Abstract

The aim of this research was to investigate transitions between foot conformation, lameness and footrot in sheep. Data came from one lowland flock of approximately 700 ewes studied for 18 months. Multilevel multistate analyses of transitions between good and poor foot conformation states in ewes, and lame and non-lame states in ewes and lambs were conducted. Key results were that the longer sheep had feet in good conformation, the more likely they were to stay in this state; similarly, the longer a ewe was not lame the more likely she was not to become lame. Ewes with poor foot conformation were more likely to become lame (OR: 1.83 (1.24-2.67)) and to be > 4 years (OR: 1.50(1.09-2.05)). Ewes with footrot were less likely to move to good foot conformation (OR: 0.48 (0.31-0.75)) and were more likely to become lame (OR: 3.81(2.60-5.59)). Ewes lame for > 4 days and not treated with parenteral antibacterials had a higher risk of developing (OR: 2.00 (1.08-3.61)), or remaining in (OR: 0.49 (0.29-0.95)) poor foot conformation compared with ewes never lame. Treatment of ewes lame with footrot with parenteral antibacterials increased the probability of transition from a lame to a non-lame state (OR: 1.46 (1.05-2.02)) and these ewes, even if lame for > 4 days, were not more likely to develop poor foot conformation. The risk of a ewe becoming lame increased when at least one of her offspring was lame (OR: 2.03 (1.42-2.92)) and when the prevalence of lameness in the group was ≥ 5% (OR: 1.42 (1.06-1.92)). Lambs were at increased risk of becoming lame when they were male (OR: 1.42 (1.01-2.01)), single (OR: 1.86 (1.34-2.59)) or had a lame dam or sibling (OR: 3.10 (1.81-5.32)). There were no explanatory variables associated with lambs recovering from lameness. We conclude that poor foot conformation in ewes increases the susceptibility of ewes to become lame and that this can arise from untreated footrot. Treatment of ewes lame with footrot with parenteral antibacterials leads to recovery from lameness and prevents or resolves poor foot conformation which then reduces the susceptibility to further lameness with footrot.

1. Introduction

Over 90% of sheep farmers in the UK report lameness in their flocks with a within flock prevalence of 8-10% (Grogono- Thomas and Johnston, 1997; Kaler and Green, 2008a). Over 90% of lameness in sheep is caused by footrot with or without separation of hoof horn (Kaler and Green, 2008a). The currently accepted pathogenesis of footrot is that, after initial damage, the interdigital skin is invaded by the ubiquitous bacterium *Fusobacterium necrophorum* leading to interdigital dermatitis. This is followed by entry of *Dichelobacter nodosus* (essential for footrot) which can, given a pathogenic strain, a conducive environment and a susceptible host, cause separation of hoof horn (Beveridge, 1941; Egerton and Roberts, 1969). With less pathogenic strains of *D. nodosus*, a dry, hot or cold environment or a resistant host, separation of the hoof horn might not occur and footrot presents as an interdigital inflammation.

Evidence from observational research suggests that farmers who treat individual lame sheep with parenteral and topical antibacterials within 3 days of seeing them lame, have a within flock prevalence of lameness of <2% (Wassink et al., 2003; Kaler and Green, 2008b). This was confirmed in a within flock intervention study where the prevalence of lameness caused by footrot was significantly lower in groups of sheep where individual lame sheep were treated promptly with parenteral and topical antibacterials compared with groups where lame sheep were treated with foot trimming and topical antibacterial spray (Wassink et al., 2010). In addition, over 90% of sheep treated for footrot with parenteral and topical antibacterials without foot trimming recovered within 10 days whilst <30% sheep treated with foot trimming recovered in this time period (Kaler et al., 2010).

Beveridge (1941) suggested that after apparent recovery from footrot some sheep have abnormal foot conformation and might continue to harbour *D. nodosus* for several months. In addition, routine trimming of hoof horn (that is, trimming of feet of all sheep in a flock whether they are lame or not) can lead to damage to the hoof horn and permanently misshapen feet

(Egerton et al., 1989). No epidemiological studies have been conducted to investigate associations between foot conformation and the occurrence of footrot.

Animals might become diseased more than once with some diseases and so move between diseased and non-diseased states over time. Fitting separate models for transitions between each state, i.e. diseased to healthy and *vice versa*, is the traditional approach (Dohoo et al., 2003) but has two major drawbacks: first, by fitting separate models we cannot test explicitly if the effects of predictor variables are state dependent, and, secondly, the assumption of independence between individual random effects for each state might not be correct because there might be unobserved random factors affecting the states (Steele et al., 2004).

