Purpose: Eosinophil count elevations are predictive of adverse outcomes in patients with asthma, yet little is known regarding longitudinal eosinophil patterns and their association with clinical outcomes. The goal of this study was to assess associations between longitudinal persistence of eosinophil elevations and both clinical outcomes and health care resource utilization (HCRU).

Methods: Data were extracted from 2 databases in the United Kingdom. Patients included were aged ≥ 13 years, had active asthma, and had ≥ 3 blood eosinophil count (BEC) recordings. Patients were categorized by BEC as: never high (all BEC ≤ 300 cells/ μ L), intermittently high (≥ 1 BEC > 300 cells/ μ L but $< 75\%$ of BEC > 300 cells/ μ L), or persistently high ($\geq 75\%$ of BEC > 300 cells/ μ L). Asthma exacerbations, asthma control (risk domain, overall, and full), and HCRU were evaluated for 12 months after the last BEC.

Results: The study population comprised 148,021 patients. Persistently high, intermittently high, and never high eosinophil patterns were detected in 13.6%, 40.5%, and 45.9% of patients, respectively. Patients with ≥ 1 elevated BEC were at greater risk for severe asthma exacerbations, regardless of whether the elevation was persistent (rate ratio [RR]: 1.28 [95% CI 1.24–1.33]; $P < 0.001$) or intermittent (RR: 1.24 [95% CI 1.21–1.27]; $P < 0.001$), compared with patients with no eosinophil elevations. Full asthma control was achieved by $< 25\%$ of patients across eosinophil pattern groups, and HCRU did not appreciably differ, although patients with persistently high BEC had the shortest hospital stay duration among the groups.

Conclusion: These data suggest that elevated blood eosinophils, regardless of persistency, signify increased risk of severe asthma exacerbations.

Keywords: asthma control, asthma exacerbation, biomarker, eosinophilia, phenotype, type 2 inflammation

Introduction

Despite the availability of multiple effective treatment options, many patients with asthma do not achieve adequate symptom control and are at elevated risk of flare-ups (exacerbations).¹⁻³ Exacerbations can be life-threatening and contribute to disease-related morbidity, impaired health-related quality of life, progressive loss of lung function, and higher health care resource utilization (HCRU).^{4,5} Moreover, standard treatment of exacerbations involves oral corticosteroids (OCS), which are associated with risk of acute and chronic adverse events as well as increased HCRU and costs.^{6,7} Characterizing patient-related and clinical parameters that are

associated with uncontrolled asthma and exacerbation risk has the potential to improve outcomes by identifying patients who require additional monitoring and therapeutic intervention.^{8–10} Moreover, understanding asthma etiology at the individual level enhances the ability to implement targeted treatment,^{1,11} thereby augmenting the likelihood of achieving asthma control.

Asthma is not a monolithic condition, rather it is a heterogeneous disease with varied etiologic underpinnings.^{2,11} Eosinophil elevations measured in sputum or blood denote a particular asthma endotype, eosinophilic asthma, which is driven by eosinophilic airway inflammation.^{2,11,12} High blood eosinophil counts (BECs) are linked to multiple adverse outcomes in patients with asthma, including increased risk for exacerbations, severe exacerbations, asthma-related hospital readmissions, and poor asthma control.^{13–19} In an historical cohort of patients with asthma from the United Kingdom (UK), a BEC >400 cells/ μ L conferred a 42% greater risk of severe exacerbations, a 28% greater risk of acute respiratory events, and a 26% lower likelihood of achieving asthma control during a 1-year follow-up period compared with patients whose BECs were \leq 400 cells/ μ L.¹⁵ Moreover, exacerbation rates demonstrated a dose-response relationship with BECs starting at a reference category of \leq 200 cells/ μ L. The comparatively small proportion of patients with severe, uncontrolled eosinophilic asthma accounts for a disproportionate share of asthma-related HCRU and costs.^{20,21} In a population-based analysis conducted in the UK, patients with severe, uncontrolled, eosinophilic asthma comprised <1% of the study population, yet accounted for 2.5 to 7.6 times greater HCRU and direct asthma-related costs than the general population.²¹

In clinical practice, BEC assessments for the identification of eosinophilic asthma are infrequently considered and, when applied, are often limited to a single time point. This approach may provide an incomplete picture because BEC levels are not fixed over time.^{22–26} Indeed, eosinophil counts in sputum or blood samples of patients with asthma have been shown to vary appreciably in sequential measurements.^{22,23,25} Few studies, particularly those derived from real-world data, have parsed asthma endotypes by longitudinal persistence of BEC elevations, and it is not known whether persistence of BEC elevations is associated with health outcomes. This study was performed to characterize patients with varying degrees of persistence in BEC elevation and to assess the association

of eosinophil elevation patterns with clinical outcomes and HCRU in patients with asthma.

