'm'$ and $qn \xrightarrow{\pi_{\mathcal{B}}} q'n'$. We lift the definitions of source and target nodes to paths in the product: $\text{source}(\pi) = (\text{source}(\pi_{\mathcal{A}}), \text{source}(\pi_{\mathcal{B}})) \in V$, $\text{target}(\pi) = (\text{target}(\pi_{\mathcal{A}}), \text{target}(\pi_{\mathcal{B}})) \in V$. Moreover, write $\Delta_{\mathcal{A}}(\pi)$, $\Delta_{\mathcal{B}}(\pi)$, $\Gamma_{\mathcal{A}}(\pi)$ and $\Gamma_{\mathcal{B}}(\pi)$ for the effects and guards of π in nets \mathcal{A} and \mathcal{B} , respectively.

Since both \mathcal{A} and \mathcal{B} are deterministic and \mathcal{B} is complete, Due to our normal form assumption, a trace $w \in T_{\mathcal{A}}(pm)$ uniquely determines a path from state (p, q) in their product. We therefore identify witnesses for non-inclusion with the paths they induce in the product.

Definition 5 (Witnesses). Assume $T_{\mathcal{A}}(pm) \not\subseteq T_{\mathcal{B}}(qn)$ for processes pm and qn of \mathcal{A} and \mathcal{B} . A witness for (pm, qn) is a path π in the product of \mathcal{A} and \mathcal{B} such that $(pm, qn) \xrightarrow{\pi} (p'm', q'n')$ and for some $a \in \text{Act}$, $p'm' \xrightarrow{a}$ but $q'n' \not\xrightarrow{a}$.

Every witness π for (pm, qn) completely exhausts the counter in the process of \mathcal{B} : $(pm, qn) \xrightarrow{\pi} (p'm', q'0)$. This is because a process of a complete net can only not make an a -step in case the counter is empty.

Example 1. Consider two nets given by self-loops $p \xrightarrow{a, 0} p$ and $q \xrightarrow{a, -1} q$, respectively. Their product is the cycle $L = (p, q) \xrightarrow{a, 0, -1} (p, q)$ with effects $\Delta_{\mathcal{A}}(L) = 0$ and $\Delta_{\mathcal{B}}(L) = -1$. The only witness for (pm, qn) for initial counter-values $m, n \in \mathbb{N}$ is L^n , which has length polynomial in the sizes of the nets and the initial counter-values, but not in the sizes of the nets alone.

The previous example shows that if binary-encoded initial counter-values are part of the input, we can only bound the length of shortest witnesses exponentially. However, we will see that it suffices to consider witnesses of a certain regular form only. This leads to small certificates for non-inclusion, which can be stepwise guessed and verified in space logarithmic in the size of the nets.

A crucial ingredient for our characterization is the monotonicity of witnesses, a direct consequence of the monotonicity of the steps in OCNs (Lemma 1):

Lemma 3. *If π is a witness for (pm, qn) then for all $m' \geq m$ and $n' \leq n$ some prefix of π is a witness for (pm', qn') .*

The intuition behind the further characterization of witnesses is that in order to show non-inclusion, one looks for a path that is enabled in the process of \mathcal{A} and moreover exhausts the counter in the process of \mathcal{B} . Since any sufficiently long path will revisit control states in the product, we can compare such paths with respect to their effect on the counters and see that some are “better” than others. For instance, a cycle that only increments the counter in \mathcal{B} and decrements the one in \mathcal{A} is surely suboptimal considering our goal to find a (shortest) witness. The characterization Theorem 1 essentially states that if a witness exists, then also one that, apart from short paths, combines only the most productive cycles.

Definition 6 (Loops). *A non-empty path π in the product is called a cycle if $\text{source}(\pi) = \text{target}(\pi)$. Such a cycle is a loop if none of its proper subpaths is a cycle. The slope of loop π is the ratio $S(\pi) = \Delta_{\mathcal{A}}(\pi)/\Delta_{\mathcal{B}}(\pi)$, where for $n > 0$ and $k \in \mathbb{Z}$ we let $n/0 = \infty > k$, $0/0 = 0$ and $-n/0 = -\infty < k$. Based on the effect of a loop we distinguish four types of loops: $(<, <)$, $(>, \geq)$, (\leq, \geq) , and $(\geq, <)$. The type of π is $\text{Type}(\pi) = (\blacktriangleleft, \blacktriangleright)$ iff $\Delta_{\mathcal{A}}(\pi) \blacktriangleleft 0$ and $\Delta_{\mathcal{B}}(\pi) \blacktriangleright 0$.*

Note that no loop is longer than $|V|$ because it visits exactly one node twice.

Example 2. Consider two DOCN such that their product is the graph depicted below, where we identify transitions with their action labels for simplicity and let $v_0 = (p, p') \in V$. The paths $t_0t_1t_2$, t_3t_4 and t_6 are loops with slopes $3/1$, $2/1$ and $1/1$ and types $(>, \geq)$, $(>, \geq)$ and $(<, <)$, respectively. The path $(t_0t_1t_2)(t_3t_4)^9t_5(t_6)^{20}$ is a witness for $(p0, p'10)$ of length 42. By replacing 8 occurrences of the loop (t_3t_4) with $(t_0t_1t_2)^8$ we derive the longer witness $(t_0t_1t_2)^9(t_3t_4)t_5(t_6)^{20}$, which has essentially the same structure but is more efficient in the sense that for the same effect on \mathcal{B} it achieves a higher counter-effect on \mathcal{A} .

Theorem 1. *Fix a DOCN \mathcal{A} , a complete DOCN \mathcal{B} , and let $K \in \mathbb{N}$ be the number of nodes in their product. There is a bound $c \in \mathbb{N}$ that depends polynomially on K , such that the following holds for any two processes pm and qn of \mathcal{A} and \mathcal{B} . If $T(pm) \not\subseteq T(qn)$, then there is a witness for (pm, qn) that is either no longer than c or has one of the following forms:*

1. $\pi_0 L_0^{l_0} \pi_1$, where L_0 is a loop of type $(\geq, <)$ and π_0, π_1 are no longer than c ,
2. $\pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \pi_2$, where L_0 and L_1 are loops of type $(>, \geq)$ and $(<, <)$ with $S(L_0) > S(L_1)$ and π_0, π_1, π_2 are no longer than c ,
3. $\pi_0 L_0^{l_0} \pi_1$, where L_0 is a loop of type $(<, <)$ and π_0, π_1 are no longer than c ,

where in all cases, the number of iterations $l_0, l_1 \in \mathbb{N}$ are polynomial in K and the initial counter-values m and n of the given processes.

Proof (sketch). The overall idea of the proof is to explicitly rewrite witnesses into one of the canonical forms of Theorem 1. More specifically, we introduce a system of path-rewriting rules which simplify witnesses by removing, reducing or changing some loops as in Example 2. We show that the rules preserve witnesses and any sequence of successive rule applications must eventually terminate with a normalized path, to which none of the rules is applicable. Such a witness can be decomposed as

$$\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \dots \pi_k L_k^{l_k} \pi_{k+1} \quad (3)$$

where the L_i are (pairwise different) loops and the π_i are short, i.e. polynomially bounded in K . Moreover the rules are designed in such a way that almost all l_i are polynomially bounded. By almost all we mean except one in the first and third form of the witness or two in the witness of the second form. This means that unravelling of those loops with polynomially bounded l_i and glueing them with surrounding π_i to get paths π_0, π_1, π_2 does not blow up of the length of π_0, π_1, π_2 above polynomial bound c . \square

Notice that the bound c in the claim of Theorem 1 depends only on the number of states. We now derive a decision procedure for trace inclusion that works in logarithmic space. The NL lower bound already holds for the trace inclusion problem of DFA, which can be shown by a straightforward reduction from s-t-connectivity.