The aim of this research was to increase our understanding of the occurrence and persistence of footrot. To do this multilevel multistate analyses were used to overcome the limitations of separate state models, (Goldstein, 2004; Steele et al., 2004) and to investigate factors associated with transitions between good and poor foot conformation states in ewes and transitions between lame and non-lame states in ewes and lambs. We explored the complex relationships between these states and the presence of footrot, host and environment factors and the effect of treatment.

2. Materials and methods

2.1. Source of data

The data were collected as part of an intervention study (Wassink et al., 2010) that tested the efficacy of prompt treatment of sheep lame with footrot, with or without separation of hoof horn, with parenteral and topical antibacterials on a commercial flock. The flock consisted of mainly North Country mules with some Roussin, Suffolk and Hartline breeds. Sheep lambed indoors from the second week of March 2005 and were turned out with their lambs onto lowland pastures from 24 hours after parturition.

All ewes and lambs were individually identified. Information on foot conformation and presence of footrot (separation of the hoof horn and a characteristic smell) was collected when

97 the feet of 419 ewes were inspected in March 2005, September 2005 and March 2006. Foot
98 conformation was scored as 0 (undamaged sole, heel or wall area with foot with a perfect
99 shape) or 1 (some damage/misshapen sole, heel or wall of foot) by one of the four observers
100 who were trained by GJW. These data were used in Model 1.
101 Ewes were stratified by age, body condition score, foot conformation and presence of footrot
102 and the family group was allocated to one of four groups (two intervention and two control) by
103 stratified random sampling. Control and intervention groups were matched by pasture type.
104 Data collection started when the youngest lamb in a group was 4 weeks of age.
105 The locomotion of all sheep, in both intervention and control groups, was scored by
106 researchers using a validated locomotion scoring scale (Kaler et al., 2009). In the two
107 intervention groups, all sheep with locomotion score ≥2 (visible nodding of head in time with
108 shortened stride and uneven posture) were caught within 3 days of first being seen lame. Sheep
109 with footrot were treated with parenteral and topical antibacterials (Terramycin LA 200mg/ml,
110 Pfizer Ltd; 20 mg per kg bodyweight for ewes; Engemycin LA 200 mg/ml, Intervet/Schering-
111 Plough Animal Health; 15mg per kg bodyweight for lambs, and Terramycin Aerosol Spray,
112 150ml pack, 4g oxytetracycline hydrochloride 3.92% w/w, Pfizer Ltd.). Treated sheep were
113 observed until not lame (no visible nodding of head or uneven posture) or if still lame after 10
114 days, they were retreated. In the two control groups, the farm shepherd (who was blind to the
115 locomotion score) treated the sheep that he considered lame: sheep with footrot were treated by
116 foot trimming and application of topical antibacterials.
117 These data were used for Models 2 and 3. They included 692 ewes (including the 419 ewes
118 above) and their 1217 lambs which were observed between 3rd May and 19th Sep 2005; lambs
119 were weaned on 20/08/2005 and were not monitored after this time
120
121 *2.2. Defining states, transitions and episodes*

For Model 1, a sheep were defined as in a state of good foot conformation when the maximum conformation score on all feet was 0 and poor when any foot had a conformation score ≥1.For Models 2 and 3, sheep were categorised into two states; non-lame, locomotion score <2 and lame when a ewe or lamb had a locomotion score ≥ 2. An episode for Models 1, 2 & 3 was a continuous period of time spent in a state until a transition occurred to another state.

2.3. Discrete –time data structure (Table 1)

For Model 1 on foot conformation, the length of each discrete time interval was 6 months and there were two intervals per sheep. For Models 2 and 3 on lameness, the length of the discrete time interval was 10 days; there were up to 12 intervals per sheep. For each episode *j* for sheep *k* there was an original state *i* (coded as 1= good conformation, 2= poor conformation for Model 1, and 1= non-lame, 2= lame for Models 2 and 3), the duration spent in that state was categorised into discrete time intervals t_i (measured as t=1, 2……n with n being the maximum duration of an episode) and an outcome event at the end of the discrete time interval, *y*, with 0 = no change in state, and 1 = occurrence of a change in state. For example, for a sheep that started an episode in a non-lame state that changed state to lame at the 4th discrete time interval; there would be four discrete time intervals for that sheep-episode (1, 2, 3, 4) with outcomes, that is change in state, (0, 0, 0, 1) which would then lead to the start of a new episode. Explanatory variables were interacted with the original indicator state variable in the model to give state specific effects. See Table 1 for an example of the data structure.