Methods

Data Source and Study Design

Data were extracted from the Optimum Patient Care Research Database (OPCRD) and the Clinical Practice Research Datalink (CPRD) GOLD database. OPCRD comprises data obtained through the Optimum Patient Care Quality Improvement services, which contains information from both anonymized electronic medical records (EMRs) and patient responses to disease-specific questionnaires. At data extraction, OPCRD contained data for approximately 10 million patients from more than 700 practices in the UK. CPRD GOLD is a primary care database of anonymized medical records that includes data for more than 11 million patients from 674 general practices in the UK.²⁷ Data obtained from CPRD were limited to patients whose records could be linked to Hospital Episode Statistics, a comprehensive source for hospital admission and outpatient HCRU data. Patient-level data from OPCRD and CPRD are de-identified at the source, and patients have the option to opt-out of sharing their health information.

Baseline data represented the 12 months prior to the index date, defined as the most recent BEC measurement for which there were \geq 12 months of subsequent outcomes data (Figure 1). Asthma outcomes and HCRU were evaluated for 12 months after the index date (the outcome year). The year of the index date for patients included in the data sets ranged from 2006 to 2018.

Study Population

For inclusion in the study, patients were required to be aged \geq 13 years on the index date and have: a diagnostic code for asthma recorded at any time that was not followed by a code that asthma was resolved; \geq 3 BECs recorded after the date of first asthma diagnosis; active asthma, defined as \geq 1 prescription for an inhaler containing an inhaled corticosteroid (ICS) or a short-acting β -agonist (SABA) in the 12 months before the index date; and continuous EMR data for 12 months prior to and 12 months after the index date. Patients were excluded if they had a diagnosis of chronic lower respiratory disease other than asthma or chronic obstructive pulmonary disease (COPD) or if there was uncertain information regarding the age of asthma onset. Age of asthma onset was

Figure 1 Study design. Patients were categorized as persistently high, intermittently high, or never high based on blood eosinophil counts (BECs) from the first asthma diagnosis to the index date. The index date was the date of the last BEC with at least 12 months' outcome data and without prescriptions for oral corticosteroids or anti-interleukin-5 therapy in the prior 4 weeks. The baseline and outcome years were 1 year prior to and 1 year after the index date.

Abbreviation: HCRU, health care resource utilization.

defined as first recording of asthma diagnosis dated in the first 3 years of electronic medical recording or in the fourth or fifth year of electronic medical recording not preceded or followed by an inhaler treatment prescription within 90 days after that date.

Measurements and Outcomes

Blood Eosinophil Counts

Patients were categorized by longitudinal patterns of BEC elevations as: never high (all BECs ≤ 300 cells/ μL), intermittently high (≥ 1 BEC > 300 cells/ μL but $< 75\%$ of BECs > 300 cells/ μL), or persistently high ($\geq 75\%$ of BECs > 300 cells/ μL). To qualify as persistently high, patients with 3 measurements were not allowed to have any BEC ≤ 300 cells/ μL , patients with 4–7 measurements were allowed to have only 1 BEC ≤ 300 cells/ μL , patients with 8–11 measurements were allowed to have 2 BECs ≤ 300 cells/ μL , patients with 12–15 measurements were allowed to have 3 BECs ≤ 300 cells/ μL , patients with 16–19 measurements were allowed to have 4 BECs ≤ 300 cells/ μL , and patients with 20–23 measurements were allowed to have 5 BECs ≤ 300 cells/ μL . Blood eosinophil counts ≤ 300 cells/ μL that were measured during anti-interleukin-5 therapy or ≤ 4 weeks after an OCS prescription (0.2% of values) were not considered valid, as the counts may have been reduced by therapy.

Baseline Asthma Disease Burden

Characteristics of asthma examined during the baseline year included Global Initiative for Asthma (GINA) step of asthma management according to 2018²⁸ and 2019²⁹ definitions, medication use, severe asthma exacerbations, acute respiratory events, and symptom

control metrics. A severe asthma exacerbation was defined according to American Thoracic Society/European Respiratory Society criteria³⁰ as an asthma-related hospitalization or emergency department (ED) visit and/or a prescription for acute OCS. An acute respiratory event was defined as an asthma-related hospitalization or ED visit, a prescription for acute OCS, and/or a prescription for antibiotics in conjunction with an asthma-related primary care consultation. Baseline symptom control, measured in patients with an annual asthma review within 15 months of the baseline period, was scored from 0 to 3 based on Royal College of Physicians questions for asthma.³¹ Poor symptom control was characterized by the presence of any 3 of following symptoms: difficulty sleeping due to asthma, usual asthma symptoms during the day (cough, wheeze, chest tightness, or breathlessness), interference of asthma with usual activities, or > 2 puffs of SABA prescribed per week on average over the baseline year. Uncontrolled asthma in patients treated at GINA step 4 or treatment at GINA step 5 irrespective of control status was categorized as difficult-to-treat asthma.