Theorem 2. *Let pm and qn be processes of OCN \mathcal{A} and DOCN \mathcal{B} , respectively, where m, n are given in binary. There is a nondeterministic algorithm that decides $T(pm) \subseteq T(qn)$ in logarithmic space.*

Proof. Let $\mathcal{A} = (Q_{\mathcal{A}}, Act, \delta_{\mathcal{A}})$ and $\mathcal{B} = (Q_{\mathcal{B}}, Act, \delta_{\mathcal{B}})$, and let $K \in \mathbb{N}$ be the number of states in their product. By Lemma 2, we can assume w.l.o.g. that \mathcal{A} is deterministic and \mathcal{B} is complete and deterministic and so Theorem 1 applies.

If the initial counter-values are $m = n = 0$, Theorem 1 implies a polynomial bound on the length of shortest witnesses. In that case, one can simply stepwise guess and verify a witness, explicitly storing the intermediate processes with binary encoded counter-values in logarithmic space. Such a procedure is impossible with arbitrary initial counter-values as part of the input, because one does not even have the space to memorize them.

For the general case, we argue that one can nondeterministically guess a template (consisting of short paths) and verify in logspace that there is indeed some witness that fits this template. Theorem 1 allows us to either guess a short ($\leq c \in poly(K)$) witness or one of forms 1,2 or 3, together with matching short

paths π_i, L_i . The effect and guard of these paths are bounded by their lengths and hence by c . This means $\mathcal{O}(\log K)$ space suffices to stepwise compute the binary representation of these values and verify that the conditions the form imposes on the types and slopes of the loops are met. It remains to check if exponents $l_0, l_1 \in \mathbb{N}$ exist, that complete the description of a witness π . To see why these checks can be implemented in logarithmic space, first recall that one can verify inequalities of the form

$$m \cdot A + B \geq n \cdot C + D \quad (4)$$

in $\mathcal{O}(\log(A+B+C+D))$ space, if $m, n \in \mathbb{N}$ are given in binary (see Appendix B).

For templates of the first two forms, it suffices to check if $m \geq \Gamma_{\mathcal{A}}(\pi_0 L_0)$, because the type of L_0 implies that $\Gamma_{\mathcal{A}}(\pi_0 L_0^l) \leq \Gamma_{\mathcal{A}}(\pi_0 L_0)$ for all $1 < l \in \mathbb{N}$. This means that the process pm of \mathcal{A} can go to, and repeat the loop L_0 arbitrarily often. In case its effect in \mathcal{B} is negative (in templates of form 1), this immediately implies the existence of a suitable l_0 . For templates of form 2) the existence of $l_0, l_1 \in \mathbb{N}$ completing the description of a witness is guaranteed because the slope of the first loop is bigger than that of the second.

For templates of the third kind recall that, because \mathcal{B} is complete, a path $\pi = \pi_0 L_0^{l_0} \pi_1$ is a witness iff there is some edge T in the product such that $\Delta_{\mathcal{B}}(T) = -1$ and both $m \geq \Gamma_{\mathcal{A}}(\pi T)$ and $n + \Delta_{\mathcal{B}}(\pi T) = -1$. Equivalently, we can write this as

$$m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) = m + \Delta_{\mathcal{A}}(\pi_0) + \Delta_{\mathcal{A}}(L_0) \cdot l_0 \geq \Gamma_{\mathcal{A}}(\pi_1 T) \quad \text{and} \quad (5)$$

$$n + 1 = -\Delta_{\mathcal{B}}(\pi T) = -\Delta_{\mathcal{B}}(\pi_0) - \Delta_{\mathcal{B}}(L_0) \cdot l_0 - \Delta_{\mathcal{B}}(\pi_1 T). \quad (6)$$

Eliminating l_0 , we see that this is true iff

$$m + \Delta_{\mathcal{A}}(\pi_0) + \Delta_{\mathcal{A}}(L_0) \cdot \frac{\Delta_{\mathcal{B}}(\pi_0) + \Delta_{\mathcal{B}}(\pi_1) + n}{-\Delta_{\mathcal{B}}(L_0)} \geq \Gamma_{\mathcal{A}}(\pi_1). \quad (7)$$

Simplifying further we can bring this into the form $m \cdot A - n \cdot B \geq C$ where A, B, C are polynomial in c . The condition can be checked in $\mathcal{O}(\log K)$ space. \square

4 Universality of Nondeterministic One-Counter Nets

To contrast the result of the previous section we now turn to the problem of checking trace inclusion between a finite process and a nondeterministic OCN. This problem is known to be decidable, even for general Petri nets [10] and it can be easily seen to be (logspace) inter-reducible with the trace universality problem, because OCNs are closed under products with finite systems.

For OCN, trace universality can be decided using a simple well-quasi-order based saturation method that determinizes the net on the fly. We will see that this procedure is optimal: The problem is Ackermannian, i.e. it is non-primitive recursive and lies exactly at level ω of the Fast Growing Hierarchy [4].

Let \mathbb{N}_{\perp} be the set of non-negative integers plus a special least element \perp and let \max be the total function that returns the maximal element of any

nonempty finite subset and \perp otherwise. Consider a set $S \subseteq Q \times \mathbb{N}$ of processes of a OCN $\mathcal{N} = (Q, Act, \delta)$. We lift the definition of traces to sets of processes in the natural way: the *traces* of S are $T(S) = \bigcup_{qn \in S} T(qn)$. By the monotonicity of trace inclusion (Lemma 1), the traces of a finite set of processes are determined only by the traces of its maximal elements.

Definition 7. Let $Q = \{q_1, q_2, \dots, q_k\}$ be the states-set of some OCN. For a finite set $S \subseteq Q \times \mathbb{N}$ define the macrostate as the vector $M_S \in \mathbb{N}_{\perp}^k$ where for each $0 < i \leq k$, $M_S(i) = M_S(q_i) = \max\{n \mid q_i n \in S\}$. In particular, the macrostate for a singleton set $S = \{q_i n\}$ is the vector with value n at the i -th coordinate and \perp on all others. The norm of a macrostate $M \in \mathbb{N}_{\perp}^k$ is $|M|_{\infty} = \max\{M(i) \mid 0 < i \leq k\}$. We define a step relation \xRightarrow{a} for all $a \in Act$ on the set of macrostates as follows:

$$(n_1, n_2, \dots, n_k) \xRightarrow{a} (m_1, m_2, \dots, m_k) \quad (8)$$

iff $m_i = \max\{n \mid \exists n_j \neq \perp. q_j n_j \xrightarrow{a} q_i n\}$ for all $0 < i \leq k$. The traces of macrostate M are $T(M) = \bigcup_{0 < i \leq k} T(q_i M(i))$, where $T(q \perp) = \emptyset$. For two macrostates M, N we say M is covered by N and write $M \sqsubseteq N$, if it is point-wise smaller, i.e., $M(i) \leq N(i)$ for all $0 < i \leq k$. For convenience, we will write $\{q_1 = n_1, q_2 = n_2, \dots, q_l = n_l\}$ for the macrostate with value $M(i) = n_i$ whenever $q_i = n_i$ is listed and \perp otherwise.

Steps on macrostates correspond to the classical powerset construction and each macrostate represents the finite set of possible processes the OCN can be in, where all non-maximal ones (w.r.t. their counter-value) are pruned out.

The next lemma directly follows from these definitions and monotonicity (Lemma 1).

Lemma 4.

1. The covering-order \sqsubseteq is a well-quasi-order on \mathbb{N}_{\perp}^k , the set of all macrostates. Moreover, $M \sqsubseteq N$ implies $T(M) \subseteq T(N)$.
2. If $M \xRightarrow{a} N$ then $|N|_{\infty} \leq |M|_{\infty} + 1$.
3. For any finite set $S \subseteq Q \times \mathbb{N}$ it holds that $T(S) = T(M_S)$.

Dealing with macrostates allows us to treat universality as a reachability problem: By point 3 of Lemma 4 we see that a process qn is *not* trace universal, $Act^* \neq T(qn)$, if and only if $M_{\{qn\}} \xRightarrow{*} (\perp, \perp, \dots, \perp)$. We take the perspective of a pathfinder, whose goal it is to reach $(\perp)^k$.