2.4. Multilevel multistate discrete time models

The discrete -time analysis is a modified logistic regression that models hazard probability in a discrete time intervals. The hazard probability is a conditional probability that an event occurs in a particular time period, given that it has not occurred in the previous time period and is described by an odds ratio. In the analysis, the probability or hazard of a change in state (π) at time interval *t* in episode *j* is expressed as in equation (1):

$$\pi_{ijk(t)} = \Pr\left(y_{jk(t)} = 1 \mid y_{ijk(t-1)} = 0\right) \quad (1)$$

i = original state, j = episode, k = sheep /lamb

Models 1 and 2 had two hierarchical levels, level 2 (k), ewes and level 1, discrete time interval within episodes. Model 3 had 3 levels, level 3 (l), the family group (lambs and ewe), level 2 (k), the lamb and level 1, the discrete time interval within episodes. The majority of ewes and lambs had one or two episodes so a random term for variation between episodes within ewes / lambs was not included in the models. A logit link function was used to express the ratio of probability of a change in state to probability of no change in the state as expressed in equations 2 & 3. Models 1 and 2 took the form:

$$\text{logit}\left[\pi_{ik(t)}\right] = \beta 0_i + \alpha_i(t) + \beta\, x_{ik(t)} + u_k^{(i)} \quad (2)$$

and Model 3 took the form:

$$\text{logit}\left[\pi_{ikl(t)}\right] = \beta 0_i + \alpha_i(t) + \beta\, x_{ikl(t)} + u_k^{(i)} + u_l^{(i)} \quad (3)$$

where $\beta 0_i$ is a state specific intercept , $\alpha_i(t)$ a set of dummy variables for the discrete time interval t depicting duration of state, $\beta\, x_{ik(t)}$ covariates includes a vector of explanatory variables varying by time or sheep with a dummy variable for original foot conformation or lameness state (explanatory variables are described in Tables 2 & 3). Covariate effects and random variability indexed at level 2 ($u_k^{(i)}$) and 3 ($u_l^{(i)}$) varied by original state. The random effects were assumed to have a multivariate normal distribution with an unspecified covariance matrix and a non zero correlation between random effects. Models were assumed to have a binomial error distribution. The models were run in MLwiN 2.10 (Rasbash et al., 2000) and fitted with MCMC for 500,000 iterations with a burn in of 5000. Chain mixing and stability were evaluated visually.

3. Results

3.1. Descriptive results

3.1.1. Model 1- foot conformation of ewes

The final dataset for Model 1 had 419 ewes with a total of 275 episodes of good foot conformation and 308 of poor foot conformation. With two 6-month discrete time intervals there were 838 records. Ewes had a maximum of two transitions, one between March 2005 and September 2005 and one between September 2005 and March 2006. Approximately 50% (141/275) of episodes with good foot conformation had a transition to poor; 119 / 141 episodes started with a good conformation in March 2005, approximately 80% (94) had a transition within 6 months and the rest in 7-12 months. Approximately 60% (187/308) of episodes with poor foot conformation had a transition to good; 117/187 episodes started with a poor conformation in March 2005; 52% (68) had a transition within the first 6 months and the rest in 7-12 months. Significantly more good to poor (67% versus 33%; $p<0.05$) foot conformation transitions occurred in the first time interval than in the second; and significantly more poor to good transitions (64% versus 36%; $p<0.05$) occurred in the second time interval than the first.

3.1.2. Model 2-lameness in ewes

The dataset for Model 2 had 692 ewes contributing 1120 episodes of which 863 were non-lame and 257 were lame episodes; there were a total of 7571, 10-day discrete time intervals. A total of 222/863 episodes in non lame sheep ended with a transition to lame. Approximately 24% of these occurred within 10 days, 38% within 20, 49% within 30, 77% within 60, 93% within 90 and the rest (7%) after 90 days. A total of 244/257 episodes in lame sheep had a transition to non-lame. The majority (77%) of the lame to non-lame transitions occurred within 10 days, with 91% within 20 days, 95% within 30 days, and the remaining 5% within 31 - 60 days.

