## ABSTRACT

Tables are presented for the solution of the transient onedimensional heat flow in a solid body of constant material properties with the heating rate at one boundary dependent on time. These tables allow convenient and rapid estimation of the temperature distribution in the many practical cases where the mathematical model applies. Examples illustrating use of the tables are given.

## IITIRODUCTION

An inportant case of the heat-conduction equation concerns the largeslab geometry where one boundary is insulated and the heat input at the other boundary is an arbitrary function of time. This mathematical model approximates, for example, the aerodynamic heating of a flight vehicle re-entering the earth's atmosphere. Complex problems of this nature are normally handled by numerical integration and employ large-scale digital computers. However, the design engineer needs to determine rapidiy the transient non-uniform temperature distribution in the skin of such a vehicle for any specified flight condition. In this respect the analytical solution offers considerable advantage over the numerical procedure as the entire heating history need not be considered to obtain the temperature distribution at any instant of time.

There has been considerable interest in this problem in recent years, and various solutions have been presented for the transient one-dimensional heat flow in a solid body of constant material properties with the heating rate at one boundary dependent on time.

This is a linear boundaryovalue problem which readily yields its solution to any of the elegant methods available for treating such problems. The solution for a constant flux into the solid is given in the standard work of Carslaw and Jaeger [1]*. A small-scale chart gives this infinite series solution over a range of parameters. Carslaw and Jaeger also give the solution for a time-dependent flux which can be expressed

[^0]as a single term. These single-term-flux solutions are, however, limited in their usefulness as most actual heating rates are more complex functions of time.

Sutton [2, 3] and Chen [4] presented the solution in integral form for an arbitrary heating rate. However, these integrals can be very difficult to evaluate depending on the form of the heating rate. This type of solution is only of academic interest to the engineer who seeks a convenient and rapid solution. Even the solutions given in reference [1] for certain time variations of the heat input are of limited practical usefulness as the computation labor involved in evaluating the infinite series is a major burden.

Solutions for a more general variation of the heat flux have been presented. Sutton [2] give a solution for a polynomial variation of the heat input with time. Certain terms in the solution were neglected so that the temperature distribution could be given as a polynomial in time and position. This reference includes an involved table of coefficients which can be used to calculate the desired temperatures. The solution is, however, accurate only for large times due to simplification of the solution.

A polynomial variation of the heat input was also considered by Bergles and Kaye [5] . The exact solution was given in terms of the infinite series of the repeated integrals of the error functions. The design charts given by Kaye and Yeh [6] can be used to rapidly estimate these infinite series. Such graphical solutions conserve on space; however, a limited range of parameters is considered, and their accuracy is limited to two significant figures.

The polynomial time variation of the heating rate is sufficiently general to be of considerable practical interest. In view of the fact that available graphical and tabular solutions are inaccurate and inconvenient to use, accurate tabular solutions were prepared based on the analysis of reference [5].

## ARALYSIS

Consider transient one-dimensional heat flow in a solid body of constant material properties with the heating rate at one boundary dependent on time for the slab shown in Fig. 1. The following solution is presented in quite general terms by consideration of heat generation and initial temperature distribution.

The general differential equation, assuming a heat-generation term of the form

$$
\begin{equation*}
P(\mathbb{N})=K+M N^{2} \tag{1}
\end{equation*}
$$

is given by

$$
\begin{equation*}
\partial^{2} \tau(N, x) / \partial N^{2}-\partial \tau(N, x) / \partial x+k+M N^{2}=0 \tag{2}
\end{equation*}
$$

The initial temperature distribution is assumed to be represented by an even order polynomial of the form

$$
\begin{equation*}
\mathcal{T}(N, 0)=F N^{2}+G N^{4} \tag{3}
\end{equation*}
$$