We can decide universality by stepwise guessing a shortest terminating path from the initial macrostate, and thus a witness for non-universality. Whenever we see a macrostate that covers one of its predecessors, we can safely discard this candidate, because omitting the intermediate path would result in a shorter witness by Lemma 4.1.

We show non-primitive recursiveness by reduction from the control state reachability problem for incrementing counter machines [3, 4].

Definition 8 (Counter machines). A (Minsky)-counter machine (CM) is an automaton with a finite set of states Q , finitely many counters C_1, C_2, \dots, C_k , and transitions are of the form $Q \times \text{Act} \times Q$ where Act is $\{\text{inc}, \text{dec}, \text{ifz}\} \times \{1, 2, \dots, k\}$. A configuration of such a CM consists of a state and a valuation of the counters. Performing a transition $(p, (op, i), q)$ changes a configuration precisely: the state changes from p to q and we make operation op on the counter c_i , where inc , dec and ifz mean increment, decrement and zero-test, respectively. Such a step is forbidden if the requested operation is dec and the value of c_i is 0, or if $c_i > 0$ and the operation is ifz .

An incrementing counter machine (ICM) is a CM in which counters can spontaneously increment without performing any transitions. Such increments we call incrementing errors. Control state reachability is the decision problem that asks if there is a run of a given CM from an initial configuration to some given state $q_f \in Q$.

Our reduction is based on the following simple observation. Consider a OCN $\mathcal{N} = (Q, \text{Act}, \delta)$ that contains a universal state u : it has self-loops $u \xrightarrow{a,0} u \in \delta$ for every action $a \in \text{Act}$. A Pathfinder who wants to prove non-universality must avoid macrostates with $M(u) \neq \perp$, because no continuation of a path leading to such a macrostate can be a witness. We can use this idea to construct macrostates that prevent Pathfinder from making certain actions.

Definition 9 (Obstacles). Let $S \subseteq \text{Act}$ be a set of actions in a OCN that contains a universal state u . A state $q \in Q$ is called an S -obstacle if $q \xrightarrow{a,0} u \in \delta$ for all actions $a \in S$. We say q ignores S , if $q \xrightarrow{a,0} q \in \delta$ for all $a \in S$.

Note that if a macrostate contains an S -obstacle, then Pathfinder must avoid all actions of S . In order to remove an obstacle, Pathfinder must play an action that is not the label of any of its incoming transitions.

Theorem 3. Trace universality for OCN is not primitive recursive.

Proof. By reduction (using logspace) from the control state reachability problem for ICM, which has non-primitive recursive complexity [3]. We construct a OCN-process $\text{Init}(0)$ that is not universal iff a given ICM reaches a final state from its initial configuration. The idea is to enforce a faithful simulation of the ICM by pathfinder, who wants to show non-universality of the OCN by stepwise rewriting the initial macrostate $\{\text{Init} = 0\}$ to the all-bottom-macrostate \perp^l .

We construct a OCN \mathcal{N} which has a unique action for every transition of the ICM, as well as actions τ_i that indicate incrementing errors for every counter c_i , and actions \sharp and $\$$ to mark the beginning and end of a run, respectively. This way we make sure there is a strict correspondence between words and ICM-runs. The states of \mathcal{N} are

- a new initial state Init and a universal state u ,
- a state q_i for every state q_i of the ICM,
- a state C_i for every counter c_i of the ICM,

- a state z , which ignores every action but the end marker $\$$. State z will be used to access the constant 0.

A configuration $q(c_1, c_2, \dots, c_k)$ of the ICM is represented by a macrostate $\{q = 0, z = 0, C_1 = c_1, C_2 = c_2, \dots, C_k = c_k\}$. We will define the transitions of \mathcal{N} such that the only way for Pathfinder to reach \perp^l is by rewriting the initial macrostate $\{Init = 0\}$ to the one representing the initial ICM configuration and then to stepwise announce the transitions of an accepting run of the ICM. Using the idea of obstacles, we define the rules of the net \mathcal{N} so that the only way Pathfinder can avoid the universal state u and reach the macrostate \perp^l is by first transforming the initial macrostate $\{Init = 0\}$ to the one that represents the initial ICM configuration and then announcing transitions (as well as actions demanding increment errors) of a valid and accepting run of the ICM.

Initialization. To set up $M_0 = \{q_0 = 0, z = 0, C_0 = 0, C_1 = 0, \dots, C_k = 0\}$, representing the initial ICM configuration, we add $\#$ -labelled transitions with effect 0 from $Init$ to q_0, z and C_i for all $0 \leq i \leq k$. Moreover, we make $Init$ an obstacle for every action but $\#$. This way, Pathfinder has to play $\#$ as the first move (and set up M_0) in order to avoid a universal macrostate.

Finite control. For any transition $t = q \xrightarrow{(a,i)} q'$ of the ICM, we add a transition $q \xrightarrow{t,0} q'$ to \mathcal{N} that, in a macrostate-step, will replace the value 0 in dimension q by \perp and introduce value 0 in dimension q' . Moreover, we make every state q an obstacle for all actions announcing ICM-transitions not originating in q . This prevents Pathfinder from announcing transitions from q unless the current macrostate has $M(q) = 0$ and $M(q_i) = \perp$ for all $q_i \neq q$.

Simulation of the Counters. Every transition operates on one of the counters c_i for $0 \leq i \leq k$. Below we list the corresponding transitions in the OCN \mathcal{N} for this counter. Every state of \mathcal{N} not explicitly mentioned ignores the action in question. In the macrostate, the values of these states are therefore unchanged.

increments For ICM-transitions t that increase the i th counter, \mathcal{N} contains a t -labelled transition from state C_i to C_i with effect +1. Additionally, to deal with spontaneous increment errors, there is a τ_i -labelled increasing self-loop in state C_i . All other states ignore the τ_i .

decrements For ICM-transitions t that decrease the i th counter, \mathcal{N} contains a t -labelled transition from state C_i to C_i with effect -1 .

This means that the next macrostate M could lose the value for this counter and have $M(C_i) = \perp$ if previously, the value was 0. In that case, the decrementing step from value 0 to value 0 is valid in the ICM because it can first (silently) increment and then do the (visible) decrement step. In order to avoid losing the state C_i in the macrostate, the OCN contains a transition $z \xrightarrow{t,0} C_i$ from the constant-zero state z to state C_i . Recall that z is present in the macrostate because z ignores every action except end marker $\$$. Consequently, no correctly set up macrostate will set $M(C_i) = \perp$.

zero-tests For ICM-transitions t that test the i th counter for 0, we add a t -labelled transition $C_i \xrightarrow{t, -1} u$ from state C_i to the universal state. This prevents Pathfinder from using these actions if the current macrostate has $M(C_i) > 0$ because it would make the next macrostate universal. If however $M(C_i) = 0$, such a step is safe because the punishing transition is not enabled in the OCN-process C_i0 .

Lastly, we only add transitions to \mathcal{N} so that the final state q_f is the only original ICM-state which is not an obstacle for $\$$. This prevents Pathfinder from playing the end-marker $\$$ unless the simulation has reached the final state. \square

In order to estimate an upper bound, we recall a recent result of Figueira, Figueira, Schmitz, and Schnoebelen [4], that allows us to provide the exact complexity of the OCN trace universality problem in terms of its level in the Fast-Growing Hierarchy. The main idea is to estimate the maximal length of a path in the well quasi order based algorithm using bounds on the difference of sizes of consecutive configurations. The proof of the following theorem can not be presented due to space limitations; it can be found in Appendix D.

