Abstract

In this paper we investigate distributed computation in dynamic networks in which the network topology changes from round to round. We consider a worst-case model in which the communication links for each round are chosen by an adversary, and nodes do not know who their neighbors for the current round are before they broadcast their messages. The model allows the study of the fundamental computation power of dynamic networks. In particular, it captures mobile networks and wireless networks, in which mobility and interference render communication unpredictable. In contrast to much of the existing work on dynamic networks, we do not assume that the network eventually stops changing; we require correctness and termination even in networks that change continually. We introduce a stability property called *-interval connectivity* (for ℓ), which stipulates that for every ℓ consecutive rounds there exists a stable connected spanning subgraph. For $\ell=1$ this means that the graph is connected in every round, but changes arbitrarily between rounds. Algorithms for the dynamic graph model must cope with these unceasing changes.

We show that in 1-interval connected graphs it is possible for nodes to determine the size of the network and compute any computable function of their initial inputs in $O(n)$ rounds using messages of size $O(n)$, where n is the size of the input to a single node. Further, if the graph is ℓ -interval connected for $\ell \geq 2$, the computation can be sped up by a factor of ℓ , and any function can be computed in $O(n/\ell)$ rounds using messages of size $O(n/\ell)$. We also give two lower bounds on the gossip problem, which requires the nodes to disseminate pieces of information to all the nodes in the network. We show an $\Omega(n)$ bound on gossip in 1-interval connected graphs against centralized algorithms, and an $\Omega(n/\ell)$ bound on exchanging ℓ pieces of information in ℓ -interval connected graphs for a restricted class of randomized distributed algorithms.

The T -interval connected dynamic graph model is a novel model, which we believe opens new avenues for research in the theory of distributed computing in wireless, mobile and dynamic networks.

1 Introduction

The study of dynamic networks has gained importance and popularity over the last few years. Driven by the growing ubiquity of the Internet and a plethora of mobile devices with communication capabilities, novel distributed systems and applications are now within reach. The networks in which these applications must operate are inherently dynamic; typically we think of them as being large and completely decentralized, so that each node can have an accurate view of only its local vicinity. Such networks change over time, as nodes join, leave, and move around, and as communication links appear and disappear.

In some networks, e.g., peer-to-peer, nodes participate only for a short period of time, and the topology can change at a high rate. In wireless ad-hoc networks, nodes are mobile and move around unpredictably. Much work has gone into developing algorithms that are guaranteed to work in networks that eventually stabilize and stop changing; this abstraction is unsuitable for reasoning about truly dynamic networks.

The objective of this paper is to make a step towards understanding the fundamental possibilities and limitations for distributed algorithms in dynamic networks in which eventual stabilization of the network is not assumed. We introduce a general dynamic network model, and study computability and complexity of essential, basic distributed tasks. Under what conditions is it possible to elect a leader or to compute an accurate estimate of the size of the system? How efficiently can information be disseminated reliably in the network? To what extent does stability in the communication graph help solve these problems? These and similar questions are the focus of our current work.

The dynamic graph model. In the interest of broad applicability our dynamic network model makes few assumptions about the behavior of the network, and we study it from the worst-case perspective. In the current paper we consider a fixed set of nodes that operate in synchronized rounds and communicate by broadcast. In each round the communication graph is chosen adversarially, under an assumption of δ -interval connectivity: throughout every block of δ consecutive rounds there must exist a connected spanning subgraph that remains stable.

We consider the range from 1-interval connectivity, in which the communication graph can change completely from one round to the next, to δ -interval connectivity, in which there exists some stable connected spanning subgraph that is not known to the nodes in advance. We note that edges that do not belong to the stable subgraph can still change arbitrarily from one round to the next, and nodes do not know which edges are stable and which are not. We do not assume that a neighbor-discovery mechanism is available to the nodes; they have no means of knowing ahead of time which nodes will receive their message.

In this paper we are mostly concerned with deterministic algorithms, but our lower bounds cover randomized algorithms as well. The computation model is as follows. In every round, the adversary first chooses the edges for the round; for this choice it can see the nodes' internal states at the beginning of the round. At the same time and independent of the adversary's choice of edges, each node tosses private coins and uses them to generate its message for the current round. Deterministic algorithms generate the message based on the internal state alone. In both cases the nodes do not know which edges were chosen by the adversary. Each message is then delivered to

the sender’s neighbors, as chosen by the adversary; the nodes transition to new states, and the next round begins. Communication is assumed to be bidirectional, but this is not essential. We typically assume that nodes know nothing about the network, not even its size, and communication is limited to b bits per message.

To demonstrate the power of the adversary in the dynamic graph model, consider the problem of *local token circulation*: each node v has a local Boolean variable t_v , and if $t_v = 1$, node v is said to “have the token”. In every round exactly one node in the network has the token, and it can either keep the token or pass it to one of its neighbors. The goal is for all nodes to eventually have the token in some round. This problem is impossible to solve in 1-interval connected graphs: in every round, the adversary can see which node v has the token, and provide that node with only one edge (v, w) . Node v then has no choice except to eventually pass the token to w . After w receives it, the adversary can turn around and remove all of w ’s edges except (w, v) , so that w has no choice except to pass the token back to v . In this way the adversary can prevent the token from ever visiting any node except v .

Perhaps surprisingly given our powerful adversary, even in 1-interval connected graphs it is possible to reliably compute any computable function of the initial states of the nodes, and even have all nodes output the result at the same time (simultaneity).

The dynamic graph model we suggest can be used to model various dynamic networks. Perhaps the most natural scenario is mobile networks, in which communication is unpredictable due to the mobility of the agents. There is work on achieving continual connectivity of the communication graph in this setting (e.g., [12]), but currently little is known about how to take advantage of such a service. The dynamic graph model can also serve as an abstraction for static or dynamic wireless networks, in which collisions and interference make it difficult to predict which messages will be delivered, and when. Finally, dynamic graphs can be used to model traditional communication networks, replacing the traditional assumption of a bounded number of failures with our connectivity assumption.

Although we assume that the node set is static, this is not a fundamental limitation. We defer in-depth discussion to future work; however, our techniques are amenable to standard methods such as logical time, which could be used to define the permissible outputs for a computation with a dynamic set of participants.

Contribution. In this paper we mainly study the following problems in the context of dynamic graphs.

Counting, in which nodes must determine the size of the network.

-gossip, in which k pieces of information, called *tokens*, are handed out to some nodes in the network, and all nodes must collect all k tokens.

We are especially interested in the variant of *-gossip* where the number of tokens is equal to the number of nodes in the network, and each node starts with exactly one token. This variant of gossip allows any function of the initial states of the nodes to be computed. However, it requires counting, since nodes do not know in advance how many tokens they need to collect. We show that both problems can be solved in $O(n)$ rounds in ϵ -interval connected graphs. Then we extend the

algorithm for ℓ -interval connected graphs with known n , obtaining an $O(n \log n)$ -round protocol for counting or all-to-all gossip. When n is not known, we show that both problems can be solved in $O(n \log n)$ rounds.

We also give two lower bounds, both concerning token-forwarding algorithms for gossip. A *token-forwarding algorithm* is one that does not combine or alter tokens, only stores and forwards them. First, we give an $\Omega(n \log n)$ lower bound on ℓ -gossip in ℓ -interval connected graphs. This lower bound holds even against centralized algorithms, in which each node is told which token to broadcast by some central authority that can see the entire state of the network. We also give an $\Omega(n \log n)$ lower bound on ℓ -gossip in ℓ -interval connected graphs for a restricted class of randomized algorithms, in which the nodes' behavior depends only on the set of tokens they knew in each round up to the current one. This includes the algorithms in the paper, as well as other natural strategies such as round robin, choosing a token to broadcast uniformly at random, or assigning a probability to each token that depends on the order in which the tokens were learned.

For simplicity, the results we present here assume that all nodes start the computation in the same round. It is generally not possible to solve any non-trivial problem if some nodes are initially asleep and do not participate. However, if 2-interval connectivity is assumed, it becomes possible to solve ℓ -gossip and counting even when computation is initiated by one node and the rest of the nodes are asleep.

Related work. For static networks, information dissemination and basic network aggregation tasks have been extensively studied (see e.g. [5, 16, 29]). In particular, the ℓ -gossip problem is analyzed in [35], where it is shown that n tokens can always be broadcast in time $O(n \log n)$ in a static graph. The various problems have also been studied in the context of alternative communication models. A number of papers look at the problem of broadcasting a single message (e.g. [8, 23]) or multiple messages [11, 26] in wireless networks. Gossiping protocols are another style of algorithm in which it is assumed that in each round each node communicates with a small number of randomly-chosen neighbors. Various information dissemination problems for the gossiping model have been considered [17, 19, 21]; gossiping aggregation protocols that can be used to approximate the size of the system are described in [20, 31]. The gossiping model differs from our dynamic graph model in that the neighbors for each node are chosen at random and not adversarially, and in addition, pairwise interaction is usually assumed where we assume broadcast.

A dynamic network topology can arise from node and link failures; fault tolerance, i.e., resilience to a bounded number of faults, has been at the core of distributed computing research from its very beginning [5, 29]. There is also a large body of previous work on general dynamic networks. However, in much of the existing work, topology changes are restricted and assumed to be “well-behaved” in some sense. One popular assumption is eventual stabilization (e.g., [1, 6, 7, 36, 18]), which asserts that changes eventually stop occurring; algorithms for this setting typically guarantee safety throughout the execution, but progress is only guaranteed to occur after the network stabilizes. Self-stabilization is a useful property in this context: it requires that the system converge to a valid configuration from any arbitrary starting state. We refer to [13] for a comprehensive treatment of this topic. Another assumption, studied for example in [22, 24, 30], requires topology changes to be infrequent and spread out over time, so that the system has enough time to recover from a change before the next one occurs. Some of these algorithms use link-

reversal [14], an algorithm for maintaining routes in a dynamic topology, as a building block.

Protocols that work in the presence of continual dynamic changes have not been widely studied. There is some work on handling nodes that join and leave continually in peer-to-peer overlay networks [15, 27, 28]. Most closely related to the problems studied here is [32], where a few basic results in a similar setting are proved; mainly it is shown that in δ -interval connected dynamic graphs (the definition in [32] is slightly different), if nodes have unique identifiers, it is possible to globally broadcast a single message and have all nodes eventually stop sending messages. The time complexity is at least linear in the value of the largest node identifier. In [2], Afek and Hendler give lower bounds on the message complexity of global computation in asynchronous networks with arbitrary link failures.

A variant of δ -interval connectivity was used in [25], where two of the authors studied clock synchronization in *asynchronous* dynamic networks. In [25] it is assumed that the network satisfies δ -interval connectivity for a small value of δ , which ensures that a connected subgraph exists long enough for each node to send one message. This is analogous to 1-interval connectivity in synchronous dynamic networks.

The time required for global broadcast has been studied in a probabilistic version of the edge-dynamic graph model, where edges are independently formed and removed according to simple Markovian processes [9, 10]. Similar edge-dynamic graphs have also been considered in control theory literature, e.g. [33, 34].