The boundary conditions are as follows:

$$
\begin{align*}
& \partial \mathcal{T}(0, x) / \partial \mathbb{N}=0  \tag{4}\\
& \partial \mathcal{T}(1, x) / \partial \mathbb{N}=Q(x) \tag{5}
\end{align*}
$$

where the heat flux in Eq. (5) can be expressed as a polynomial of $(s+1)$ terms

$$
\begin{equation*}
Q(X)=\sum_{s=0}^{\sum_{s}^{s} X^{s}} \tag{6}
\end{equation*}
$$

Equations (2) to (6) were solved by means of the Laplace transformation. The solution for the temperature distribution is given by

$$
\begin{align*}
& \tau(N, X)=\sum_{\sum_{s} H_{s} X^{s} Z_{2 s+1}-(2 F+4 G) Z_{1}-24 G X Z_{3}+} \\
& (2 F+K) X+(12 G+M) X^{2}+(M+12 G) X N^{2}+F N^{2}+G N^{4} \tag{7}
\end{align*}
$$

where

$$
\begin{align*}
& \mathrm{z}_{2 s+1} \equiv 2^{2 s+1} s!X^{1 / 2} \sum_{r=0}\left\{i^{2 s+1} \text { erfc }\left[(2 r+1-N) / 2 x^{1 / 2}\right]+\right.  \tag{8}\\
& \left.i^{2 s+1} \operatorname{erfc}\left[(2 r+1+N) / 2 x^{1 / 2}\right]\right\}
\end{align*}
$$

It is seen that the solution to Eq. (2) can be simply represented as a polynomial in the functions of time and position defined by Eq. (8). The transient temperature distribution can be readily computed if the various temperature distribution functions are computed and arranged in tabular form.

COMPUTATION OF TEMPERAIURE DISIRIBUIION FUNCTIONS
The infinite series of the repeated integrals of the error function, which comprises the temperature distribution function given by Eq. (8), was evaluated using the IBM 704 digital computer.

The repeated integrals of the error function were taken from the tables of Kaye [7]. The tables, together with appropriate differences, were stored in the machine. The Everett central-difference interpolation
method was chosen as it is more accurate and converges more rapidly than the forward-difference methods such as those of Newton or Gauss. Values of the index s were chosen from 0 to 5, and the position ratio $N$ varied from 0 to 1.0 in steps of 0.2 . The values of relative time X were chosen over a range of $0-40$ so that linear intexpolation could be used in the tables. Linear interpolation is valid throughout all but two per cent of the final tables which are presented in the Appendix.

## APPLICATIONS

The problem of the slab with prescribed heat flux at its surface is of increasing importance in technical applications. The general requirement for employment of the present model is that the heat flux be independent of the temperature of the body. Heat can be supplied, for example, by a flat heater embedded in the solid; in this case there is no loss of heat at the surface, and the boundary condition is accurately satisfied if the thermal capacity of the heater is negligible. The boundary condition is also satisfied for a flight vehicle re-entering the earth's atmosphere where the allowable surface temperature is small compared with the gas temperature and can be neglected.

A special case of the present solution was derived in reference [6] for use in estimating the transient temperature distribution in a wedgeshaped wing flying at supersonic speeds. The flux variation was obtained from specified time variation of the surface coefficient of heat transfer and of the temperature difference between the adiabatic wall and the wall. The assumption of a time variation of the temperature difference is,
however, equivalent to specifying the solution to the equation. The close agreement noted in that investigation between the analytical and numerical results is, therefore, to be expected since information from the numerical solution was used as a boundary condition for the analytical solution. An analytical solution for aerodynamic heating using a heat-transfer coefficient and adiabatic-wa 11 temperature which are time dependent is given in reference $[8]$. The complexity of this solution is so great, however, that it is apparent that the numerical approach is more desirable for this type of aerodynamic heating problem.

The present solution is applicable to situations where the temperature gradient in all but one direction can be neglected. The temperature distribution for certain simple two and three-dimensional geometries, such as the brick-shaped solid, can be treated using the tables and the standard product solution technique of Newman.

The tables have sufficiently fine intervals at low values of the relative time so that the very thick slabs or semi-infinite solids can be readily considered. Only the large values of the position ratio are used in this case.