Theorem 4. *Trace universality of OCN is Ackermannian (Complete for \mathfrak{F}_ω).*

5 Conclusion

We have shown NL-completeness of the trace inclusion problem for deterministic one-counter nets, where initial counter-values are part of the input. Our proof is based on a characterization of the shape of possible witnesses in terms of a small number of polynomially-sized templates. Realizability of such templates can be verified in space logarithmic only in the size of the underlying state space. Our procedure is therefore independent of the number of action symbols and transitions in the input nets. To prove the characterization theorem we use witness rewriting rules, the correctness of which crucially depends on the monotonicity of trace inclusion w.r.t. counter-values. In fact, we only make use of this property in the net on the left but similarly one can define rules that exploit only the monotonicity in the process on the right. With some additional effort one can extend this argument also for trace inclusion between DOCN and DOCA or vice versa (see [14]).

The second part of the paper explores the complexity of the universality problem for nondeterministic OCN, and trace inclusion between finite systems and OCN that easily reduces to OCN universality. Here we show that the simplest known algorithm which uses a well-quasi-order based saturation technique has already optimal complexity: The problem is Ackermannian, i.e., not primitive recursive.

A Normal-Form Assumption

We consider here what is sometimes called *realtime* automata, in which no silent (ε -labelled) transitions are present. In the absence of zero-tests, the usual syntactic restriction for deterministic Pushdown Automata, (no state with outgoing ε -transition may have outgoing transitions labelled by $a \neq \varepsilon$) and the lack of an explicit zero-test in our model implies that all states on ε -cycles are essentially deadlocks. A process in such a state can either silently exhaust the counter and deadlock or divert into an infinite ε loop. With respect to their traces, those processes are equivalent. This means one can eliminate ε -transitions by removing ε -cycles and replacing the remaining short paths by direct steps (and normalize the effects of single transitions back to $\{-1, 0, 1\}$). Such a reduction works in $\mathcal{O}(\log n)$ space. Allowing ε -transitions thus leaves the complexity of trace inclusion invariant.

Lemma 2 (Normal Form). *Given OCNs \mathcal{A} and \mathcal{B} with state sets N and M , one can in logarithmic space construct nets $\mathcal{A}', \mathcal{B}'$ in normal form, with states N and $M' \supseteq M$, respectively, such that for all $(p, n, q, m) \in N \times \mathbb{N} \times M \times \mathbb{N}$*

$$T_{\mathcal{A}}(pm) \subseteq T_{\mathcal{B}}(qn) \iff T_{\mathcal{A}'}(pm) \subseteq T_{\mathcal{B}'}(qn). \quad (2)$$

Moreover, the constructed net \mathcal{B}' is deterministic if the original net \mathcal{B} is.

Proof. Let $\mathcal{A} = (N, Act, \delta_A)$ and $\mathcal{B} = (M, Act', \delta_B)$. If \mathcal{A} is not already deterministic, we can make it so by uniquely re-labeling all its transitions t by actions a_t and adding corresponding transitions (p', a_t, d', q') to the other net \mathcal{B} for any existing $(p', a, d', q') \in \delta_B$, where a is the original label of $t \in \delta_A$. So assume \mathcal{A} is deterministic and pick a new action label $\$ \notin Act$. We add $\$$ -labelled cycles with effect 0 to all states of \mathcal{A} : The new net $\mathcal{A}' = (N, Act \cup \{\$\}, \overline{\delta_A})$ has transitions $\overline{\delta_A} = \delta_A \cup \{(s, \$, 0, s) \mid s \in N\}$. To compensate this, we add $\$$ -cycles to all states of \mathcal{B} in the same way. We add a sink state L (for losing), which has counter-decreasing cycles for all actions, and connect all states without outgoing a -transitions to L by a -labelled transitions. $\mathcal{B}' = (M \cup \{L\}, Act \cup \{\$\}, \overline{\delta_B})$ where

$$\begin{aligned} \overline{\delta_B} = & \delta_B \cup \{(s, \$, 0, s) \mid s \in M\} \\ & \cup \{(s, a, 0, L) \mid a \in Act \text{ and } s \xrightarrow{a} s' \notin \delta \text{ for any } s' \in M\} \\ & \cup \{(L, a, -1, L \mid a \in Act \cup \{\$\}\}. \end{aligned}$$

We see that if a word w of length k witnesses non-inclusion $T_{\mathcal{A}}(qn) \not\subseteq T_{\mathcal{B}}(q'n')$ then there is a word that witnesses non-inclusion $T_{\mathcal{A}'}(qn) \not\subseteq T_{\mathcal{B}'}(q'n')$. To see this, observe that in this case, any w -labelled path in \mathcal{B}' that starts in state q' must end in state L . This means any such path takes the initial process $q'n'$ to some process Ln'' where $n'' \leq n' + k$ and now by playing n'' times a label $\$$ we get a new witness. Conversely, if there is a witness w for $T_{\mathcal{A}'}(qn) \not\subseteq T_{\mathcal{B}'}(q'n')$ then the shortest such witness must be of the form $w = w'\k where w' does not contain actions $\$$ because as $\$$ -labelled steps leave any process not in state L unchanged. This means w' witnesses $T_{\mathcal{A}}(qn) \not\subseteq T_{\mathcal{B}}(q'n')$. \square

B Checking Weighted Inequalities in Logspace

Lemma 5. *Inequalities of the form $m \cdot A + B \geq n \cdot C + D$ where all coefficients are non-negative integers given in binary can be verified in $\mathcal{O}(\log(A+B+C+D))$ deterministic space.*

Proof. Assume w.l.o.g. that the bit-representations of m and n are of the same length, as are those of A, B, C and D , and we have the least significant bit on the right.

To check $m \geq n$, we can stepwise read their binary representation from right to left, flipping an “output” bit Out on the way: Initially, $Out := 1$; in every step set $Out := 0$ if the current bit in m is strictly smaller than that in n ; set $Out := 1$ if the current bit in m is strictly bigger than that in n and otherwise proceed without touching Out . The inequality holds iff $Out = 1$ after completely reading the input.

To check the weighted variant, we use the same algorithm but multiply $m \cdot A$, and $n \cdot C$ on the fly, using standard long binary multiplication. We use a scratchpad to store the intermediate sums, starting with values B and D . In a step that reads the i th bit $m[i]$ of m , we want to add $A \cdot 2^i$ to the intermediate sum if $m[i] = 1$. We can do that by shifting the binary representation of A left i times and adding the result to the current scratchpad. We see that none of the bits up to $i - 1$ in the scratchpad are affected by this operation. We can therefore discard (and use for the comparison in our simple algorithm above) the rightmost bit of the scratchpad in every step. The claim now follows from the observation that the necessary size of the scratchpad is bounded by $B + A + 1$. \square

C Proof of Theorem 1

We show that it is safe to consider only witnesses in a reduced form, and derive bounds on the length of certain subpaths. For this, we introduce path rewriting rules that exchange occurrences of some loops by others. We then show (in Lemma 6) that these rules preserve witnesses and (Lemma 7) cannot be applied indefinitely. For *reduced* witnesses, those to which no rules are applicable, we derive (Lemma 8) bounds on the multiplicities of loops that are less productive than others, which will enable us to prove Theorem 1.

For the rest of this section let V and E be the sets of nodes and edges in the product of \mathcal{A} and \mathcal{B} .

We start with an easy observation: Because no loop L is longer than $|V|$, we conclude that $(\Delta_{\mathcal{A}}(L), \Delta_{\mathcal{B}}(L)) \in \{-V \dots V\} \times \{-V \dots V\}$, so there are $F_0 := (2 \cdot |V| + 1)^2$ different values the pair $\Delta_{\mathcal{A}}(L), \Delta_{\mathcal{B}}(L)$ can have. Moreover, if a witness exists, then also one that does not contain different loops with the same effects: if $\pi_0 L_0 \pi_1 L_1 \pi_2$ is a witness where $|\pi_1| > 0$ and L_0, L_1 are two loops with $\Delta(L_0) = \Delta(L_1)$, then either some prefix of $\pi_0 L_0^2 \pi_1 \pi_2$ (if $\Delta_{\mathcal{A}}(L_0) \geq 0$) or some prefix of $\pi_0 \pi_1 L_1^2 \pi_2$ (if $\Delta_{\mathcal{A}}(L_0) < 0$) must also be a witness by Lemma 3. We can therefore consider w.l.o.g. only *sane* paths, which are of the form

$$\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \dots \pi_r L_r^{l_r} \pi_{r+1} \quad (9)$$

where $r \leq F_0$, all π_i are acyclic and all loops have pairwise different effects.