3.1.3. Model 3- lameness in lambs

The dataset for Model 3 had a total 1217 lambs (707 sibling groups). There were 1379 non-lame episodes and 204 lame episodes; with a 10-day discrete time interval the final dataset had

10542 records. There were 194/1379 episodes when non-lame lambs had a transition to lame; 19% within 10 days, 31% within 20, 43% within 30, 88% within 60 days and the remaining 12% occurring after 60 days. The majority (202/204) of episodes in lame lambs had a transition to non-lame, with 86% occurring within 10 days and 97% within 20 days and the remaining 3% within 21 - 30 days.

3.2. Multilevel multistate models

3.2.1. Model 1- foot conformation of ewes (Table 4)

The probability of a transition from good to poor foot conformation decreased in the second time interval if the ewe had spent the first six months in a state of good foot conformation, however, the first six month spent in poor foot conformation did not significantly affect the transition from poor to good foot conformation. Ewes that had footrot at the start of a time interval had a significantly lower probability of changing from poor to good foot conformation. Ewes that were lame for > 4 days and were not treated with parenteral antibacterials were significantly more likely to change from good to poor foot conformation and less likely to change from poor to good compared with sheep that were not lame. There was no significant association between ewes lame for ≤ 4 days, whether they were treated with antibacterials or not, and ewes lame for > 4 days and treated with parenteral antibacterials and the probability of transition from good to poor or poor to good foot conformation compared with non lame ewes.

3.2.2. Model 2 – lameness in ewes (Table 5)

The greater the number of 10-day intervals a ewe spent lame the less likely she was to move to a non-lame state and vice versa. Ewes with poor foot conformation, footrot or > 4 years of age at the start of the study were significantly more likely to move from a non-lame to lame state compared with ewes with good foot conformation, no footrot or ≤ 4 years of age respectively. A prevalence of lameness of ≥ 5% in the group or at least one lame offspring at the start of the time interval significantly increased the probability of a non-lame to lame transition compared

with a prevalence of lameness of <5% or when there were no lame offspring. The only variable with a significant effect on lame to non-lame transitions in ewes was treatment with parenteral antibacterials.

3.2.3. Model 3- lameness in lambs (Table 6)

The time a lamb spent in a lame or non-lame state did not significantly affect its probability of having a transition to a non-lame or lame state respectively (Table 6). Male lambs had a significantly higher probability of changing from a non-lame to a lame state compared with female as did lambs born as singles compared with twins. Lambs grazing flood plain pasture had a significantly increased risk of changing from non-lame to lame compared with those on parkland but there was no significant effect of pasture type on transitions from lame to non-lame. A lame sibling or mother at the start of the time interval significantly increased the likelihood of a lamb moving from non-lame to lame. There were no significant factors associated with lame to non-lame transitions in the lambs.

All the models (Tables 4, 5, 6) converged with visually stable chain mixing.

4. Discussion

The results from the current study assist in elucidating risks and posing hypotheses for persistence of footrot in this flock. The models allow us to consider transitions between foot conformation (Model 1, Table 4) and lameness states (Models 2 and 3, Tables 5 and 6) that occurred over time in these sheep. This flock was studied closely and the dataset collected is a rare resource. Over 90% of lameness in sheep that were inspected (all sheep with locomotion score >1) in the intervention group was footrot (Hawker, 2008). Based on this finding it was assumed that all lame sheep (in both the groups) had footrot. In support of this assumption is the finding that over 90% of lameness in sheep flocks in the UK is attributed to footrot (Kaler and Green, 2008a). Whilst it is not possible to be certain that the results are generalisable to all

248 flocks with footrot in a temperate climate, it is likely that the biological patterns are externally
249 valid.
250 The use of multilevel multistate analysis (Steele et al., 2004) is an informative approach to
251 investigate the state specific effects of exposures with certain variables affecting transitions
252 between states, some in only one direction. Steele et al. (2004) reported little impact on model
253 parameter estimates when the discrete intervals were increased in length. In the current model,
254 testing 5 and 8 day time intervals for lameness state transitions gave similar results to the 10-
255 day interval (results not shown). Foot conformation was observed at 6 month intervals, so there
256 is a possibility that two transitions, e.g. a sheep moving from good to poor to good
257 conformation, were missed. However, hoof horn grows at approximately 3 mm per month
258 (unpublished data) and it seems likely therefore that missed transitions would be a rare
259 occurrence because hoof horn damage would take months to resolve. For the sceptic, the
260 results from the analysis in the current paper at least provide evidence for factors associated
261 with a change in foot conformation after 6 months.
262 There were two periods of transition in the foot conformation model, March to September 2005
263 and September 2005 to March 2006. In the first time period when *D. nodosus* was probably
264 surviving on pasture and spreading between sheep the majority of transitions were good to
265 poor. The majority of transitions from poor to good foot conformation occurred between
266 September 2005 and March 2006 which included winter, when the ground and air temperature
267 were below that postulated for survival of *D. nodosus* on pasture (Egerton et al., 1989),
268 especially in January and February when ewes in this study were outdoors and so exposed to
269 this cooler climate. Assuming *D. nodosus* invades or recrudesces in damaged feet, the lack of
270 exposure to *D. nodosus* and the cold environment in this winter period, might have favoured
271 healing of skin and horn and so a transition from poor to good foot conformation. Once housed
272 in mid- February 2006, this flock was on deep straw (40 – 50cm of dry straw underfoot) until
273 March 2006. This dry environment might also have helped foot conformation to improve.