Finally, a somewhat related computational model is population protocols, introduced in [3], where the system is modeled as a collection of finite-state agents with pairwise interactions. Population protocols typically (but not always) rely on a strong fairness assumption which requires every pair of agents to interact infinitely often in an infinite execution. We refer to [4] for a survey. Unlike our work, population protocols compute some function in the limit, and nodes do not know when they are done; this can make sequential composition of protocols challenging. In our model nodes must eventually output the result of the computation, and sequential composition is straightforward.

2 Network Model

2.1 Dynamic Graphs

A synchronous dynamic network is modelled by a dynamic graph (V, E) , where V is a static set of nodes, and E is a function mapping a round number t to a set of undirected edges E_t . Here E is the set of all possible undirected edges over V .

Definition 2.1 (δ -Interval Connectivity). A dynamic graph (V, E) is said to be δ -interval connected for $\delta > 0$ if for all $t \in \mathbb{N}$, the static graph $(V, E_{[t, t+\delta]})$ is connected. If (V, E) is δ -interval connected we say that (V, E) is *always connected*.

Definition 2.2 (δ -Interval Connectivity). A dynamic graph (V, E) is said to be δ -interval connected if there exists a connected static graph (V, E') such that for all $t \in \mathbb{N}$, $(V, E' \cup E_t)$ is connected.

Note that even though in an Δ -interval connected graph there is some stable subgraph that persists throughout the execution, this subgraph is not known in advance to the nodes, and can be chosen by the adversary “in hindsight”.

Although we are generally interested in the undirected case, it is also interesting to consider *directed dynamic graphs*, where the communication links are not necessarily symmetric. The Δ -interval connectivity assumption is then replaced by Δ -interval strong connectivity, which requires that G be strongly connected (where Δ is defined as before). In this very weak model, not only do nodes not know who will receive their message before they broadcast, they also do not know who received the message *after* it is broadcast. Interestingly, all of our algorithms for the undirected case work in the directed case as well.

The causal order for dynamic graphs is defined in the standard way.

Definition 2.3 (Causal Order). Given a dynamic graph G , we define an order \prec , where $u \prec v$ iff u and v . The *causal order* is the reflexive and transitive closure of \prec . We also write $u \prec v$ if there exists some w such that $u \prec w \prec v$.

Definition 2.4 (Influence Sets). We denote by $I_u(t)$ the set of nodes whose state in round t causally influences node u in round t . We also use the short-hand $I_u(t)$.

2.2 Communication and Adversary Model

Nodes communicate with each other using *anonymous broadcast*, with message sizes limited to ℓ . At the beginning of round t , each node u decides what message to broadcast based on its internal state and private coin tosses; at the same time and independently, the adversary chooses a set E_t of edges for the round. For this choice the adversary can see the nodes’ internal states at the beginning of the round, but not the results of their coin tosses or the message they have decided to broadcast. (Deterministic algorithms choose a message based only on the internal state, and this is equivalent to letting the adversary see the message before it chooses the edges.) The adversary then delivers to each node u all messages broadcast by nodes v such that $(v, u) \in E_t$. Based on these messages, its previous internal state, and possibly more coin tosses, the node transitions to a new state, and the round ends. We call this anonymous broadcast because nodes do not know who will receive their message prior to broadcasting it.

2.3 Sleeping Nodes

Initially all nodes in the network are asleep; computation begins when a subset of nodes, chosen by the adversary, is woken up. Sleeping nodes remain in their initial state and do not broadcast any messages until they receive a message from some awake node or are woken up by the adversary. Then they wake up and begin participating in the computation; however, since messages are delivered at the end of the round, a node that is awakened in round t sends its first message in round $t+1$.

We refer to the special case where all nodes are woken up at once as *synchronous start*.

2.4 Initial Knowledge

Each node in the network starts execution of the protocol in an initial state which contains its own ID, its input, and possibly additional knowledge about the network. We generally assume one of the following.

No knowledge: nodes know nothing about the network, and initially cannot distinguish it from any other network.

Upper bound on size: nodes know some upper bound U on the size n of the network. The upper bound is assumed to be bounded by some function of the true size, e.g., $U = O(n)$.

Exact size: nodes know the size n of the network.

2.5 Computation Model

We think of each node in the network as running a specialized Turing machine which takes the node's UID and input from its input tape at the beginning of the first round, and in subsequent rounds reads the messages delivered to the node from the input tape. In each round the machine produces a message to broadcast on an output tape. On a separate output tape, it eventually writes the final output of the node, and then enters a halting state.

The algorithms in this paper are written in pseudo-code. We use x_i to denote the value of node i 's local variable x at the beginning of round r , and i_{in} to denote the input to node i .

3 Problem Definitions

We assume that nodes have unique identifiers (UIDs) from some namespace \mathcal{N} . Let \mathcal{D} be a problem domain. Further, let \mathcal{F} denote the set of all partial functions from \mathcal{N} to \mathcal{D} .

A *problem* over \mathcal{D} is a relation $R \subseteq \mathcal{F} \times \mathcal{D}$, such that if $(f, d) \in R$ then f is finite and $d \in \mathcal{D}$. Each instance (f, d) induces a set \mathcal{N} of nodes, and we say that an algorithm *solves* instance (f, d) if in any dynamic graph G , when each node i starts with $f(i)$ as its input, eventually each node outputs a value o_i such that $(f, d) \in R$.

We are interested in the following problems.

Counting. In this problem the nodes must determine the size of the network. Formally, the counting problem is given by

$\mathcal{D} = \mathbb{N}$ is finite and

-Verification. Closely related to counting, in the \mathcal{V} -verification problem nodes are given an integer k and must determine whether or not $n \geq k$, eventually outputting a Boolean value. Formally,

$\mathcal{D} = \{0, 1\}$ and $(f, d) \in R$ iff

-Committee. In this problem the nodes must form sets (“committees”), where each committee has a unique identifier that is known to all its members. Each node outputs a value, and we require the following properties.

1. (“Safety”) The size of each committee is at most k , that is, for all C we have $|C| \leq k$.
2. (“Liveness”) If $\text{ID}(C) = \text{ID}(D)$ then all nodes in the graph join one committee, that is, for all C we have $C = D$.

-Gossip. The gossip problem is defined over a token domain T . Each node receives in its input a set of tokens, and the goal is for all nodes to output all tokens. Formally,

- is finite and

We are particularly interested in the following variants of the problem.

All-to-All gossip: instances where for all C we have $|C| \leq k$.

-gossip with known T : in this variant nodes know T , i.e., they receive T as part of the input.

Leader Election. In weak leader election all nodes must eventually output a bit b , such that exactly one node outputs $b = 1$. In strong leader election, all nodes must output the same ID of some node in the network.

4 Relationships

A problem P is *reducible* to Q if whenever all nodes start the computation in initial states that represent a solution to P , there is an algorithm that computes a solution to Q and requires linear time in the parameter n to the problem Q .

4.1 -Committee -Verification

Claim 4.1. *-verification reduces to -committee.*

Proof. Suppose we start from a global state that is a solution to k -committee, that is, each node has a local variable id such that at most k nodes belong to the same committee, and if $id(C) = id(D)$ then all nodes belong to one committee. We can verify whether or not k -verification as follows. For n rounds, each node maintains a Boolean flag $flag$, which is initially set to 0 . In rounds where $id(C) \neq id(D)$, the node broadcasts its committee ID, and when $id(C) = id(D)$ the node broadcasts 0 . If a node receives a committee ID different from its own, or if it hears the special value 0 , it sets $flag$ to 1 . At the end of the n rounds all nodes output $flag$.

First consider the case where $k = 1$. In this case all nodes have the same committee ID, and no node ever sets its $flag$ to 1 . At the end of the protocol all nodes output 0 , as required. Next,

suppose that \mathcal{C}_i , and let v be some node. There are at most k nodes in v 's committee. In every round, there is an edge between some node in v 's committee and some node in a different committee (because the communication graph is connected), and therefore at least one node in v 's committee sets its flag to 1. After at most $\frac{n}{k}$ rounds no nodes remain, and in particular v itself must have its flag set to 1. Thus, at the end of the protocol all nodes output 1. \square

Claim 4.2. k -committee reduces to k -verification.

Proof. Again, suppose the nodes are initially in a state that represents a solution to k -verification: they have a Boolean flag f which is set to 1 iff $v \in \mathcal{C}_v$. We solve k -committee as follows: if $f = 1$, then each node outputs its own ID as its committee ID. This is a valid solution because when the only requirement is that no committee have more than k nodes. If $f = 0$, then for $\frac{n}{k}$ rounds all nodes broadcast the minimal ID they have heard so far, and at the end they output this ID as their committee ID. Since $f = 0$ indicates that $v \notin \mathcal{C}_v$, after $\frac{n}{k}$ rounds all nodes have heard the ID of the node with the minimal ID in the network, and they will all join the same committee, as required. \square

4.2 Counting vs. k -Verification

Since we can solve k -verification in $O(\frac{n}{k})$ time in k -interval connected graphs, we can find an upper bound on the size of the network by checking whether $f = 1$ for values of k starting from 1 and doubling with every wrong guess. We know how to verify whether $f = 1$ in $O(\frac{n}{k})$ time, and hence the time complexity of the entire procedure is $O(n \log n)$. Once we establish that $f = 1$ for some value of k , to get an actual count we can then go back and do a binary search over the range $[1, k]$ (recall that $f = 1$ iff $v \in \mathcal{C}_v$, otherwise we would not have reached the current value of k).

In practice, we use a variant of k -committee where the ID of each committee is the set containing the IDs of all members of the committee. The k -verification layer returns this set as well, so that after reaching a value of k at node v , we simply return the size of v 's committee as the size of the network. Since $f = 1$ implies that all nodes join the same committee, node v will output the correct count.

4.3 Hierarchy of Problems

There is a hardness hierarchy among the problems considered in this paper as well as some other natural problems.

1. Strong leader election / consensus (these are equivalent).
2. Decomposable functions such as Boolean AND / OR
3. Counting.
4. k -gossip (with unknown k).

The problems in every level are reducible to the ones in the next level, and we know that k -gossip can be solved in $O(k \log n)$ time in k -interval connected graphs for $k \geq 1$, or $O(k \log n)$ assuming synchronous start. Therefore all the problems can be solved in $O(k \log n)$ time, even with no prior knowledge of the network, and even when the communication links are directed (assuming strong connectivity).

5 Upper Bounds

In this section we give algorithms for some of the problems introduced in Section 3, always with the goal of solving the counting problem. Our strategy is usually as follows:

1. Solve some variant of gossip.
2. Use (1) as a building block to solve k -committee,
3. Solving k -committee allows us to solve k -verification and therefore also counting (see Section 4).

We initially focus on the case of synchronous start. The modifications necessary to deal with asynchronous start are described in Section 5.5.

5.1 Always-Connected Graphs

5.1.1 Basic Information Dissemination

It is a basic fact that in 1-interval connected graphs, a single piece of information requires at most $\log n$ rounds to reach all the nodes in the network, provided that it is forwarded by all nodes that receive it. Formally, let S denote the set of nodes that has “reached” by round t . If u knows a token and broadcasts it constantly, and all other nodes broadcast the token if they know it, then all the nodes in S know the token by round $t + 1$.