Each rule consists of conditions (lines above the bar) and a conclusion ρ , which is a path, below the bar. Their names indicate which type of loops are

handled: E.g., **UUL** exchanges loops of type $(>, \geq)$ (up) for others of the same type on the left.

We say a rule is applicable to a sane path π if there are $0 < x, y, l_0, l_1 \in \mathbb{N}$ and two different loops L_0 and L_1 such that all conditions are satisfied. In this case the rule can rewrite π to ρ , its conclusion and we say ρ is the result of applying the rule to π .

Example 3. Consider Example 2 again: The substitution suggested there is an application of the rule **UUL** to the path $\pi = (t_0 t_1 t_2)(t_3 t_4)^9 t_5 (t_6)^{20}$, where $L_0 = (t_0 t_1 t_2)$, $L_1 = (t_3 t_4)$ and $x = y = 8$. The result is a reduced witness for $(p0, p'10)$ of length 50. Shorter reduced witnesses for $(p0, p'10)$ exist, for example $(t_0 t_1 t_2)^6 t_5 t_6^{16}$, but because of their different loop structure, these cannot be obtained from π by applying rewriting rules, as these do not change the structure, i.e., which loops occur and in which order, of a path. This means that our rules do not necessarily preserve minimality of witnesses.

In the next two Lemmas 6 and 7, we show that the rewriting rules preserve witnesses and that continuous rule application must eventually terminate.

Lemma 6. *If π is a sane witness for $(pm, p'm')$ and ρ is the result of applying one of the rules to π , then ρ is also a sane witness for $(pm, p'm')$.*

Proof. Each rule only modifies the number of times some loops are iterated, and never completely removes a loop. Therefore, sane paths are always rewritten to other sane paths.

Let's say we rewrite $\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \pi_2$ to ρ . The key observation is that the conditions of the rule imply that we can always decompose the paths π and ρ into $\pi = \alpha\gamma$ and $\rho = \beta\gamma$, s.t. $\Delta_{\mathcal{B}}(\alpha) = \Delta_{\mathcal{B}}(\beta)$ and $\Delta_{\mathcal{A}}(\alpha) \leq \Delta_{\mathcal{A}}(\beta)$. By monotonicity (Lemma 1) and the assumption that π is a witness, it is therefore sufficient to show that the result ρ is still enabled in the initial position $(pm, p'm')$. We proceed by case distinction for the used rule.

UUL. Since π is a witness, its prefix $\alpha = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1}$ must be enabled in $(pm, p'm')$ and because $Type(L_0) = (>, \geq)$, so is the prefix $\beta = \pi_0 L_0^{l_0+x} \pi_1 L_1^{l_1-y}$ of the result ρ . Assume that $(pm, p'm') \xrightarrow{\alpha} (qn, q'n')$ and $(pm, p'm') \xrightarrow{\beta} (q\hat{n}, q'n')$. The condition $S(L_0) \geq S(L_1)$ of the rule implies that $\hat{n} \geq n \geq \Gamma(\pi_2)$ and therefore that ρ is enabled in $(pm, p'm')$.

UUR. The prefix $\pi_0 L_0^{l_0-x}$ of π must be enabled and since the last condition of the rule demands that $l_0 - x > |\pi_1 L_1|$, so is the path $\pi_0 L_0^{l_0-x} \pi_1 L_1$. The fact that $Type(L_1) = (>, \geq)$, means that also $\pi_0 L_0^{l_0-x} \pi_1 L_1^{l_1+y}$ and therefore the result ρ is enabled in $(pm, p'm')$.

UD. $Type(L_1) = (<, <)$ implies $S(L_1) < \infty$. Since $S(L_0) < S(L_1)$, we know that $S(L_0) < \infty$ and hence $\Delta_{\mathcal{B}}(L_0) > 0$. The path $\pi_0 L_0^{l_0-x}$ is a prefix of π and is therefore enabled in $(pm, p'm')$. As $l_0 - x \geq |\pi_1|$ by assumption, we get that

$$m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0-x}) \geq l_0 - x \geq |\pi_1| \geq \Gamma(\pi_1) \quad (10)$$

and similarly, by $\Delta_{\mathcal{B}}(L_0) > 0$,

$$m' + \Delta_{\mathcal{B}}(\pi_0 L_0^{l_0-x}) \geq l_0 - x \geq |\pi_1| \geq \Gamma'(\pi_1). \quad (11)$$

This means that the prefix $\beta = \pi_0 L_0^{l_0-x} \pi_1$ of ρ is enabled in $(pm, p'm')$. Let us now consider the prefix $\alpha = \pi_0 L_0^{l_0-x} L_0^x \pi_1 L_1^y$ of π . Because $\Delta_{\mathcal{B}}(L_0) \cdot x = -\Delta_{\mathcal{B}}(L_1) \cdot y$ we get $\Delta_{\mathcal{B}}(\alpha) = \Delta_{\mathcal{B}}(\beta)$. By $S(L_0) < S(L_1)$ we obtain that $\Delta_{\mathcal{A}}(\alpha) \leq \Delta_{\mathcal{A}}(\beta)$. Because $\pi = \alpha L_1^{l_1-y} \pi_2$ is a witness for $(pm, p'm')$, we can apply Lemma 1 to conclude $\rho = \beta L_1^{l_1-y} \pi_2$ must be a witness for $(pm, p'm')$.

DDL. We know that $m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) + \Delta_{\mathcal{A}}(\pi_1) \geq \Gamma(L_1^{l_1})$, because π is enabled in $(pm, p'm')$. As L_1 is a type $(<, <)$ loop we also know that $\Delta_{\mathcal{A}}(L_1) < 0$. Therefore, $\Gamma(L_1^{l_1}) \geq l_1$ and

$$m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) \geq l_1 - \Delta_{\mathcal{A}}(\pi_1). \quad (12)$$

Assume towards a contradiction that $m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) < \Gamma(L_0^x \pi_1)$. This means that

$$m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) < \Gamma(L_0^x) + |\pi_1| \leq |L_0| \cdot x + |\pi_1|. \quad (13)$$

This, together with Eq. (12) yields $l_1 - \Delta_{\mathcal{A}}(\pi_1) < |L_0| \cdot x + |\pi_1|$ and thus $l_1 < |L_0| \cdot x + 2|\pi_1|$ which contradicts the condition that $l_1 > |L_0| \cdot x + 2|\pi_1|$. Hence, $m + \Delta_{\mathcal{A}}(\pi_0 L_0^{l_0}) \geq \Gamma(L_0^x \pi_1)$. By the same argument we get that $m' + \Delta_{\mathcal{B}}(\pi_0 L_0^{l_0}) \geq \Gamma'(L_0^x \pi_1)$. So the prefix $\beta = \pi_0 L_0^{l_0+x} \pi_1$ of ρ is enabled in $(pm, p'm')$. Consider the prefix $\alpha = \pi_0 L_0^{l_0} \pi_1 L_1^y$ of π . By the assumption that $\Delta_{\mathcal{B}}(L_0^x) = \Delta_{\mathcal{B}}(L_1^y)$ we get that $\Delta_{\mathcal{B}}(\alpha) = \Delta_{\mathcal{B}}(\beta)$. Because of $S(L_0) < S(L_1)$ we get $\Delta_{\mathcal{A}}(L_0^x) \geq \Delta_{\mathcal{A}}(L_1^y)$ and therefore that $\Delta_{\mathcal{A}}(\alpha) \leq \Delta_{\mathcal{A}}(\beta)$. By Lemma 1 we conclude that the path $\rho = \beta L_1^{l_1-y} \pi_2$ is a witness for $(pm, p'm')$.