The inverse problem arises when the surface hest flux versus time is sought from knowledge of an interior temperature versus time. Stolz [9] presented one of the few general treatments of the subject and developed a numerical inversion method. The present anolytical method is applicable to all cases where the heat fIux can be expressed as a polynomial and. where the initial temperature is uniform.

The interior temperature at a location near the surface is monotored as a function of time. The values of $N$ and $X$ are readily calculated if
the properties are known and the corresponding $Z$ are obtained from the tables. The coefficients of the surface heat flux are then solved from the series of simultaneous equations derived from the data.

$$
\begin{aligned}
& H_{0} Z_{1}+H_{1} Z_{3} X+\cdots \cdot=t-t_{b} \\
& H_{0} Z_{1}^{\prime}+H_{1} Z_{3}^{\prime} X^{\prime}+\cdots \cdot=t^{\prime}-t_{b} \\
& \text { etc. }
\end{aligned}
$$

## EXAMPLES

## Satellite Re-entry

The temperature distribution in the skin of a flight vehicle can be readily estimated by the present method for an important case of aerodynamic heating. The solution given by Eq. (7) is' valid for a situation where the heat input to body can be determined independent of the surface temperature. This occurs, for example, when a vehicle re-enters the earth's atmosphere as its allowable surface temperature is small compared 'with the gas temperature and can be neglected [10]. For hypersonic re-entry velocities the heat input is determined primarily by the solution to the equation of motion.

Scala [11] presents the aerodynamic heating rate for the ballistic re-entry of a satellite from an initial orbit of 900,000 feet. The ballistic parameter $W / C_{D} A_{D}$ is chosen to be $200 \mathrm{lb} / \mathrm{ft}^{2}$, and the re-entry velocity is approximately $24,000 \mathrm{ft} / \mathrm{sec}$ at a path angle of 92.5 degrees from the local vertical. The heating rate obtained in that study is presented in Fig. 2. Figure 3 includes one-dimensional transient heatconduction calculations used in the heat' sink section of Scala's work.

The temperature profiles were obtained by numerical analysis involving use of a large digital computer. The temperature distribution will now be approximated by means of the present method.

The heating rate to the satellite as given in Fig. 2 is first expressed as a polynomial in time. A simple four-point curve fit suffices to give a good representation of the temporal variation of the heating rate.

$$
\begin{equation*}
q / A=1.76 \times 10^{-4} \theta^{3}-9.887 \times 10^{-3} \theta^{2}+0.57110 \tag{9}
\end{equation*}
$$

The thickness of the material is five inches. The product of $\rho c_{p}$ is $44 \mathrm{Btu} / \mathrm{ft}^{3} 0_{\mathrm{F}}$, and the thermal conductivity is assumed to be 43.2 $\mathrm{Btu} / \mathrm{hr}$ ft $\mathrm{O}_{\mathrm{F}}[12]$. Using these properties the heating rate is expressed in the form of Eq. (6).

$$
\begin{equation*}
Q=15.77 \times 10^{5} x^{3}-13.91 \times 10^{4} x^{2}+12.63 \times 10^{3} x \tag{10}
\end{equation*}
$$

The solution as given by Eq. (7) for a uniform initial temperature of 170 F is

$$
t-170=15.77 \times 10^{5} x^{3} z_{7}-13.91 \times 10^{4} x^{2} z_{5}+12.63 \times 10^{3} \mathrm{x}_{3}
$$

Temperature profiles were calculated for the same flight times as used in the computer solution. For a time of 100 sec , for example, the value of $\mathrm{X}=\alpha \theta / 1^{2}=0.1571$. At $N=1.0$ the value of $\mathrm{z}_{7}$ using inear interpolation is 0.2044 . The temperature profiles as caiculated by the present method are shown to be in close agreement with the computer solution in Fig. 3. The small deviations in the profiles are due to consideration of gas-cap radiation and use of a temperature-dependent thermal conductivity in the computer solution. Approximately two hours of desk-calculator computations were necessary to obtain the four temperature profiles.