Claim 5.1. *For any node u and round t we have $|S| \geq 2^t$.*

Proof. By induction on t . For $t = 0$ the claim is immediate. For the step, suppose that $|S| \geq 2^{t-1}$, and consider round t . If $u \in S$ then the claim is trivial, because u broadcasts the token. Thus, suppose that $u \notin S$. Since S is connected, there is some edge (v, w) in the cut $(S, V \setminus S)$. From the definition of the causal order we have $v \prec w$, and therefore $v \in S$. □

Note that we can employ this property even when there is more than one token in the network, provided that tokens form a totally-ordered set and nodes forward the smallest (or biggest) token they know. It is then guaranteed that the smallest (resp. biggest) token in the network will be known by all nodes after at most $\log n$ rounds. Note, however, that in this case nodes do not necessarily *know* when they know the smallest or biggest token.

5.1.2 Counting in linear time with $\log n$ -bit messages

We begin by describing a linear-time counting/gossip protocol which uses messages of size $\log n$. The protocol is extremely simple, but it demonstrates some of the ideas used in some of our later algorithms, where we eliminate the large messages using a stability assumption (ϵ -interval connectivity) which allows nodes to communicate with at least one of their neighbors for at least $\frac{1}{\epsilon}$ rounds.

In the simple protocol, all nodes maintain a set S containing all the IDs (or tokens) they have collected so far. In every round, each node broadcasts S and adds any IDs it receives. Nodes terminate when they first reach a round r in which $|S| = n$.

```

for  $r = 1$  do
  broadcast  $S$ 
  receive  $S$  from neighbors
  if  $|S| = n$  then terminate and output
end

```

Algorithm 1: Counting in linear time using large messages

Claim 5.2. For any node v and rounds $r < n$ we have $|S_v^r| \leq n - r$.

Proof. By induction on r . For $r = 0$ the claim is immediate.

Suppose that for all nodes v and rounds $r < r_0$ such that v and v' are neighbors we have $|S_v^r| \leq n - r$.

Let r_0 and $r_0 + 1$ be two rounds such that $r_0 < n$.

If $|S_v^{r_0}| = n - r_0$ then we are done, because $|S_v^{r_0+1}| \leq |S_v^{r_0}| + 1 = n - r_0 + 1 = n - (r_0 + 1)$. Thus, assume that $|S_v^{r_0}| < n - r_0$.

Since the communication graph in round r_0 is connected, there is some edge (v, v') such that v and v' are neighbors.

We have $|S_{v'}^{r_0}| \leq n - r_0$, and consequently $|S_v^{r_0+1}| \leq |S_v^{r_0}| + |S_{v'}^{r_0}| \leq n - r_0 + n - r_0 = 2n - 2r_0 = n - (r_0 + 1)$.

Also, from the induction hypothesis, $|S_v^{r_0+1}| \leq n - (r_0 + 1)$. Together we obtain $|S_v^{r_0+1}| \leq n - (r_0 + 1)$, as desired. \square

Claim 5.3. For any node v and round $r < n$ we have $|S_v^r| \leq n - r$.

Proof. It is easily shown that for all v we have $|S_v^0| = 1$. From the previous claim we have $|S_v^r| \leq n - r$ for all $r < n$, and the claim follows. \square

The correctness of the protocol follows from Claim 5.3: suppose that for some round r and node v we have $|S_v^r| = n - r$. From Claim 5.3, then, $|S_v^{r+1}| \leq n - (r + 1)$. Applying the claim again, we see that $|S_v^{r+2}| \leq n - (r + 2)$, and since $|S_v^r| = n - r$ for all r , we obtain $|S_v^r| = n - r$. This shows that nodes compute the correct count. For termination we observe that the size of S never exceeds n , so all nodes terminate no later than round n .

5.1.3 t -committee with $\log t$ -bit messages

We can solve t -committee in $O(t)$ rounds as follows. Each node i stores a local variable id_i in addition to id . A node that has not yet joined a committee is called *active*, and a node that has joined a committee is *inactive*. Once nodes have joined a committee they do not change their choice.

Initially all nodes consider themselves leaders, but throughout the protocol, any node that hears an ID smaller than its own adopts that ID as its leader. The protocol proceeds in $O(t)$ cycles, each consisting of two phases, *polling* and *selection*.

1. Polling phase: for $\log t$ rounds, all nodes propagate the ID of the smallest active node of which they are aware.
2. Selection phase: in this phase, each node that considers itself a leader selects the smallest ID it heard in the previous phase and invites that node to join its committee. An invitation is represented as a pair (l, i) , where l is the ID of the leader that issued the invitation, and i is the ID of the invited node. All nodes propagate the smallest invitation of which they are aware for $\log t$ (invitations are sorted in lexicographic order, so that invitations issued by the smallest node in the network will win out over other invitations. It turns out, though, that this is not necessary for correctness; it is sufficient for each node to forward an arbitrary invitation from among those it received).

At the end of the selection phase, a node that receives an invitation to join its leader's committee does so and becomes inactive. (Invitations issued by nodes that are not the current leader can be accepted or ignored; this, again, does not affect correctness.)

At the end of the $O(t)$ cycles, any node i that has not been invited to join a committee outputs

```

for
  // Polling phase
  if
    |
    | - ; // The node nominates itself for selection
  else
    |
    | -
  end
  for
    broadcast -
    receive from neighbors
  end
  // Update leader
  // Selection phase
  if
    |
    | // Leaders invite the smallest ID they heard
  else
    |
    | // Non-leaders do not invite anybody
  end
  for
    broadcast
    receive from neighbors
    order) ; // (in lexicographic
  end
  // Join the leader's committee, if invited
  if
    |
    |
  end
end
if
  |
  end

```

Algorithm 2: k -committee in always-connected graphs

Claim 5.4. *The protocol solves the k -committee problem.*

Proof. We show that after the protocol ends, the values of the local variables constitute a valid solution to k -committee.

1. In each cycle, each node invites at most one node to join its committee. After $\frac{n}{\Delta}$ cycles at most $\frac{n}{\Delta}$ nodes have joined any committee. Note that the first node invited by a leader u to join u 's committee is always u itself. Thus, if after $\frac{n}{\Delta}$ cycles node u has not been invited to join a committee, it follows that u did not invite any other node to join its committee; when it forms its own committee in the last line of the algorithm, the committee's size is 1.
2. Suppose that $\Delta \geq 2$, and let u be the node with the smallest ID in the network. Following the polling phase of the first cycle, all nodes v have $\text{poll}_v = u$ for the remainder of the protocol. Thus, throughout the execution, only node u issues invitations, and all nodes propagate u 's invitations. Since $\frac{n}{\Delta}$ rounds are sufficient for u to hear the ID of the minimal active node in the network, in every cycle node u successfully identifies this node and invites it to join u 's committee. After $\frac{n}{\Delta}$ cycles, all nodes will have joined.

□

Remark. The protocol can be modified easily to solve Δ -gossip if $\Delta \geq 2$. Let t be the token node u received in its input (or u if node u did not receive a token). Nodes attach their tokens to their IDs, and send pairs of the form (ID, t) instead of just ID . Likewise, invitations now contain the token of the invited node, and have the structure (ID, t) . The min operation disregards the token and applies only to the ID. At the end of each selection phase, nodes extract the token of the invited node, and add it to their collection. By the end of the protocol every node has been invited to join the committee, and thus all nodes have seen all tokens.

5.2 Δ -interval Connected Graphs

We can count in linear time in Δ -interval connected graphs using the following algorithm: each node maintains two sets of IDs, S and T . S is the set of all IDs known to the node, and T is the set of IDs the node has already broadcast. Initially S contains only the node's ID and T is empty. In every round, each node broadcasts $\min(S \setminus T)$ and adds this value to T . (If $S \setminus T = \emptyset$, the node broadcasts nothing.) Then it adds all the IDs it receives from its neighbors to S .

While executing this protocol, nodes keep track of the current round number (starting from zero). When a node reaches a round r in which $S \setminus T = \emptyset$, it terminates and outputs r as the count.

```

for  $i = 1$  do
  if  $i < n$  then
    broadcast
  end
  receive from neighbors
  if  $i = n$  then terminate and output
end
return

```

Algorithm 3: Counting in n -interval connected graphs

5.2.1 Analysis

Let $d(u, v)$ denote the shortest-path distance between u and v in the stable subgraph G , and let $N_r(u)$ denote the r -neighborhood of u in G , that is, $N_r(u) = \{v \in V \mid d(u, v) \leq r\}$. We use x_i and y_i to denote the values of local variables x and y at node u in the beginning of round i . Note the following properties:

1. $x_i \leq x_{i+1}$ for all u and i .
2. If u and v are neighbors in G , then $x_{i+1}(v) = x_i(u) + 1$ for all i , because every value sent by u is received by v and added to x .
3. x_i and y_i are monotonic, that is, for all u and i we have $x_i(u) \leq x_{i+1}(u)$ and $y_i(u) \leq y_{i+1}(u)$.

Claim 5.5. For every two nodes $u, v \in V$ and round i such that $d(u, v) \leq i$, either $x_i(u) = x_i(v)$ or $y_i(u) = y_i(v)$.

Proof. By induction on $d(u, v)$. For $d(u, v) = 0$ the claim is immediate. Suppose the claim holds for round $i-1$, and consider round i . Let u, v be nodes such that $d(u, v) \leq i$; we must show that either $x_i(u) = x_i(v)$ or $y_i(u) = y_i(v)$. If $d(u, v) = 1$, then the claim holds: x is broadcast in the first round, and thereafter we have $x_i(u) = x_{i-1}(v) + 1 = x_i(v)$ for all i . Otherwise, let w be a neighbor of u along the shortest path from u to v in G ; that is, w is a neighbor of v such that $d(u, w) = 1$ and $d(w, v) = d(u, v) - 1$. Since $d(w, v) \leq i-1$, we have

From the induction hypothesis on w and v in round $i-1$, either $x_{i-1}(w) = x_{i-1}(v)$ or $y_{i-1}(w) = y_{i-1}(v)$. Applying property 2 above, this implies the following.

() Either $x_i(u) = x_i(v)$ or $y_i(u) = y_i(v)$.

If ℓ or r then we are done, because $\ell < r$. Suppose then that $\ell = r$ and $\ell < r$. It is sufficient to prove that this shows that in round t node v broadcasts ℓ and adds it to S , yielding $S \cup \{\ell\}$ and proving the claim.

We show this using ℓ . If $\ell < r$, then $\ell < r$, because we assumed that $\ell < r$. Otherwise $\ell = r$ states that $\ell < r$, and since we assumed that $\ell = r$, this again shows that $\ell < r$. \square

Claim 5.6. *If $\ell < r$, then for all nodes v we have $\ell < r$.*

Proof. Let v . For any node w , Claim 5.5 shows that either $\ell < r$ or $\ell = r$. Thus, either $\ell < r$ or $\ell = r$. Since v and w is connected we have $\ell < r$, and therefore in both cases we have $\ell < r$. \square

Claim 5.7. *The algorithm terminates in linear time and outputs the correct count at all nodes.*

Proof. Termination is straightforward: the set S only contains IDs of nodes that exist in the network, so its size cannot exceed n . All nodes terminate no later than round $2n$.