DDR. Let $\alpha = \pi_0 L_0^{l_0} \pi_1$ and let $(pm, p'm') \xrightarrow{\alpha} (qn, q'n')$. Due to the type of L_0 and because π is a witness, we know that the prefix $\beta = \pi_0 L_0^{l_0-x} \pi_1 L_1^y$ of ρ is enabled in $(pm, p'm')$. Since $\Delta_{\mathcal{B}}(L_0) \cdot x = \Delta_{\mathcal{B}}(L_1) \cdot y$, we get that $(pm, p'm') \xrightarrow{\beta} (q\hat{n}, q'n')$ for some $\hat{n} \in \mathbb{N}$. The condition $S(L_0) \geq S(L_1)$ of the rule implies that $\Delta_{\mathcal{A}}(L_0^x) \leq \Delta_{\mathcal{A}}(L_1^y) < 0$, and therefore that $\hat{n} \geq n$. We conclude that the path $L_1^{l_1} \pi_2$ is enabled in $(qr, q'r')$ and therefore that $\rho = \pi_0 L_0^{l_0-x} \pi_1 L_1^{l_1+y} \pi_2$ is enabled in $(pm, p'm')$ as required. \square

Lemma 7. *Any sequence of successive applications of rules to a given path π must eventually terminate.*

Proof. Consider a π to which we apply the rewriting rules. W.l.o.g. assume π is sane, as otherwise no rule is applicable by definition. The *decomposition* of π is the sequence

$$Dec(\pi) = (\pi_0, L_0, l_0)(\pi_1, L_1, l_1) \dots (\pi_k, L_k, l_k)\pi_{k+1} \quad (14)$$

in $(E^* \times E^* \times \mathbb{N})^* E^*$ such that $\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \dots \pi_k L_k^{l_k} \pi_{k+1}$, where $k \leq F_0$ and for all indices $0 \leq i \leq k$,

1. L_i is a loop,
2. π_i is acyclic,
3. for any two transitions $t \in \pi_i$ and $t' \in L_i$ with $target(t) = target(t')$ holds that $target(L_i) = target(t)$.

The last condition demands that any loop L_i shares exactly one node with the acyclic path π_i it succeeds and thus ensures that the decomposition of a path is unique.

As no application of a rule completely removes all occurrences of loops nor introduces new ones nor touches the intermediate paths, we observe that rule applications only change the exponents l_i in the decomposition of the path.

Based on the order of loops in the decomposition of π , and their potential for rule application, we now define a notion of *weights* for paths, and show that these weights have to strictly decrease along a well-order whenever a rule is applied.

Let (L_0, L_1, \dots, L_k) be the sequence of loops that occur in the decomposition of π . Let us fix some linear order \prec on $\{L_0, L_1, \dots, L_k\}$ that satisfies the following conditions for any two different loops L_i, L_j with $i < j$.

1. If $Type(L_i) = Type(L_j) = (>, \geq)$ and $S(L_i) \geq S(L_j)$ then $L_i \prec L_j$.
2. If $Type(L_i) = Type(L_j) = (>, \geq)$ and $S(L_i) < S(L_j)$ then $L_i \succ L_j$.
3. If $Type(L_i) = Type(L_j) = (<, <)$ and $S(L_i) < S(L_j)$ then $L_i \prec L_j$.
4. If $Type(L_i) = Type(L_j) = (<, <)$ and $S(L_i) \geq S(L_j)$ then $L_i \succ L_j$.

Surely, such a linearization exists, as the conditions above only restrict \prec between loops of the same type and slopes are linearly ordered. Consider the permutation $\sigma : \mathbb{N}_{\leq k} \rightarrow \mathbb{N}_{\leq k}$ given by $\sigma(i) < \sigma(j) \iff L_i \prec L_j$. The *weight* of π is

$$W(\pi) = (l_{\sigma(k)}, l_{\sigma(k-1)}, \dots, l_{\sigma(0)}) \in \mathbb{N}^{k+1}. \quad (15)$$

The weight of π is the ordered tuple of exponents l_i of loops that occur in π . Because rules do not change the order of loop occurrences, the path before and after applying a rule have comparable weights. The very definition of weights ensures that rule applications must strictly reduce the weight of a path.

Claim. If ρ is the result of applying a rewriting rule to π then $W(\rho) \sqsubset_{lex} W(\pi)$ where \sqsubset_{lex} is the lexicographic extension of the pointwise ordering of tuples of naturals.

Assume the decompositions of π, ρ are

$$\begin{aligned} Dec(\pi) &= (\pi_0, L_0, l_0)(\pi_1, L_1, l_1) \dots (\pi_k, L_k, l_k)\pi_{k+1} \text{ and} \\ Dec(\rho) &= (\pi_0, L_0, l'_0)(\pi_1, L_1, l'_1) \dots (\pi_k, L_k, l'_k)\pi_{k+1}. \end{aligned} \quad (16)$$

We show for every type of rule that if the occurrences of loop L_i increase then those of some loop L_j with $L_i \prec L_j$ strictly decrease.

If the rule used to derive ρ was **UUL** then $l'_i = l_i + x$ and $l'_j = l_j - y$ for some $i < j$, $0 < x, y$ and type $(>, \geq)$ loops L_i, L_j with $S(L_i) \geq S(L_j)$. By condition 1) in the definition of \prec we get $L_i \prec L_j$.

For rule **UUR** we know $l'_i = l_i - x$ and $l'_j = l_j + y$ for some $0 < x, y$ and type $(>, \geq)$ loops L_i, L_j with $S(L_i) < S(L_j)$. By condition 2) in the definition of \prec , we get $L_i \succ L_j$.

For rule **DDL** we know $l'_i = l_i + x$ and $l'_j = l_j - y$ for type $(<, <)$ loops L_i, L_j with $S(L_i) < S(L_j)$. By condition 3) in the definition of \prec , we know $L_i \prec L_j$.

For rule **DDR** we know $l'_i = l_i - x$ and $l'_j = l_j + y$ for some $0 < x, y$ and type $(<, <)$ loops L_i, L_j with $S(L_i) > S(L_j)$. So condition 4) in the definition of \prec , implies $L_i \succ L_j$.

Lastly, if the rule used to derive ρ was **UD** we immediately see that $l'_i < l_i$ and $l'_j < l_j$, which implies the claim. \square

Lemmas 6 and 7 allow us to focus on witnesses that are *reduced*, i.e., which are sane and to which none of the rewriting rules is applicable. We can now derive bounds on the multiplicities of loops in reduced paths.

Lemma 8. *Let $\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \pi_2$ be a reduced path where L_0, L_1 are loops occurring with multiplicities $l_0 > 0$ and $l_1 > 0$.*

1. If $Type(L_0) = Type(L_1) = (>, \geq)$ and $S(L_0) \geq S(L_1)$ then $l_1 \leq |V|$
2. If $Type(L_0) = Type(L_1) = (>, \geq)$ and $S(L_0) < S(L_1)$ then $l_0 \leq |\pi_1| + 2|V|$
3. If $Type(L_0) = Type(L_1) = (<, <)$ and $S(L_0) < S(L_1)$ then $l_1 < |V|^2 + 2|\pi_1|$
4. If $Type(L_0) = Type(L_1) = (<, <)$ and $S(L_0) \geq S(L_1)$ then $l_0 < |V|$
5. If $Type(L_0) = (>, \geq)$, $Type(L_1) = (<, <)$ and $S(L_0) \leq S(L_1)$ then $l_0 \leq |\pi_1| + |V|$ or $l_1 \leq |V|$.