The rest of the temperature history can be calculated by fitting a curve to the remaining portion of the heat flux versus time plot and proceeding as above. The initial temperature distribution must, however, be included. An even-order-polynomial curve can be fitted to the temperature distribution at the time of application of the new heat input. Several such steps should serve in most cases to solve the problem if the entire heat-input history cannot be expressed accurately as a single polynomial.

Evaluation of Diffusivity
The present solution can be used to rapidly evaluate the thermal diffusivity of a material. Diffusivity experiments achieve one-dimensional heat flow by a. use of a large slab sample where only a small central portion is used for measurements, b. insulation of the sides so as to prevent heat losses, and c. use of a guard heater to prevent radial heat loss.

An experiment to determine the diffusivity of copper at $932{ }^{\circ}{ }_{F}$ ( $500^{\circ} \mathrm{C}$ ) is devised using a large-slab sample. A heat source, such as an electric resistance element, is uniformly applied to the surface; whereas, the back face is insulated. Thermocouples are instailed at two interior locations, $x=1.0$ and 2.0 inches. The block is initially at a uniform temperature $t_{b}=72^{\circ} \mathrm{F}$. The heating, with a heat source producing a heat flux $\mathrm{q} / \mathrm{A} \sim 10^{6} \mathrm{Btu} / \mathrm{hr} \mathrm{ft}^{2}$, is commenced at time $\theta=0$, and the temperatures at the interior locations are monotored. The time required for each of these points to reach $932{ }^{\circ} \mathrm{F}$ is then recorded.

$$
\begin{array}{lll}
x=2.0 \text { in. }, & N^{\prime}=0.8, & \theta^{\prime}=31.3 \mathrm{sec} . \\
x=1.0 \text { in., } & N^{\prime \prime}=0.4, & \theta^{\prime \prime}=41.8 \mathrm{sec} .
\end{array}
$$

The analytical solution as obtained from Eq. (7) is given as

$$
\begin{equation*}
\mathcal{T}(N, X)=t-t_{b}=H_{0} Z_{1}(N, X)=(q / A)(1 / k) Z_{1} \tag{12}
\end{equation*}
$$

It is readily seen that the temperature distribution functions mast be equal for the two points. Thus

$$
\begin{equation*}
Z_{i}^{\prime}\left(N^{\prime}, X^{\prime}\right)=Z_{1}^{\prime \prime}\left(N^{\prime \prime}, X^{\prime \prime}\right) \tag{13}
\end{equation*}
$$

subject to the condition that

$$
\begin{equation*}
x^{\prime} / x^{\prime \prime}=\theta^{\prime} / \theta^{\prime \prime}=31.3 / 41.8 \tag{14}
\end{equation*}
$$

The tables for $Z_{1}, N=0.4$, and 0.8 give the desired solution

$$
\begin{aligned}
& z_{1}^{\prime}=z_{1}^{\prime \prime}=0.8684 \\
& X^{\prime}=0.7152, \quad x^{\prime \prime}=0.9551
\end{aligned}
$$

from which'the diffusivity is calculated.

$$
\alpha=1^{2} \mathrm{x} / \theta=(2.5 / 12)^{2} 0.7152 /(31.3 / 3600)=3.57 \mathrm{ft}^{2} / \mathrm{hr}
$$

It is noted that the evaluation of the diffusivity requires no measurement of the heat flux. If the density and specific heat are known from other simple experiments, this experimental determination also yields the thermal conductivity indirectly. The thermal conductivity can, however, be directly evaluated from Eq. (12) if the heat flux is measured.

The analytical solution to Eq. (7) for constant heat flux has been modified and used with success in diffusivity experiments by Butler and Inn [13] and Sheer; et al. [14] among others. These investigators made use of the linearity of the temperature distribution at values of the relative time $X>0.5$. The present method is more general as the data can be taken for any value of the relative time.