Correctness follows from Claim 5.6. Suppose that in round t node v has ℓ , and let S . We must show that $\ell < r$.

From Claim 5.6, if $\ell < r$ then $\ell < r$. By definition of ℓ we have $\ell < r$ and hence from Property 3 we obtain $\ell < r$, which is not the case. Thus, $\ell = r$ and $\ell < r$. Applying the same reasoning as in Claim 5.6 to round t , we see that either $\ell < r$ or $\ell = r$. Since the first cannot occur it must be the case that $\ell = r$, and we are done. \square

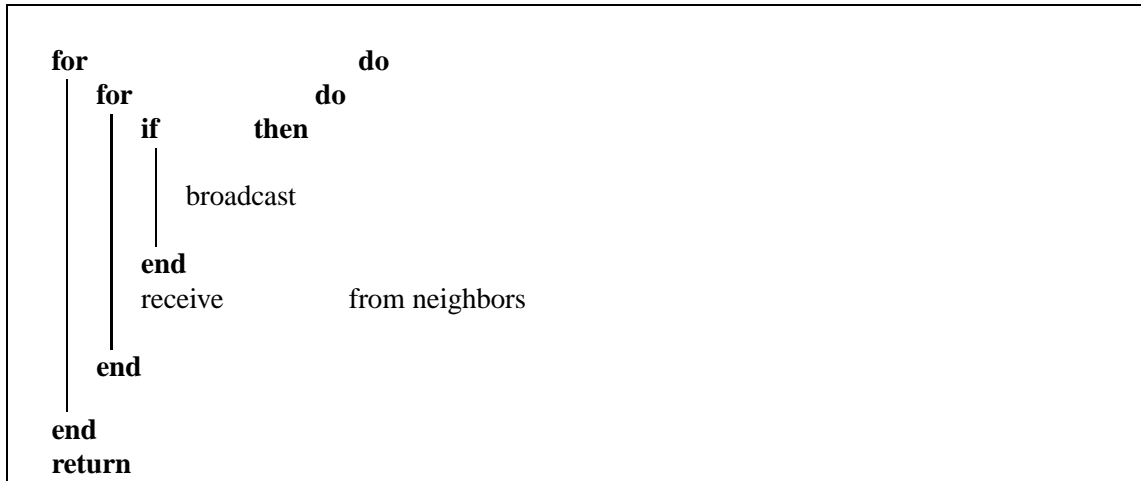

5.3 Finite-Interval Connected Graphs

Next we generalize the protocol above, in order to solve k -committee in Δ -interval connected graphs. The general protocol requires $2k$ rounds (and assumes that k is known in advance). The idea is the same as for always-connected graphs, except that instead of selecting one node at a time to join its committee, each leader selects a batch of k nodes and disseminates their IDs throughout the network. We generalize and refine Claim 5.5 for the case where there are initially up to k tokens, but only the smallest k tokens need to be disseminated.

5.3.1 k -gossip in Δ -interval connected graphs

The “pipelining effect” we used in the Δ -interval connected case allows us to disseminate k tokens in $2k$ rounds, given that the graph is Δ -interval connected. The idea is to use a similar protocol to the Δ -interval connected case, except that the protocol is “restarted” every k rounds: all nodes empty the set S (but not T), which causes them to re-send the tokens they already sent, starting from the smallest and working upwards. The k smallest tokens will thus be propagated through the network, and larger tokens will “die out” as they are not re-sent.

This is captured formally by the following protocol. The tokens are now assumed to come from a well-ordered set T . The input at each node v is an initial set S_v of tokens. In addition, it is assumed that all nodes have a common guess n for the size of the network. The protocol guarantees that the n smallest tokens in the network are disseminated to all nodes, provided that the graph is n -interval connected and that $\Delta \leq n$.

Function disseminate()

We refer to each iteration of the inner loop as a *phase*. Since a phase lasts n rounds and the graph is n -interval connected, there is some connected subgraph that exists throughout the phase. Let G_t be a connected subgraph that exists throughout phase t , for $t = 1, \dots, \lceil n \rceil$. We use

$d(v, w)$ to denote the distance between nodes v, w in G_t .

Let S_t denote the set of nodes that know token t by the beginning of round $(t-1)n + 1$, that is, at the beginning of phase t . In addition, let T_t be the set of n smallest tokens in T .

Our goal is to show that when the protocol terminates we have $S_t = T_t$ for all $t = 1, \dots, \lceil n \rceil$.

For a node v , a token t , and a phase t , we define $d_t(v, T_t)$ to be the distance of v from the nearest node in T_t that knows t at the beginning of phase t :

Here and in the sequel, we use the convention that $d_t(v, T_t) = \infty$ if v does not know t at the beginning of phase t . For convenience, we use $d_t(v, T_t)$ to denote the value of $d_t(v, T_t)$ in round $(t-1)n + 1$ of phase t . Similarly we denote $d_t(v, T_t)$ and $d_t(v, T_t)$.

The following claim characterizes the spread of each token in each phase. It is a generalization of Claim 5.5, and the proof is similar.

Claim 5.8. For any node v , token t , and round r such that $(t-1)n + 1 \leq r \leq tn$, either v knows t at round r or $d_t(v, T_t) \leq r - (t-1)n$.

Proof. By induction on r . For $r = (t-1)n + 1$ the claim is immediate.

Suppose the claim holds for round r of phase ϕ , and consider round $r+1$. If r is even, then $r+1$ is odd and the claim holds trivially. Thus, suppose that r is odd. Hence, r is even, and the induction hypothesis applies: either r includes at least $\frac{r}{2}$ tokens that are smaller than $\frac{r}{2}$. In the first case we are done, since $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$; thus, assume that r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. However, if r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, then so does $r+1$, and the claim is again satisfied; thus we assume that r includes *exactly* $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$.

It is sufficient to prove that $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$: if this holds, then in round $r+1$ node v broadcasts $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, which is either v or a token smaller than $\frac{r}{2}$; thus, either $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, and the claim holds.

First we handle the case where r is even. In this case, $r+1$ is odd. Since we assumed that r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, we have $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, which implies that $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$.

Next suppose that r is odd. Let v be a node such that v is a neighbor of v along the path from v to v in r , such that v is a neighbor of v . From the induction hypothesis, either v or v includes at least $\frac{r}{2}$ tokens that are smaller than $\frac{r}{2}$. Since the edge between v and v exists throughout phase ϕ , node v receives everything v sends in phase ϕ , and hence v includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. Finally, because we assumed that r includes exactly $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, and does not include v itself, we have $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, as desired. \square

Claim 5.9. For each of the $\frac{r}{2}$ smallest tokens t and phases ϕ , we have t is learned by v in phase ϕ .

Proof. The proof is by induction on r . For $r=1$ the claim is immediate. For the induction step, suppose that r is even, and consider phase ϕ .

Let $N_r(v)$ denote the r -neighborhood of v , that is, $N_r(v) = \{u \mid \text{dist}(v, u) \leq r\}$. From Claim 5.8 applied to round r of phase ϕ , for all v , either v includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. Since v is one of the $\frac{r}{2}$ smallest tokens in the network, this latter case is impossible. Thus, every node v has $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, which implies that r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. In addition, r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, because nodes never forget tokens they have learned.

Since v is connected, $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. Combining with the induction hypothesis we obtain $r+1$ includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$, and the claim follows. \square

Procedure `disseminate` terminates at the end of phase ϕ , or, equivalently, at the beginning of phase $\phi+1$. By this time, if the guess for the size of the network was correct, all nodes have learned the $\frac{r}{2}$ smallest tokens.

Corollary 5.10. If r is even, then r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$ for each of the $\frac{r}{2}$ smallest tokens t .

Proof. The claim follows from Claim 5.9, because r includes at least $\frac{r}{2}$ tokens smaller than $\frac{r}{2}$. \square

5.3.2 k -committee in Δ -interval connected graphs

We can solve the k -committee problem in Δ rounds using Algorithm 5. The idea is similar to Algorithm 2, except that leaders invite k nodes to join their committee in every cycle instead of just one node. Each node begins the protocol with a unique ID which is stored in the local variable id .

```

for  $i = 1$  to  $\Delta$  do
  if  $id \leq \Delta$  then
     $id = id + 1$ ; // The node nominates itself for selection
  else
     $id = 0$ ;
  end
  disseminate
  if  $id \leq \Delta$  then
    // Leaders invite the  $k$  smallest IDs they collected
    // (or less in the final cycle, so that the total does not
    // exceed  $k$ )
    if  $id \leq \Delta - k$  then
       $invite[id]$ 
    else
       $invite[id - \Delta + k]$ 
    end
  else
    // Non-leaders do not invite anybody
  end
  disseminate
  // Join the leader's committee, if invited
  if  $id \in invite$  then
     $id = id + 1$ 
  end
end
if  $id \leq \Delta$  then
  end

```

Algorithm 5: k -committee in Δ -interval connected graphs

Claim 5.11. *The protocol above solves k -committee in Δ rounds.*

5.3.3 Counting in Graphs with Unknown Finite-Interval Connectivity

The protocol above assumes that all nodes know the degree of interval connectivity present in the communication graph; if the graph is not δ -interval connected, invitations may not reach their destination, and the committees formed may contain less than δ nodes even if $\delta \leq n$. However, even when the graph is not δ -interval connected, no committee contains *more* than δ nodes, simply because no node ever issues more than δ invitations. Thus, if nodes guess a value for δ and use the δ -committee protocol above to solve δ -verification, their error is one-sided: if their guess for δ is too large they may falsely conclude that $\delta \leq \delta$ when in fact $\delta > \delta$, but they will never conclude that $\delta > \delta$ when $\delta \leq \delta$.

This one-sided error allows us to try different values for δ and δ without fear of mistakes. We can count in $O(n^2 \log n)$ time in graphs where δ is *unknown* using the following scheme. I assume the version of δ -verification that returns the set S of all nodes if $\delta \leq \delta$, or the special value \perp if $\delta > \delta$.

```

for  $\delta = 1$  do
  for  $\delta = 1$  do
    if  $\delta$ -verification assuming  $\delta$ -interval connectivity returns  $\perp$  then
      return  $\delta$ 
    end
  end
end

```

Algorithm 6: Counting in $O(n^2 \log n)$ time in δ -interval connected graphs where δ is unknown

The time required for δ -verification assuming δ -interval connectivity is $O(n^2)$ for all δ , and thus the total time complexity of the i -th iteration of the outer loop is $O(n^2 \log n)$.

If the communication graph is δ -interval connected, the algorithm terminates the first time we reach values of δ and δ such that $\delta \leq \delta$ and $\delta \leq \delta$. Let 2^k be the smallest power of 2 that is no smaller than δ ; clearly $2^k \leq \delta < 2^{k+1}$. Let us show that the algorithm terminates when we reach 2^k .

First consider the case where $\delta \leq 2^k$, and hence $2^k \leq \delta$. When we reach the last iteration of the inner loop, where $\delta = 2^k$, we try to solve δ -verification assuming δ -interval connectivity. This must succeed, and the algorithm terminates.