Proof. The fourth condition of any rule is satisfied e.g. by $x = \Delta_{\mathcal{B}}(L_1)$ and $y = \Delta_{\mathcal{B}}(L_0)$. So if $0 < x, y \in \mathbb{N}$ is the smallest satisfying pair we know $x, y \leq |V|$. The bounds are now easily derived by contradiction:

1. If $l_1 \geq |V|$ then $l_1 - y \geq l_1 - |V| > 0$ and rule **UUL** is applicable.
2. If $l_0 > |\pi_1| + 2|V|$ then $l_0 - x > |\pi_1| + 2|V| - x \geq |\pi_1| + |L_1| \geq |\pi_1 L_1|$ and therefore rule **UUR** is applicable.
3. If $l_1 \geq |V|^2 + 2|\pi_1|$ then $l_1 \geq |L_0| \cdot x + 2|\pi_1|$ and $l_1 - y \geq l_1 - |V| > 0$, so rule **DDL** is applicable.
4. If $l_0 > |V|$ then $l_0 - x > 0$, so rule **DDR** is applicable.
5. If $l_1 > |V|$ and $l_0 > |\pi_1| + |V|$, then $l_1 - y > 0$, $l_0 - x > 0$ and $l_0 - x > |\pi_1|$, so rule **UD** is applicable.

In each case we conclude that one of the rules is applicable, which contradicts the assumption that π is reduced. \square

Finally, we are ready to prove Theorem 1.

Theorem 1. *Fix a DOCN \mathcal{A} , a complete DOCN \mathcal{B} , and let $K \in \mathbb{N}$ be the number of nodes in their product. There is a bound $c \in \mathbb{N}$ that depends polynomially on K , such that the following holds for any two processes pm and qn of \mathcal{A} and \mathcal{B} . If $T(pm) \not\subseteq T(qn)$, then there is a witness for (pm, qn) that is either no longer than c or has one of the following forms:*

1. $\pi_0 L_0^{l_0} \pi_1$, where L_0 is a loop of type $(\geq, <)$ and π_0, π_1 are no longer than c ,
2. $\pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \pi_2$, where L_0 and L_1 are loops of type $(>, \geq)$ and $(<, <)$ with $S(L_0) > S(L_1)$ and π_0, π_1, π_2 are no longer than c ,
3. $\pi_0 L_0^{l_0} \pi_1$, where L_0 is a loop of type $(<, <)$ and π_0, π_1 are no longer than c ,

where in all cases, the number of iterations $l_0, l_1 \in \mathbb{N}$ are polynomial in K and the initial counter-values m and n of the given processes.

Proof. We show that we can sufficiently increase the bound c such that whenever $T(pm) \not\subseteq T(qn)$ but no witness exists that is shorter than c or of forms 1) or 2), then there must be a witness of form 3).

Assume $T(pm) \not\subseteq T(qn)$ and consider a reduced witness π , that is minimal in length: no shorter witness is reduced. Recall that this also means that π is sane: it is of form described in Eq. (9). By monotonicity (Lemma 3) and because π is of minimal length among the reduced witnesses, we see that it cannot contain loops of type (\leq, \geq) . Moreover, because π is not of form 1), we can safely assume that π it contains only loops of types $(>, \geq)$ and $(<, <)$. This is because if a witness contains two or more different type $(\geq, <)$ loops, then there exists another (sane) witness, that only unfolds the first such loop. Relaxing the bound on the length of paths between loops to $F_1 := F_0(2|V| + |V|^2)$, we can write π as

$$\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \dots \pi_k L_k^{l_k} \pi_{k+1} \quad (17)$$

where $k \leq F_0$, all $|\pi_i| < F_1$ and the number of iterations of loop L_i is $l_i > |V|$.

Consider a block $\pi_{pos} = L_i^{l_i} \pi_{i+1} L_{i+1}^{l_{i+1}} \pi_{i+2} \dots \pi_j L_j^{l_j}$ that is part of the decomposition above, such that all loops are type $(>, \geq)$. If for indices $i \leq x < y \leq j$ we have $S(L_x) \geq S(L_y)$, then by Lemma 8.1 we get $l_y \leq |V|$. Therefore, π_{pos} can be rewritten to the form

$$\pi_{pos} = L_i^{l_i} \pi_{i+1} L_{i+1}^{l_{i+1}} \pi_{i+2} \dots \pi_j L_j^{l_j} \pi_{j+1} \quad (18)$$

where the lengths of π_i are bounded by $F_2 := F_0 \cdot (|V|^2 + F_1)$ and the slopes of loops are strictly increasing: $S(L_x) < S(L_y)$ for any two indices $i \leq x < y \leq j$. By Lemma 8.2 this means that $l_x \leq |\pi_{x+1}| + 2|V| \leq F_2 + 2|V| =: F_3$. We conclude that the prefix $\pi' = L_i^{l_i} \pi_{i+1} L_{i+1}^{l_{i+1}} \pi_{i+2} \dots \pi_{j-1} L_{j-1}^{l_{j-1}}$ is no longer than $(j - i) \cdot (|V| \cdot F_3 + F_2)$ and therefore

$$\pi_{pos} = \pi' L_j^{l_j} \pi_{j+1} \quad (19)$$

where $|\pi'|$ is bounded by $F_4 := F_0(|V| \cdot F_3 + F_2)$ and $|\pi_{j+1}|$ by F_2 .

We continue to show by a similar argument that we can bound the number of iterations of all but the most productive loop in a block consisting of only decreasing (type $(<, <)$) loops. Consider a block $\pi_{neg} = L_i^{l_i} \pi_{i+1} L_{i+1}^{l_{i+1}} \pi_{i+2} \dots \pi_j L_j^{l_j}$ that is part of the decomposition in Eq. (17), where all loops are type $(<, <)$. If $S(L_x) \geq S(L_y)$ for some indices $i \leq x < y \leq j$, then by Lemma 8.4 we know $l_y < |V|$. This means that π_{neg} is of the form

$$\pi_{neg} = \pi_i L_i^{l_i} \pi_{i+1} L_{i+1}^{l_{i+1}} \pi_{i+2} \dots \pi_j L_j^{l_j} \pi_{j+1} \quad (20)$$

where all π_i have lengths bounded by F_2 and $S(L_x) < S(L_y)$ for any two indices $i \leq x < y \leq j$. By Lemma 8.3 we get $l_y \leq |V|^2 + 2|\pi_x| \leq |V|^2 + 2F_2 =: F'_3$ and conclude that the suffix $\pi'' = \pi_{i+1}L_{i+1}^{l_{i+1}}\pi_{i+2} \dots \pi_j L_j^{l_j} \pi_{j+1}$ is no longer than $(j-i) \cdot (|V| \cdot F'_3 + F_2)$. Therefore, π_{neg} is of the form

$$\pi_{neg} = \pi_i L_i^{l_i} \pi'' \quad (21)$$

where π_i is bounded by F_2 and π'' by $F'_4 := F_0(|V| \cdot F'_3 + F_2)$.

Eqs. (19) and (21) characterize the form of maximal subpaths of the witness π in Eq. (17), along which the type of loops does not change. They allow us to write π as

$$\pi = \pi_0 L_0^{l_0} \pi_1 L_1^{l_1} \pi_2 \dots \pi_k L_k^{l_k} \pi_{k+1} \quad (22)$$

where for all indices $0 \leq i < k$:

1. π_i is no longer than $F_5 := F_3 + F'_3 + F_4 + F'_4$.
2. All $l_i > |V|$.
3. Consecutive loops L_i and L_{i+1} have different types.
4. If loops L_i, L_j for $0 \leq i < j \leq k$ have the same type then $S(L_i) < S(L_j)$.

In the remainder of this proof, we further increase the polynomial bound for the gaps π_i between the loops; this allows to conclude that π contains at least one type $(<, <)$ loop and finally, that π is of form 3).

Observe that if all loops L_i in Eq. (22) are of type $(>, \geq)$ then the witness is already of form $\pi = \pi_0 L^l \pi_1$ as in Eq. (19), where π_0, π_1 are short and L is the most effective loop. In this case, consider the run

$$(pm, qn) \xrightarrow{\pi_0 L^l} (p'm', q'n') \quad (23)$$

induced by the prefix $\pi_0 L^l$. Because \mathcal{B} is complete we know $\Delta_{\mathcal{B}}(\pi) = -n$. together with $\Delta_{\mathcal{B}}(\pi_1) \leq |\pi_1| \leq F_5$ we get $n' \leq F_5$. Because $\Gamma_{\mathcal{A}}(\pi_1) \leq |\pi_1|$, we know that $l \leq |\pi_1| \leq F_5$ as otherwise, fewer iterations l would result in a shorter witness and we assumed π to be minimal in length. Hence, we could bound π by $F_6 := F_5 + |V| \cdot F_5 + F_5$. So if we let $c \geq F_6$, our witness π must contain type $(<, <)$ loops as it is assumed not to be no shorter than c .