The presence of detectable footrot at the start of a time interval significantly reduced the likelihood of a change from poor to good foot conformation (Table 4), suggesting that *D. nodosus* prevented healing or was continuously damaging the foot. In addition, in many cases it was the individual foot with poor conformation at the start of the interval (with or without detectable footrot) that was later diagnosed with footrot (data not shown), suggesting that feet with poor conformation either increased susceptibility to footrot or that they covertly harboured *D. nodosus* as suggested by Beveridge, (1941) or both.

The fact that sheep lame for > 4 days and not treated with parenteral antibacterials had an increased risk of changing from good to poor foot conformation suggests that either the foot is more chronically damaged if disease persists for >4 days or that these sheep remained covertly infected or both. Those lame sheep treated with parenteral antibacterials were protected from this effect, even if lame for > 4 days, suggesting that parenteral antibacterials contributed towards retaining a normal foot conformation, possibly because this treatment reduced the risk of *D. nodosus* becoming or remaining quiescent in the foot. This protection of good conformation was not observed in sheep treated with foot trimming and topical spray. *Dichelobacter nodosus* penetrates deep into the hoof (Egerton et al., 1969) so that systemic treatment is more likely to clear infection than topical treatment. This highlights the importance of prompt parenteral antibacterial treatment which is the only current therapy for which there is evidence for rapid recovery from foot lesions and lameness (Kaler et al., 2010).

Susceptibility to lameness, but not poor foot conformation, increased with age in ewes suggesting some reduction in resistance to footrot with increasing age (Tables 4, 5). In ewes, the probability of transition from non-lame to lame and from good to poor foot conformation decreased with increased duration spent in a non-lame state or a state of good foot conformation respectively. This suggests that the host foot conformation plays an important role in resistance to footrot. Given that these sheep were all in a similar environment it might indicate host heterogeneity with some sheep less susceptible to *D. nodosus* than others.

Poor foot conformation and presence of footrot also increased the risk of sheep becoming lame, however, no variables other than treatment of ewes with parenteral antibacterials significantly influenced the likelihood of lame to non-lame transitions in ewes, suggesting that once a sheep is lame the former factors do not influence recovery but that treatment does assist recovery.

No variables at all were significantly associated with recovery from lameness in lambs. It is possible that the lack of a significant positive effect of parenteral antibacterials in lambs was because of the short duration of lameness episodes in lambs compared with ewes or the presence of less severe footrot lesions than ewes (Hawker, 2008), or because lambs recovered through their own immune response or possibly because of lack of power. The lack of association between treatment with foot trimming and the likelihood of ewes and lambs moving from lame to non-lame states is probably because foot trimming lame sheep increases the time to recovery from lameness and foot lesions. In Kaler et al. (2010) >90% ewes treated with parenteral antibacterials recovered within 10 days whilst <30% of those foot trimmed recovered in this time period. In fact, the non significant (probably due to lack of power) negative coefficients suggest that foot trimming might exacerbate lameness, perhaps because of damage to the foot as indicated by the negative effect of foot trimming on foot conformation (Model 1).

The significantly increased likelihood of male (vs. female) and single born (vs. twin) lambs becoming lame might be due to the fact that male and single lambs are more likely to be heavier which has been suggested to increase their susceptibility to lameness (Egerton et al., 1989).