Next, suppose that $\delta > 2^k$. Consider the iteration of the inner loop in which $\delta = 2^k$. In this iteration, we try to solve δ -verification assuming δ -interval connectivity. Since $\delta > 2^k$, this again must succeed, and the algorithm terminates.

The time complexity of the algorithm is dominated by the last iteration of the outer loop, which requires $O(n^2 \log n)$ rounds.

The asymptotic time complexity of this algorithm only improves upon the original algorithm (which assumes only 1-interval connectivity) when $\delta > 1$. However, it is possible to execute both algorithms in parallel, either by doubling the message sizes or by interleaving the steps, so that the original algorithm is executed in even rounds and Alg. 6 is executed in odd rounds. This will lead to a time complexity of $O(n^2 \log n)$, because we terminate

when either algorithm returns a count.

5.4 Exploiting Expansion Properties of the Communication Graph

Naturally, if the communication graph is always a good expander, the algorithms presented here can be made to terminate faster. We consider two examples of graphs with good expansion. As before, when the expansion is not known in advance we can guess it, paying a factor.

5.4.1 k -Connected Graphs

Definition 5.1. A static graph G is k -connected for $k \geq 1$ if the removal of any set of at most $k-1$ nodes from G does not disconnect it.

Definition 5.2 (k -interval k -connectivity). A dynamic graph G is said to be k -interval k -connected for $k \geq 1$ if for all $S \subseteq V$, the static graph $G - S$ is k -connected.

Definition 5.3 (Neighborhoods). Given a static graph G and a set S of nodes, the *neighborhood* of S in G is the set $N(S)$. The *neighborhood* of S is defined inductively, with $N(S) = S$ and $N(S) = N(S) \cup N(N(S) - S)$ for $S \subseteq V$. We omit the subscript G when it is obvious from the context.

In k -connected graphs the propagation speed is multiplied by k , because every neighborhood is connected to at least k external nodes (if there are fewer than k remaining nodes, it is connected to all of them). This is shown by the following lemma.

Lemma 5.12 (Neighborhood Growth). *If G is a static k -connected graph, then for any non-empty set S and integer $t \geq 0$, we have $|N^t(S)| \geq k^t |S|$.*

Proof. By induction on t . For $t=0$ the claim is immediate. For the step, suppose that $|N^{t-1}(S)| \geq k^{t-1} |S|$. Suppose further that $|N^t(S)| < k^t |S|$, otherwise the claim is immediate. This also implies that $|N^t(S) - N^{t-1}(S)| > 0$, because $|N^t(S)| < k^t |S|$. Thus the induction hypothesis states that

Let S_t denote the “new” nodes in the k -neighborhood of $N^{t-1}(S)$. It is sufficient to show that $|S_t| \geq k |N^{t-1}(S) - S_{t-1}|$, because then $|N^t(S)| \geq k^t |S|$, and we are done.

Suppose by way of contradiction that $|S_t| < k |N^{t-1}(S) - S_{t-1}|$, and let G_t be the subgraph obtained from G by removing the nodes in S_t . Because G is k -connected and $|S_t| < k |N^{t-1}(S) - S_{t-1}|$, the subgraph G_t is connected. Consider the cut $(S_{t-1}, N^{t-1}(S) - S_{t-1})$ in G_t . Because $|S_t| < k |N^{t-1}(S) - S_{t-1}|$ and $|S_t| < k |N^{t-1}(S) - S_{t-1}|$, we also have $|S_t| < k |N^{t-1}(S) - S_{t-1}|$. However, the cut is empty: if there were some edge (u, v) such that $u \in S_{t-1}$ and $v \in N^{t-1}(S) - S_{t-1}$, then by definition of S_t we would have $v \in S_t$. This in turn would imply that $(u, v) \in E(S_t)$, and thus $(u, v) \in E(S_t)$, a contradiction. This shows that G_t is not connected, contradicting the k -connectivity of G . \square

Now we can modify Procedure `disseminate` to require only $\frac{1}{\epsilon}$ phases. Claim 5.8 still holds, since it is only concerned with a single phase. The key change is in Claim 5.9, which we now re-state as follows.

Claim 5.13. *For each of the $\frac{1}{\epsilon}$ smallest tokens t and phases p we have*

Proof. Again by induction on p , with the base case being trivial. For the step, assume that $\frac{1}{\epsilon}$ tokens have been disseminated. As argued in the proof of Claim 5.9, at the end of phase p we have $\frac{1}{\epsilon}$ tokens, where $\frac{1}{\epsilon}$ is the number of tokens. From Lemma 5.12, $\frac{1}{\epsilon}$ tokens are disseminated and the claim follows. \square

Corollary 5.14. *If $\frac{1}{\epsilon}$ tokens are disseminated, then $\frac{1}{\epsilon}$ tokens are disseminated for each of the $\frac{1}{\epsilon}$ smallest tokens.*

Proof. Because $\frac{1}{\epsilon}$ tokens are disseminated. \square

By substituting the shortened `disseminate` in Algorithm 5, we obtain an algorithm that solves ϵ -Committee in $\frac{1}{\epsilon}$ time in $\frac{1}{\epsilon}$ -interval $\frac{1}{\epsilon}$ -connected graphs.

5.4.2 Vertex Expansion

In this section, we show that if the communication graph is always an expander, the `disseminate` procedure requires $\frac{1}{\epsilon}$ phases to disseminate the $\frac{1}{\epsilon}$ smallest tokens.

Definition 5.4. A static graph G is said to have vertex expansion ϵ if for all $S \subseteq V$, if $|S| \leq \frac{n}{2}$ then $|E(S, V \setminus S)| \geq \epsilon |S|$.

Definition 5.5 (ϵ -interval vertex expansion). A dynamic graph G is said to have ϵ -interval vertex expansion for $\epsilon > 0$ if for all $S \subseteq V$, the static graph $G[S, S]$ has vertex expansion ϵ .

Lemma 5.15. *Let G be a fixed undirected graph. If G has vertex expansion ϵ , for any non-empty set S and integer k , we have*

if
if

Proof. The case $k=1$ is trivial, the case $k=2$ follows directly from Definition 5.4. For $k > 2$, let S_1 and let S_2 . Note that any two nodes u and v are at distance at least k . It therefore holds that $|S_1 \cap S_2| = 0$. Consequently, we have $|S_1 \cup S_2| = |S_1| + |S_2|$ and certainly also $|E(S_1 \cup S_2, V \setminus (S_1 \cup S_2))| \geq \epsilon (|S_1| + |S_2|)$ and thus by Definition 5.4, $|E(S_1, V \setminus S_1)| \geq \epsilon |S_1|$. Together, this implies that $|E(S, V \setminus S)| \geq \epsilon |S|$ as claimed. \square

Analogously to ϵ -interval $\frac{1}{\epsilon}$ -connected graphs, we can modify Procedure `disseminate` to require only $\frac{1}{\epsilon}$ phases. Again, Claim 5.8 still holds and the key is to restate Claim 5.9, which now has to be adapted as follows.

Claim 5.16. We define \dots . For each of the \dots smallest tokens \dots and phases \dots , we have

$$\dots \quad \text{for} \\ \dots \quad \text{for}$$

Proof. As in the other two cases, the proof is by induction on \dots , with the base case being trivial. Again, for the step, as argued in the proof of Claim 5.9, at the end of phase \dots we have \dots , where \dots . The claim now immediately follows from Lemma 5.15. \square

Corollary 5.17. If \dots , \dots for each of the \dots smallest tokens \dots . \square

Consequently, in dynamic graphs with \dots -interval vertex expansion \dots , \dots -gossip can be solved in \dots rounds.

5.5 Asynchronous Start

So far we assumed that all nodes begin executing the protocol in the same round. It is interesting to consider the case where computation is initiated by some subset of nodes, while the rest are asleep. We assume that sleeping nodes wake up upon receiving a message; however, since messages are delivered at the *end* of each round, nodes that are woken up in round \dots send their first message in round \dots . Thus, nodes have no way of determining whether or not their messages were received by sleeping nodes in the current round.

Claim 5.18. Counting is impossible in 1-interval connected graphs with asynchronous start.

Proof. Suppose by way of contradiction that \dots is a protocol for counting which requires at most \dots rounds in 1-interval connected graphs of size \dots . Let \dots . We will show that the protocol cannot distinguish a line of length \dots from a line of length \dots .

Given a sequence \dots , let \dots denote the cyclic left-shift of \dots in which the first \dots symbols (\dots) are removed from the beginning of the sequence and appended to the end. Consider an execution in a dynamic line of length \dots , where the line in round \dots is composed of two adjacent sections \dots , where \dots remains static throughout the execution, and \dots is left-shifted by one in every round. The computation is initiated by node \dots and all other nodes are initially asleep. We claim that the execution of the protocol in the dynamic graph \dots is indistinguishable in the eyes of nodes \dots from an execution of the protocol in the static line of length \dots (that is, the network comprising section \dots alone). This is proven by induction on the round number, using the fact that throughout rounds \dots none of the nodes in section \dots ever receives a message from a node in section \dots : although one node in section \dots is awakened in every round, this node is immediately removed and attached at the end of section \dots , where it cannot communicate with the nodes in section \dots . Thus, the protocol cannot distinguish the dynamic graph \dots from the dynamic graph \dots , and it produces the wrong output in one of the two graphs. \square

If 2-interval connectivity is assumed, it becomes possible to solve gossip under asynchronous start. We begin by defining a version of the \mathcal{C} -committee and \mathcal{V} -verification problems that explicitly address sleeping nodes.

-Committee with Wakeup. In the modified \mathcal{C} -committee problem we require, as before, that no committee have more than k nodes. Sleeping nodes are not counted as belonging to any committee. In addition, if \mathcal{C} , we require all nodes to be awake and to be in the same committee.

-Verification with Wakeup. In the modified \mathcal{V} -verification problem, all awake nodes must eventually output 1 iff \mathcal{V} . Sleeping nodes do not have to output anything. (Nodes that are awakened during the execution are counted as awake and must output a correct value; however, there is no requirement for the algorithm to wake up all the nodes.)

5.5.1 \mathcal{V} -Verification with Wakeup

We modify the \mathcal{V} -verification protocol as follows. First, each node that is awake at the beginning of the computation maintains a round counter r_i which is initialized to 0 and incremented after every round. Each message sent by the protocol carries the round counter of the sender, as well as a tag indicating that it is a \mathcal{V} -verification protocol message (so that sleeping nodes can tell which protocol they need to join).

As before, each node i has a variable c_i which is initially set to its committee ID. In every round node i broadcasts the message (r_i, c_i) . If i hears a different committee ID or the special value \perp , it sets $c_i = \perp$; if it hears a round counter greater than its own, it adopts the greater value as its own round counter. When a node i is awakened by receiving a message carrying the \mathcal{V} -tag, it sets r_i and adopts the round counter from the message (if there is more than one message, it uses the largest one).