Finally, fix an index $0 \leq x \leq k$ such that in Eq. (22), L_x is a loop of type $(<, <)$ with most efficient decrease (minimal slope). That is, π is of form

$$\pi = \pi_0 L_x^{l_x} \pi_1. \quad (24)$$

We now bound both π_0 and π_1 and thereby prove that π is of form 3). We start with the suffix π_1 .

If L_x is the only loop of type $(<, <)$, we are done as then $|\pi_1| \leq F_5$. Suppose we have two indices $0 \leq y < y+2 \leq k$, where both L_y and L_{y+2} are type $(<, <)$. This means that L_{y+1} is of type $(>, \geq)$ with $S(L_{y+1}) < S(L_{y+2})$. By Lemma 8.5 and the fact that $l_{y+2} > |V|$ we know that $l_{y+1} < |\pi_{y+1}| + |V| \leq F_6$. So $\pi_{y+1} L_{y+1}^{l_{y+1}} \pi_{y+2}$ is no longer than $2 \cdot F_5 + |V| \cdot F_6 =: F_7$. Applying Lemma 8.3

to L_y and L_{y+2} we get $l_{y+2} \leq |V|^2 + 2 \cdot F_7 =: F_8$ and thus $\pi_{y+1} L_{y+1}^{l_{y+1}} \pi_{y+2} L_{y+2}^{l_{y+2}}$ is no longer than $F_9 := F_5 + (|V| \cdot F_6) + F_5 + (|V| \cdot F_8)$. Now the above argument can be repeated for any successive pair of type $(<, <)$ loops in π_1 of which there are at most F_0 . So, $|\pi_1| < F_0 \cdot F_9$.

To bound the prefix π_0 in Eq. (24), we recall (point 3 above) that consecutive loops in Eq. (22) have different types and therefore $x \leq 1$. In case $x = 0$, we immediately get $|\pi_0| \leq F_5$. If $x = 1$, then L_0 is a type $(>, \geq)$ loop with $S(L_0) < S(L_x)$ and so by Lemma 8.5 and point 2), we get $l_0 \leq |\pi_1| + |V| < F_6$. This means $|\pi_0| \leq 2F_5 + |V| \cdot F_6 = F_7$.

We conclude that $c := F_9 \cdot F_0$ is sufficient to ensure that any witness π , longer than c which is not of form 1) or 2) must have form 3). This completes our argument for the existence of witnesses in the claimed forms.

To see why l_0 and l_1 can always be bounded polynomially in $|V|$ and m' can be seen by looking at the types of the loops involved. For paths of form 1 and 3, L_0 decreases the counter on the right at least once in every iteration. Since the value $m' + \Delta_{\mathcal{B}}(\pi_0)$ before the first iteration is at most $m' + c$, we have $l_0 \leq m' + c$.

Paths of the second form can be decomposed into a prefix $\pi_0 L_0^{l_0}$ and a suffix $\pi_1 L_1^{l_1} \pi_2$, which is a path of form 3. Let $y_0 \in \mathbb{N}$ be minimal such that the effect of the path $\gamma_0 = \pi_0 L_0^{l_0} \pi_1 L_1^{y_0} \pi_2$, in which L_0 is not iterated at all is sufficient to reduce the initial value m' below 0. That is, we have $m' + \Delta_{\mathcal{B}}(\pi_0 L_0^{l_0} \pi_1 L_1^{y_0} \pi_2) \leq 0$. Note that as for forms 1 and 3, we can bound y_0 by $m' + 2c$ and therefore, $|\gamma_0|$ is no larger than $3c + |V| \cdot (m' + 2c)$. This path might not be a witness because it is not enabled on the left side. However, because of the condition on the slopes, there are $x, y \leq |V|$ such that the effect of the loops satisfy

$$\Delta_{\mathcal{B}}(L_0) \cdot x = -\Delta_{\mathcal{B}}(L_1) \cdot y \quad \text{and} \quad \Delta_{\mathcal{A}}(L_0) \cdot x > -\Delta_{\mathcal{A}}(L_1) \cdot y. \quad (25)$$

This means, increasing the iterations of the loops L_0 and L_1 by x and y , respectively, does not change the effect of the path on the right, but strictly increases the effect on the left. We increase the iterations $(l_0, l_1) = (0, y_0)$ in γ_0 as suggested above for $\Gamma(\gamma_0) < |\gamma_0| < 3c + |V| \cdot (m' + 2c)$ times. The resulting path $\gamma_1 = \pi_0 L_0^{x_1} \pi_1 L_1^{y_1} \pi_2$ is then surely witness, and iterates the loops not more than $x_1 = 3c + |V| \cdot (m' + 2c)$ and $y_1 = m' + 5c + |V| \cdot (m' + 2c)$ times. \square

D Upper bound for OCN Universality

Definition 11 (Fast-Growing Hierarchy). Consider the family of functions $F_n : \mathbb{N} \rightarrow \mathbb{N}$ where for $x, k \in \mathbb{N}$,

$$F_0(x) = x + 1 \quad \text{and} \quad F_{k+1}(x) = F_k^{x+1}(x).$$

Here, F^k denotes the k -fold application of F . Moreover, define $F_\omega(x) = F_x(x)$ for the first limit ordinal ω . For $k \leq \omega$, \mathfrak{F}_k denotes the least class of functions that contains all constants and is closed under substitution, sum, projections, limited recursion and applications of functions F_n for $n \leq k$.

Already \mathfrak{F}_2 contains all elementary functions and the union $\bigcup_{k \in \mathbb{N}} \mathfrak{F}_k$ of all finite levels contains exactly the primitive-recursive functions. A function is called Ackermannian if it is in $\mathfrak{F}_\omega \setminus \bigcup_{k \in \mathbb{N}} \mathfrak{F}_k$.

A sequence x_0, x_1, \dots, x_l of macrostates is called *good* if there are indices $0 \leq i < j \leq l$ such that $x_i \sqsubseteq x_j$ and *bad* otherwise. The sequence is t -controlled by $f : \mathbb{N} \rightarrow \mathbb{N}$ if $|x_i|_\infty < f(i + t)$ for every index $0 \leq i \leq l$.

Theorem 5 ([4]). Let $f : \mathbb{N} \rightarrow \mathbb{N}$ be a monotone function in \mathfrak{F}_γ such that $f(x) \geq \max\{1, x\}$ for some $\gamma \geq 1$. There is a function $L_{k,f}(t)$ in $\mathfrak{F}_{k+\gamma-1}$ that computes a bound on the maximal length of bad sequences in \mathbb{N}_\perp^k that are t -controlled by f .

Corollary 1. Trace universality of OCN is Ackermannian.

Proof. By Theorem 3, it suffices to show that the problem is in \mathfrak{F}_ω . Recall the procedure that, for a given process pm of a net with k control states, guesses a shortest terminating path from the initial macrostate (a witness for non-universality), and stops unsuccessfully if a macrostate covers one that has been seen before. The time and space requirements of this procedure are bounded in terms of the longest non-increasing (w.r.t. covering) sequence of k -dimensional macrostates. These are bad sequences where the norm of the initial macrostate is m , the counter-value of the process to check for universality. By point 2 of Lemma 4, such sequences are m -controlled by the successor function $f(x) = x + 1$, which is in \mathfrak{F}_1 . By Theorem 5, computing the bound and running the procedure above is in \mathfrak{F}_k . As k is part of the input, this yields a procedure in \mathfrak{F}_ω . \square