As with conformation states, there were environmental factors associated with a change in state from non-lame to lame. The association between a prevalence of lameness in the group ≥5% and non-lame to lame transitions in ewes suggests that *D. nodosus* was more abundant in these groups which would either lead to more frequent or more intense exposure resulting in an increased dose of *D. nodosus*. The strong link between lambs on flood plain pasture and a

higher probability of non-lame to lame transitions might be because this pasture type is wetter and so could damage the lambs' interdigital skin and so increase their susceptibility to footrot, or increase the suitability of the habitat for *D. nodosus*. In addition, sheep and lambs were more likely to move from non-lame to lame if any member of the family was lame at the start of a time interval. This might be due to contamination of the local environment with *D. nodosus*, shed by a lame family member(s), increasing the likelihood of disease, or it might indicate a genetic effect, where certain families are more susceptible to footrot than others, or it might be a result of interactions between host genetics and pathogen strain.

5. Conclusions

There are complex interactions between factors in the host, the environment and the group of sheep that alter the risks for changing conformation state and lameness in individual sheep. We conclude that there is a dynamic interaction between lameness, footrot and foot conformation. Footrot increases the risk of poor foot conformation, which increases the risk of further footrot and further lameness, which then increases the risk of poor foot conformation. There are relatively few factors that influence good to poor foot conformation and lame to non-lame transitions. Good to poor foot conformation occurs principally a result of environmental conditions and presence of footrot and lame to non-lame transitions occur after appropriate treatment. Appropriate treatment, parenteral and topical antibacterial therapy, leads to recovery from lameness and reduces the risk of poor foot conformation this in turn reduces susceptibility to further episodes of footrot by preventing / reversing poor foot conformation.

6. Acknowledgements

The data for this analysis were collected during a DEFRA funded project AW 0121. The analysis was funded by the Biotechnology and Biological Sciences Research Council (BBSRC) grant number- BBE01870X1. We thank the farm management, shepherd and technicians. .

Table 2: Sheep level variables in foot conformation multistate model (Model 1), lameness multistate models for ewes (Model 2) and lambs (Model 3)

		Model 1		Model 2		Model 3	
Variables	Categories	N	Percent	N	Percent	N	Percent
Ewes age at start of study :	≤ 4 years	252	60	332	48	-	-
	> 4 years	167	40	360	52	-	-
Foot conformation at start of study:	Good	-	-	469	68		-
	Poor	-	-	224	32	-	-
Presence of footrot at start of study:	No		-	548	79	-	-
	Yes	-	-	145	21	-	-
Sex of lamb:	Male	-	-	-	-	629	52
	Female	-	-	-	-	588	48
Litter size born :	Single	-	-	-	-	224	18
	Twin	-	-	-	-	993	82

Table 3: Number of observations for discrete –time variables included in foot conformation model for ewes (Model 1) and lameness models for ewes (Model 2) and lambs (Model 3)

Discrete time variables	Categories	Model 1		Model 2		Model 3	
		Good	Poor	Non-Lame	Lame	Non-Lame	Lame
Treated with parenteral antibacterials in time *t*:	No	-	-	-	279	-	193
	Yes	-	-	-	90	-	48
Treated with foot trim in time *t*:	No	-	-	-	357	-	235
	Yes	-	-	-	12	-	6
Presence of footrot at start of *t*:	No	-	334	-	-	-	-
	Yes	-	115	-	-	-	-
Lameness and treatment in time *t:*							
	Not lame	213	179	-	-	-	-
	Lame ≤ 4 days & treated with parenteral antibacterials	60	99	-	-	-	-
	Lame >4 days & treated with parenteral antibacterials	18	32	-	-	-	-
	Lame >4 days & treated with foot trimming	3	6	-	-	-	-
	Lame ≤ 4 days & no treatment	72	83	-	-	-	-
	Lame > 4 days & no treatment	23	50	-	-	-	-
Prevalence of lameness in pasture at start of *t*:	< 5%	-	-	4309	109	5873	241
	≥ 5%	-	-	2893	260	4428	0
Offspring(s) lame at start of *t*:	No	-	-	7010	325	-	-
	Yes	-	-	192	44	-	-
Mother or sibling lame at start of *t*:	No	-	-	-	-	9701	180
	Yes	-	-	-	-	600	61
Pasture type in *t*:	flood plain	-	-	4073	222	6102	141
	clover lay	-	-	979	46	1686	56
	parkland	-	-	2150	101	2513	44

Table 4: Model 1. Multilevel multistate model for transitions between foot conformation states in ewes

		Good to poor foot conformation[a,b,c]		Poor to good foot conformation[a,b,c]	
Variable	Categories	OR	95% C.I.	OR	95% C.I.
Duration spent in a state (months)					
	0 - 6	ref.	-	ref.	-
	7 - 12	0.50	0.31-0.79	0.95	0.68-1.32