All awake nodes execute the protocol until their round counter reaches n . At that point they halt and output 1 iff \mathcal{V} .

```

while  $\tau < \tau_{\text{max}}$  do
  broadcast  $\tau$ 
  receive  $\tau_1, \dots, \tau_k$  from neighbors
  if for some  $i \in \{1, \dots, k\}$   $\tau_i = \tau$  then
    |
  end
end
if  $\tau < \tau_{\text{max}}$  then
  | output 0
else
  | output 1
end
upon awakening by receipt of messages  $\tau_1, \dots, \tau_k$  :
   $\tau := \max\{\tau, \tau_1, \dots, \tau_k\}$ 

upon awakening spontaneously (by the adversary):
   $\tau := \tau_{\text{max}}$ 

```

Algorithm 7: τ -verification protocol with wakeup

Claim 5.19. Algorithm 7 solves the τ -verification with wakeup problem if all nodes start in a state that represents a solution to τ -committee with wakeup, and the graph is 2-interval connected.

Proof. The case where $\tau_{\text{max}} < \tau$ is immediate: as in the synchronous start case, all nodes are awake at the beginning of the protocol, and no node ever hears a committee ID different from its own.

Suppose that $\tau_{\text{max}} \geq \tau$. Nodes that are awakened during the protocol set their τ variable to τ_{max} , so they will output 0; we only need to concern ourselves with nodes that are awake at the beginning and have a committee ID. We show that the size of each committee shrinks by at least one node every two rounds, so that at the end of the τ_{max}/τ rounds, all nodes have τ_{max} .

Consider a cut between the nodes that belong to some committee C and still have $\tau < \tau_{\text{max}}$, and the rest of the nodes, which are either sleeping or have τ_{max} . From 2-interval connectivity, some edge (u, v) in the cut exists for the next two rounds. Assume that $u \in C$. If v is asleep in the first round, wakes up when it receives u 's message, and broadcasts τ in the second round. If v is awake in the first round it broadcasts τ_{max} in the first round. In both cases node v will change to τ_{max} by the end of the second round. \square

It remains to show that we can solve τ -committee with asynchronous start. We can do this using the same approach as before, with one minor modification: as with τ -verification, we maintain a round counter r at every node, and now each node uses the pair (r, τ) as its UID, instead of τ alone. The pairs are ordered lexicographically, with *larger* round counters winning out over smaller ones; that is, $(r_1, \tau_1) < (r_2, \tau_2)$ iff $r_1 < r_2$, or $r_1 = r_2$ and $\tau_1 < \tau_2$.

When a node receives a larger round counter than its own in a message, it adopts that value as its own round counter, and jumps to the appropriate part of the protocol (e.g., if the round counter it receives is r , in the next round it will execute the fifth round of the invitation phase, because it knows that the first $r-4$ rounds were taken up by the polling phase and the first four rounds of the invitation phase have passed already). We use round counters so that nodes that awaken during the execution of the protocol will know what the current round is, and to have the eventual leader be one of the nodes that woke up first.

Claim 5.20. *Algorithm 5, when run with round counters and using pairs of the form (i, i) instead of UIDs, solves the (n, ϵ) -committee with wakeup problem.*

Proof. First consider the case where $\epsilon \geq 1/2$, and let u be the node with the smallest UID among the nodes that initiate the computation. The first polling phase executed by u lasts ϵn rounds, during which all nodes receive u 's polling message and forward it, setting their round counter to match u 's if it does not already. At the end of u 's polling phase, all nodes are awake, all have the same round counter as u , and all have u as their leader. From this point on the execution proceeds as in the case of synchronous wakeup.

Next suppose that $\epsilon < 1/2$. In this case we only need to show that no committee contains more than ϵn members. But this, as always, is guaranteed by the fact that each committee contains only nodes invited by the node whose UID is the committee ID, and no node ever invites more than ϵn nodes to join its committee. \square

When nodes execute the full counting algorithm with asynchronous wakeup, different parts of the graph may be testing different values for ϵ at the same time. However, the round counter serves to bring any lagging nodes up-to-date. When some node u first reaches ϵn , even if other nodes are still testing smaller values for ϵ , the first polling phase of u 's (n, ϵ) -committee instance will reach all nodes and cause them to join u 's computation. (In fact they will join u 's computation sooner, because to reach ϵn it had already had to go through at least ϵn rounds testing smaller values, so all nodes will have seen its current round already.)

5.6 Randomized Approximate Counting

We next show that under certain restrictions on the adversary providing the sequence of graphs, by using randomization, it is possible to obtain an approximation to the number of nodes in time almost linear in n with high probability, even if the dynamic graph is only ϵ -interval connected. The techniques we use are based on a gossiping protocol described in [31]. We assume that the nodes know some potentially loose upper bound U on n . When arguing about randomized algorithms, we need to specify which random choices the dynamic graph G_t can depend on. We assume an adversary that is oblivious to all random choices of the algorithm.

Definition 5.6 (Oblivious Adversary). Consider an execution of a randomized algorithm \mathcal{A} . The dynamic graph G_t provided by an oblivious adversary has to be independent of all random choices of \mathcal{A} .

In the sequel, we show that in the case of an oblivious adversary, it is possible to use randomization to efficiently compute an arbitrarily good estimate of n . In particular, we show that for any $\epsilon > 0$, it is possible to compute an $(1 \pm \epsilon)$ -approximation of n with high probability (in ϵ) in time $O(n \log n)$ when using messages of size $O(\log n)$ if the maximal message size is restricted to $O(\log n)$ bits.

For simplicity, we only describe the algorithm with slightly larger message sizes in detail and merely sketch how to adapt the algorithm if messages are restricted to $O(\log n)$ bits. For parameters $\epsilon > 0$ and $\delta > 0$, we define

(1)

Initially, each node v computes ϵn independent exponential random variables with rate ϵ . Following the aggregation scheme described in [31], we define

(2)

If we choose a set S independently of the exponential random variables of the nodes, $|S|$ is a good estimate for the size of n as shown by the following lemma, which is proven in [31].

Lemma 5.21 ([31]). *For every $\epsilon > 0$ that is chosen independently of the random variables for v and $\delta > 0$, we have*

$$|S| \in [n(1 - \epsilon), n(1 + \epsilon)]$$

Before describing the algorithm in detail, we give a brief overview. In order to obtain a good estimate for the total number of nodes n , the objective of each node will be to compute ϵn and thus ϵn for each v . In each round, every node broadcasts the minimal ϵn value it has heard for every v . If we assume that the sequence of graphs is chosen by an oblivious adversary, for each node v and round r , ϵn is independent of all the exponential random variables chosen by nodes v . Hence, as a consequence of Lemma 5.21, ϵn is a good estimate of n for all v and r . Because ϵn for all v and r (Claim 5.2), each node can stop forwarding minimal ϵn values as soon as the value of ϵn exceeds the round number by a sufficient amount.

Executing the algorithm as described above would require the nodes to send exact values of exponential random variables, i.e., real values that cannot a priori be sent using a bounded number of bits. Therefore, each node v computes a rounded value ϵn of ϵn for each v as follows.

(3)

Hence, \bar{c} is rounded to the next smaller integer power of $\frac{1}{2}$. Further, we restrict \bar{c} to be within the range $[\frac{1}{2}, 1]$. We will show that with high probability, all variables \bar{c}_i will be in this range and thus restricting the range only has an effect with negligible probability. As \bar{c} is an integer power of $\frac{1}{2}$, it can be stored using $\log_2 \frac{1}{\bar{c}}$ bits. The details of the algorithm are given by Algorithm 8.

```

for  $\bar{c} \in \{ \frac{1}{2}, 1 \}$  do
  broadcast  $\bar{c}$ 
  receive  $\bar{c}_i$  from neighbors
  for  $\bar{c}_i \in \{ \frac{1}{2}, 1 \}$  do
    |
  end
  if  $\bar{c}_i = \bar{c}$  then terminate and output
end

```

Algorithm 8: Randomized approximate counting in linear time, code for node

Theorem 5.22. For $n \geq \frac{1}{\epsilon^2}$ and $\epsilon \in (0, 1]$, with probability at least $1 - \epsilon$, every node of Algorithm 8 computes the same value \bar{c} . Further $\bar{c} \in \{ \frac{1}{2}, 1 \}$.

Proof. Let E be the event that the exponential random variables X_i for all i and \bar{c}_i are within the range $[\frac{1}{2}, 1]$. For each i , we have

$$\Pr[X_i \in [\frac{1}{2}, 1]] = \frac{1}{2} \ln 2 \approx 0.347$$

and

$$\Pr[\bar{c}_i \in \{ \frac{1}{2}, 1 \}] = \frac{1}{2}$$

As the number of random variables is n , we obtain $\Pr[E] \geq 1 - \epsilon$ by a union bound.

Consider the state of some node v after $\frac{1}{\epsilon}$ rounds. Because all minimal \bar{c}_i values are always forwarded, for all i , it holds that $\bar{c}_i \geq \bar{c}$. In case of the event E , for all i and \bar{c}_i , we have

$$\bar{c}_i = \bar{c} \quad \text{and thus} \quad \bar{c} = \frac{1}{2} \quad (4)$$

We thus get

$$(4) \quad \left| \bigcup_{i \in \mathcal{N}} \mathcal{E}_i \right| \leq \sum_{i \in \mathcal{N}} |\mathcal{E}_i| \leq n \sum_{i \in \mathcal{N}} \frac{1}{n} \leq n \cdot \frac{1}{n} = 1$$

Lemma 5.21

In order to be able to apply Lemma 5.21, we use that with an oblivious adversary, for all i and j , \mathcal{E}_i is independent of all random variables \mathcal{R}_j . By applying a union bound, we obtain that with probability at least $1 - \epsilon$, event $\overline{\mathcal{E}}$ occurs or

$$(5) \quad \left| \bigcup_{i \in \mathcal{N}} \mathcal{E}_i \right| \leq \sum_{i \in \mathcal{N}} |\mathcal{E}_i| \leq n \epsilon$$

Note that \mathcal{E}_i for all i and that the union bound therefore is over n events. If (5) holds, we have

for all i and j . Therefore, in this case no node terminates before round t . Hence, all nodes get the same final value for t and by (5), it holds that \mathcal{E}_i as required. Because \mathcal{E} , (5) holds with probability at least $1 - \epsilon$ which completes the proof. \square

6 Lower Bounds for Token-Forwarding Algorithms

A token-forwarding algorithm for solving the gossip problem is an algorithm that does not manipulate the tokens in any way except storing and forwarding them. Specifically, the algorithm must satisfy the following conditions. Let \mathcal{M}_i^t denote the message broadcast by node i in round t , when the algorithm is executed in dynamic graph \mathcal{G}_t .

1. \mathcal{M}_i^t for all round t and nodes i .
2. Nodes can only learn new tokens by receiving them, either in their input or in a message from another node. Formally, let \mathcal{R}_i^t denote the set of messages \mathcal{M}_j^t receives in round t , and let

We require the following.

for all nodes v and rounds r , and
 If node v terminates in round r , then $\Phi_r(v) = 0$.

We omit the superscript v when it is obvious from the context.

6.1 Lower Bound for Centralized k -Gossip in 1-Interval Connected Graphs

For this lower bound we assume that in each round r , some central authority provides each node v with a value $x_r(v)$ to broadcast in that round. The centralized algorithm can see the state and history of the entire network, but it does not know which edges will be scheduled in the current round. Centralized algorithms are more powerful than distributed ones, since they have access to more information. To simplify, we begin with each of the k tokens known to exactly one node. This restriction is not essential. The lower bound holds as long as there is constant fraction of the nodes that still need to learn k tokens for some positive constant ϵ .

We observe that while the nodes only know a small number of tokens, it is easy for the algorithm to make progress; for example, in the first round of the algorithm at least ϵn nodes learn a new token, because connectivity guarantees that ϵn nodes receive a token that was not in their input. As nodes learn more tokens, it becomes harder for the algorithm to provide them with tokens they do not already know. Accordingly, our strategy is to charge a cost of $\frac{1}{k}$ for the k -th token learned by each node: the first token each node learns comes at a cheap cost $\frac{1}{k}$, and the last token learned costs dearly (1). Formally, the potential of the system in round r is given by

—

In the first round we have $\Phi_1 = \frac{1}{k}$, because ϵn nodes know one token each. If the algorithm terminates in round r then we must have $\Phi_r = 1$, because all n nodes must know all k tokens. We construct an execution in which the potential increase is bounded by a constant in every round; this gives us an $O(k)$ bound on the number of rounds required.

Theorem 6.1. *Any centralized algorithm for k -gossip in 1-interval connected graphs requires $O(k)$ rounds to complete in the worst case.*

Proof. We construct the communication graph for each round r in three stages.

Stage I: Adding the free edges. An edge (u, v) is said to be *free* if $x_r(u) = x_r(v)$ and $x_r(u) \neq x_r(v)$; that is, if we connect u and v , neither node learns anything new. Let F_r denote the set of free edges in round r ; we add all of them to the graph. Let C_r denote the connected components of the graph G_r . Observe that any two nodes u and v in different components must send different values, otherwise we would clearly have $x_r(u) = x_r(v)$ and $x_r(u) \neq x_r(v)$ and u and v would be in the same component.

We choose representatives u_i from each component arbitrarily. Our task now is to construct a connected subgraph over V and pay only a constant cost. We assume

that $\sum_{i \in T} \delta_i \leq \sum_{i \in B} \delta_i$, otherwise we can connect the nodes arbitrarily for a constant cost. Let δ_i denote the number of tokens node i does not know at the beginning of round t .

Stage II: We split the nodes into two sets T and B , according to the number of tokens they know, with nodes that know many tokens “on top”: $T = \{i \in V \mid \delta_i \geq 3\}$ and consequently $B = V \setminus T$.

Since top nodes know many tokens, connecting to them could be expensive. We will choose our edges in such a way that no top node will learn a new token, and each bottom node will learn at most three new tokens. We begin by bounding the size of T .

To that end, notice that $\sum_{i \in T} \delta_i \leq \sum_{i \in B} \delta_i$: for all $i \in T$ such that $\delta_i \geq 3$, either i is connected to a node in B or i is not, otherwise i would be a free edge and i would be in the same component; therefore each pair $(i, j) \in E$ contributes at least one missing token to the sum. On the other hand, since each node in B is missing at most 3 tokens, it follows that $\sum_{i \in B} \delta_i \leq 3|B|$. Putting the two facts together we obtain $\sum_{i \in T} \delta_i \leq 3|B|$, and consequently also $|T| \leq |B|$.

Stage III: Connecting the nodes. The bottom nodes are relatively cheap to connect to, so we connect them in an arbitrary line. In addition we want to connect each top node to a bottom node, such that no top node learns something new, and no bottom node is connected to more than one top node (see Fig. 1). That is, we are looking for a matching using only the edges E_{TB} and E_{BT} .

Since each top node is missing at most 3 tokens, and each bottom node broadcasts a different value, for each top node there are at least 3 edges in E_{TB} to choose from. But since we assume $|T| \leq |B|$, there is a matching; thus, each top node can be connected to a different bottom node using E_{TB} -edges.

What is the total cost of the graph? Top nodes learn no tokens, and bottom nodes learn at most two tokens from other bottom nodes and at most one token from a top node. Thus, the total cost is bounded by $2|B| + |T| \leq 3|B| + |B| = 4|B|$.

□

6.2 lower bound against knowledge-based token-forwarding algorithms

In this section we describe a lower bound against a restricted class of randomized token-forwarding algorithms. We represent randomness as a random binary string provided to each node at the beginning of the execution. In every round, the nodes may consume a finite number of random bits, and use them to determine their message for that round and their next state. In every execution nodes only use finitely many coin tosses; we use an infinite string when modelling the algorithm in order to avoid

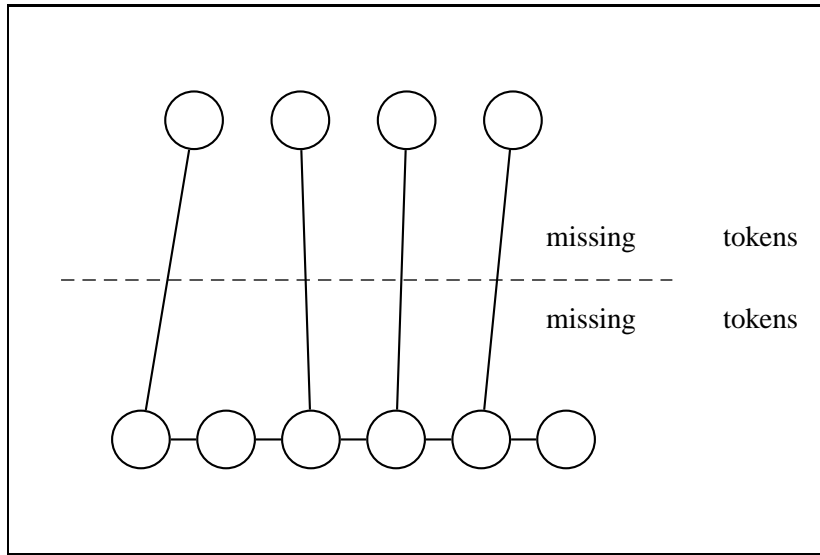

Figure 1: Illustration for the proof of the lower bound

A token-forwarding algorithm is said to be *knowledge-based* if it can be represented as a collection of functions $\{f_i^r\}$, such that in every round r , if ω_i^r is the sequence of coin-tosses for node i up to round r (inclusive), the distribution according to which node i decides which token to broadcast is given by $f_i^r(\omega_i^r)$.

We say that two dynamic graphs G_1 and G_2 are *equal up to round* r if and for all i we have ω_i^r . Let μ_i^r denote the probability distribution for node i in round r . Knowledge-based algorithms have the following property.

Lemma 6.2. *Let G_1 and G_2 be two dynamic graphs that are equal up to round r , and let ω be an instance of gossip. If i is a node such that $\omega_i^r = \omega$, then for any round $r > r$ and string ω we have*

Proof. Since G_1 and G_2 are equal up to round r , the sequences ω_i^r and ω_i^r are equal, and in particular

By definition, for all i we have $\mu_i^r = \mu_i^r$ and $\mu_i^r = \mu_i^r$; therefore, $\mu_i^r = \mu_i^r$ for all i . Consequently, for all i , the sequences ω_i^r and ω_i^r are equal, and the claim follows. \square

Theorem 6.3. *Any knowledge-based token-forwarding algorithm for n -input gossip in n -interval connected graphs over n nodes requires $\Omega(n \log n)$ rounds to succeed with probability at least $1/2$. Further, if n is even, then for sufficiently large n , deterministic algorithms require $\Omega(n \log n)$ rounds even when each node begins with at most one token.*

Proof. A lower bound of $\Omega(n \log n)$ is demonstrated trivially in a static line network where at least one token starts at one end of the line. In the sequel we assume that

Let \mathcal{A} be an knowledge-based token-forwarding algorithm for \mathcal{G} -gossip. We use the UID space as the token domain, and choose nodes S : for randomized algorithms we choose the UIDs arbitrarily, but for deterministic algorithms we must choose them carefully (see the last part of the proof). If the algorithm is randomized, we choose an input assignment where some node s starts with all \mathcal{T} tokens, and all other nodes v start with a set T_v . For deterministic algorithms, we later show that we can reach this state from some input assignment where each node starts with at most one token. For now let us suppose that we have reached some round r in which \mathcal{A} broadcasts t and for all $v \in V$ we have $|T_v| \leq \beta$. In this starting state there are $n - \beta$ nodes that do not know each token t . We abuse notation by using \mathcal{T} to denote the set of all tokens \mathcal{T} as well as the input assignment T_v to each node v .

Let \mathcal{A} broadcast t in round r . For a token t , let \mathcal{E}_t denote the expected number of times token t is broadcast by \mathcal{A} between rounds r and $r + \beta$ (exclusive). We have

$$\mathcal{E}_t \leq \beta \cdot \frac{1}{\beta} = 1$$

Thus, there are at least two tokens t, t' such that $\mathcal{E}_t, \mathcal{E}_{t'} \leq 1$. Assume w.l.o.g. that t is such. From Markov's inequality, node s broadcasts t less than β times with probability at least $1/2$ in any execution fragment starting from round r and ending before round $r + \beta$, regardless of the dynamic graph we choose. The idea in the proof is to use \mathcal{A} as a buffer between the nodes that have already learned t and those that have not; since \mathcal{A} broadcasts t infrequently with high probability, in this manner we can limit the number of nodes that learn t .

We divide the rounds between r and $r + \beta$ into segments \mathcal{S}_i . The graph remains static during each segment, but changes between segments. For each segment \mathcal{S}_i we define two sets of nodes, \mathcal{C}_i and \mathcal{D}_i , where $\mathcal{C}_i \cap \mathcal{D}_i = \emptyset$. The nodes in \mathcal{C}_i are "contaminated nodes" that might know token t at the beginning of the segment; we connect them in a clique. The nodes in \mathcal{D}_i are "clean": initially, except for s , these nodes do not know t (some of them might learn t during the segment). The only way the nodes in \mathcal{D}_i can learn t is if \mathcal{A} broadcasts it. In the first segment \mathcal{S}_1 is arranged in a line with s at one end; in subsequent segments we "close" \mathcal{D}_i to form a ring. Initially $\mathcal{C}_1 = \{s\}$ and $\mathcal{D}_1 = V \setminus \{s\}$ (recall that s , in addition to being a token, is also the UID of a node).

There are two types of segments in our construction.

Quiet segments are ones in which \mathcal{A} does not broadcast t until the last round in the segment. In the last round of a quiet segment, \mathcal{A} broadcasts t , and some nodes in the ring become contaminated. The first segment \mathcal{S}_1 is a quiet segment.

After every quiet segment there follows one or more *active* segments, in which we clean up the ring and move contaminated nodes from \mathcal{C}_i to \mathcal{D}_{i+1} . We have to do this in a way that preserves β -interval connectivity. Each active segment is triggered by \mathcal{A} broadcasting t in the previous segment; if in some active segment \mathcal{A} does not broadcast t , the next segment will be quiet.

An active segment lasts exactly β rounds, and a quiet segment lasts until the first time \mathcal{A} broadcasts t (including that round).

Next we define in detail the construction of the communication graph in each segment. We maintain the following property:

- () At the beginning of each active segment S_i , of all the nodes in S_i , only u_i and at most k nodes in the k -neighborhood of u_i in the ring know token t_i . Further, all the nodes that know t_i are on the same side of u_i . We refer to the side of u_i where these nodes are located as the *contaminated side of u_i* .
- () At the beginning of each quiet segment S_i , node u_i is the only node in the ring that knows token t_i .

Let σ_i be some ordering of the nodes in S_i (nodes that initially do not know t_i). In each segment S_i the nodes in S_i will be some contiguous subset $\sigma_i[1..k]$, where k and σ_i are given by σ_i for all i . We place u_i between $\sigma_i[k]$ and $\sigma_i[1]$ in the ring. Formally, the edges in any round r where S_i are given by

In the first segment, the edges are $\{(\sigma_i[1], \sigma_i[2]), (\sigma_i[2], \sigma_i[3]), \dots, (\sigma_i[k], \sigma_i[k+1])\}$ (we do not close the ring; this is to ensure that () holds for the first active segment).

If S_i is a quiet segment, then we define σ_i (and consequently σ_i); that is, the network does not change between S_i and S_{i+1} (except possibly for the closing of the ring after the first segment). However, if S_i is an active session, then u_i has some neighbors in the ring that knows t_i , and they might spread t_i to other nodes even when u_i does not broadcast t_i . We divide the nodes in S_i into three subsets.

The *red nodes* R_i comprise the k nodes adjacent to u_i on the contaminated side. The first k of these (the ones closer to u_i) may know t_i at the beginning of the segment; the other k may become contaminated if some of the first k broadcast token t_i . To be safe, we treat all red nodes as though they know t_i by the end of the session.

The *yellow nodes* Y_i comprise the k nodes adjacent to u_i on the uncontaminated side. These nodes may learn t_i during the segment, but only if u_i broadcasts it.

The *green nodes* G_i are all the other nodes in the ring. These nodes cannot become contaminated during the segment, because their distance from any node that knows t_i is greater than k .

Our cleanup between segments S_i and S_{i+1} consists of moving all the red nodes into G_{i+1} . Formally, if S_i is quiet, then we define σ_{i+1} and σ_{i+1} ; otherwise, if S_i is active, then we define σ_{i+1} and σ_{i+1} . This satisfies () and (): if S_i does not broadcast t_i during segment S_i , then only the red nodes can know t_i at the end, and since we removed them from the ring, at the beginning of S_{i+1} no node knows t_i except u_{i+1} . The next segment will be quiet. Otherwise, if S_i does broadcast t_i during S_i , then at the beginning of the next session (which is active) only the yellow nodes Y_i can know t_i . These nodes then become red nodes in segment S_{i+1} , and there are k of them, as required.

The cleanup step preserves δ -interval connectivity: assume that \mathcal{C}_i (the other case is similar). Then the line \mathcal{C}_i exists throughout both segment \mathcal{C}_i and segment \mathcal{C}_i : in segment \mathcal{C}_i it exists as part of the ring, and in segment \mathcal{C}_i , after we moved the red nodes into the clique \mathcal{C}_i , the first part of the line \mathcal{C}_i exists in the clique and the second part exists in the ring. The nodes in \mathcal{C}_i are all connected to each other in both segments; thus, there is a static connected graph that persists throughout both segments \mathcal{C}_i , and in particular it exists in any δ rounds that start in \mathcal{C}_i . (Note that \mathcal{C}_i may be quiet, and in this case it can be shorter than δ rounds. But in this case it will be followed by an active segment which has exactly the same edges and lasts δ rounds.)

Notice that the number of uncontaminated nodes at the beginning of every active segment is at most δ less than in the previous active session. Therefore the total number of nodes that know \mathcal{C}_i by round t is at most δ times the number of active sessions, and this in turn is bounded by δ times the number of rounds in which \mathcal{C}_i broadcasts \mathcal{C}_i . Since \mathcal{C}_i broadcasts \mathcal{C}_i less than δ times with probability at least δ , the algorithm is not finished by round t with probability at least δ .

Deterministic algorithms. If the algorithm is deterministic, we first show that there exists an input assignment in which each node begins with at most one token, from which either

1. the algorithm runs for δ rounds, or
2. we reach a round t in which some node \mathcal{C}_i has δ tokens and for all \mathcal{C}_i we have \mathcal{C}_i .

In the case of (2), we then continue with the same proof as for the input assignment where some node starts with all tokens and the rest of the nodes have no tokens (see above). Since we are free to choose the input assignment, we restrict attention to instances in which the inputs to \mathcal{C}_i nodes are their own UIDs, and the inputs to the other tokens are \mathcal{C}_i .

For deterministic algorithms the function representing node \mathcal{C}_i 's behavior must return a distribution in which one token has probability 1. We abuse notation slightly by using \mathcal{C}_i to denote this token.

We say that a process \mathcal{C}_i *fires in round* t if when process \mathcal{C}_i receives \mathcal{C}_i as its input and hears nothing in the first δ rounds, it will stay silent in those rounds and then spontaneously broadcast its token in round t . Formally, process \mathcal{C}_i fires in round t if

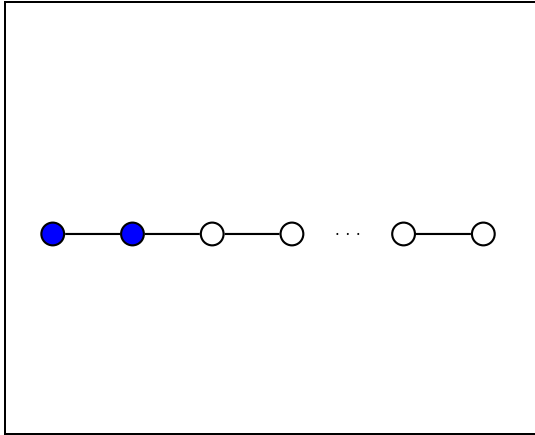

1. For all \mathcal{C}_i we have \mathcal{C}_i , and
2. \mathcal{C}_i .

If process \mathcal{C}_i does not fire in any round t , we say that \mathcal{C}_i is *passive until round* t . (Note that nodes that receive no tokens in their input have no choice but to broadcast nothing until they receive a token from someone.)

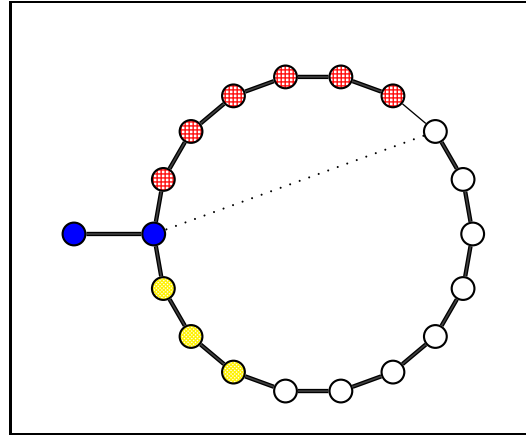

Since \mathcal{C}_i is δ -interval connected, there exist constants δ , δ such that for all \mathcal{C}_i we have \mathcal{C}_i . Let \mathcal{C}_i . We divide into two cases.

Case I. There exist \dots that are all passive until round \dots . In this case we construct the static clique over \dots and let the algorithm run. During the first \dots rounds, all nodes send only \dots , and no node learns new tokens. Consequently all nodes \dots have \dots in \dots , and the algorithm cannot terminate by round \dots .

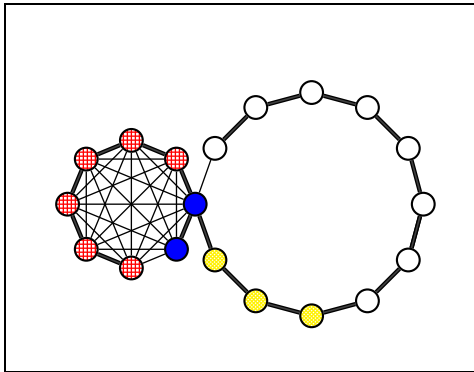

Case II. All but \dots processes fire no later than round \dots . Since \dots , by the pigeonhole principle there must exist a round \dots such that at least \dots processes fire in round \dots . Let \dots be \dots such processes. We choose the instance where each node \dots receives as input \dots if \dots , or if \dots . Let \dots be the static star with \dots at the center: \dots , where \dots for all \dots . Because all nodes fire in round \dots , when the algorithm is executed in \dots , the network is silent until round \dots . In round \dots all nodes that have a token broadcast it. Following round \dots we have \dots , and for all \dots . This is the state from which we start the main body of the proof above. \square

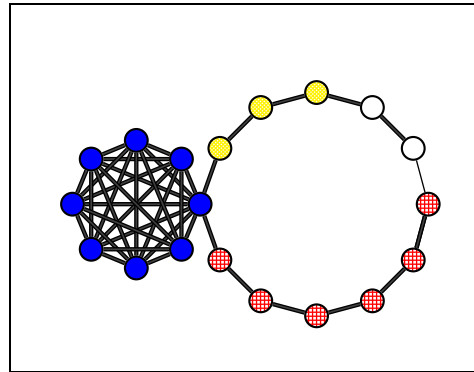

(a) The network at the beginning of the execution. Nodes that may know token are indicated in solid blue.

(b) The network at the beginning of the first phase: the line is closed to form a ring. The dotted line indicates the edge we will add at the end of the phase to re-close the ring after we remove the red nodes; double lines indicate stable edges, along which ϵ -interval connectivity is preserved between phases.

(c) The network after the end of the first phase: the red nodes are removed from the ring and placed in the clique, and the ring is repaired by connecting to u . Double lines indicate stable edges along which ϵ -interval connectivity was preserved in the transition between the phases.

(d) If u broadcast at any point during the first phase, we begin a new phase. The nodes that were yellow in the first phase become red, and the "clean" nodes on u 's other side become yellow. Double lines indicate edges that will be stable through the next two phases.

7 Conclusion

In this work we consider a model for dynamic networks which makes very few assumptions about the network. The model can serve as an abstraction for wireless or mobile networks, to reason about the fundamental unpredictability of communication in this type of system. We do not restrict the mobility of the nodes except for retaining connectivity, and we do not assume that geographical information or neighbor discovery are available to the nodes. Nevertheless, we show that it is possible to efficiently compute any computable function, taking advantage of stability if it exists in the network.

We believe that the ϵ -interval connectivity property provides a natural and general way to reason about dynamic networks. It is easy to see that without any type of connectivity assumption no non-trivial function can be computed, except possibly in the sense of computation in the limit (as in [3]). However, our connectivity assumption is easily weakened to only require connectivity once every constant number of rounds, or to only require eventual connectivity in the style of Claim 5.1, with a known bound on the number of rounds.

There are many open problems related to the model. We hope to strengthen our lower bounds for gossip and obtain an ϵ -general lower bound, and to determine whether counting is in fact as hard as gossip. Other natural problems, such as consensus and leader election, can be solved in linear time once a (possibly approximate) count is known, but can they be solved more quickly without first counting? Is it possible to compute an approximate upper bound for the size of the network in less than the time required for counting exactly? These and other questions remain intriguing open problems.