Asthma Outcomes

Asthma outcomes were evaluated during the 12 months after the index date and included severe asthma exacerbations, acute respiratory events, and measures of asthma control. Severe asthma exacerbations were based on data from CPRD and were defined as a hospitalization with asthma as the primary diagnosis, a respiratory-related ED visit, prescription for acute OCS, and/or an EMR recording of an acute exacerbation. An acute respiratory event was defined as a hospitalization with asthma as the primary diagnosis,

a respiratory-related ED visit, a prescription for acute OCS, an EMR recording of an acute exacerbation, and/or prescription for antibiotics in conjunction with an asthma-related primary care consultation. Asthma control was assessed by 3 measures: risk domain asthma control (RDAC), overall asthma control, and full asthma control. Patients achieved RDAC if they had neither an acute respiratory event nor a respiratory-related outpatient visit during the outcome year. Overall asthma control required attainment of RDAC and that the patient was receiving an average daily dose of $\leq 200\text{-}\mu\text{g}$ salbutamol/ $\leq 500\text{-}\mu\text{g}$ terbutaline.³² Full asthma control was defined as the absence of frequent (≥ 2) OCS course prescriptions, respiratory hospital admission, ED visit, or poor symptom control.

Health Care Resource Utilization

HCRU was measured for 12 months after the index date using data from CPRD and included physician office visits, outpatient visits, ED visits, and hospital admissions (all-cause, asthma as the primary diagnosis, asthma at any diagnostic position, and a respiratory condition as the primary diagnosis).

Statistical Analysis

Descriptive statistics were reported for all variables. Due to its log-normal distribution, geometric means and geometric standard deviations were calculated for BECs. To examine statistical significance of differences in distribution of characteristics among the endotypes, Pearson's chi-square tests of independent categories for categorical variables and the non-parametric Kruskal–Wallis equality-of-populations rank test for variables on a continuous or ordinal scale were performed. Relevant differences in crude distribution of characteristics between longitudinal eosinophil pattern groups were reported as the standardized mean difference (SMD) with the persistently high group as the reference. The SMD is not affected by the number of observations and provides information on the magnitude of differences and is, therefore, more informative than *P* values for these types of analyses.³³ An SMD $>10\%$ indicates a relevant difference.

To study the association between eosinophil pattern and asthma control after adjustment for potential confounders, negative binomial regression analyses were performed with the number of severe exacerbations in the outcome year as the outcome variable. For these analyses, the EMR-based definition of severe exacerbation was used in the full population of patients (OPCRD+CPRD). Covariates tested in the model included number of BECs available, mean annual rate of

BEC measurements, sex, age, smoking habits, and presence of comorbidities. Covariates were considered relevant confounders if they changed the association coefficient by $\geq 5\%$. Rate ratios and 95% confidence intervals after adjustment for confounders are reported. Statistical analyses were performed using Stata MP/6 version 15.1 (StataCorp LLC, College Station, Texas, USA).

Results

A total of 148,021 patients were eligible for inclusion in the study population: 77,715 patients from OPCRD and 70,306 from CPRD (Figure 2). The mean age was 56.0 ± 17.7 years, and 68.5% of patients were women. The median interval between asthma diagnosis and the index date was 15 years (interquartile range [IQR], 9–24 years).

Blood Eosinophil Counts

Patients had a median of 6 (IQR, 4–10) BEC measurements recorded during the study interval, with a median of 0.84 (IQR, 0.54–1.28) measurements per individual follow-up year. Persistently high BECs ($\geq 75\%$ of counts >300 cells/ μL) were detected in 13.6% of patients, intermittently high (≥ 1 count and $<75\%$ of counts >300 cells/ μL) in 40.5% of patients, and never high in 45.9% of patients. The proportion of patients with no high eosinophil recording decreased with the number of available eosinophil measurements, resulting in a larger proportion of patients in the intermittently high group as the number of measurements increased from the minimum of 3 (Figure 3). The percentage of patients in the persistently high group varied only modestly for patients with 6 or more BEC measurements.

The persistently high group had a lower mean age and a greater proportion of male patients compared with the intermittently high and never high groups (SMD $>10\%$ for all comparisons; Table 1). These patients also had a higher prevalence of nasal polyps and allergic rhinitis but a lower prevalence of anxiety/depression than the other 2 groups (Tables 1 and 2). Overall, the burden of comorbidities, as measured by the Charlson comorbidity index, was lower for patients categorized as persistently high vs intermittently high (SMD = 12.7%).

Asthma Severity During the Baseline Period

GINA step of asthma management was not appreciably more advanced in patients in the persistently high group compared with the intermittently high group (Table 3).

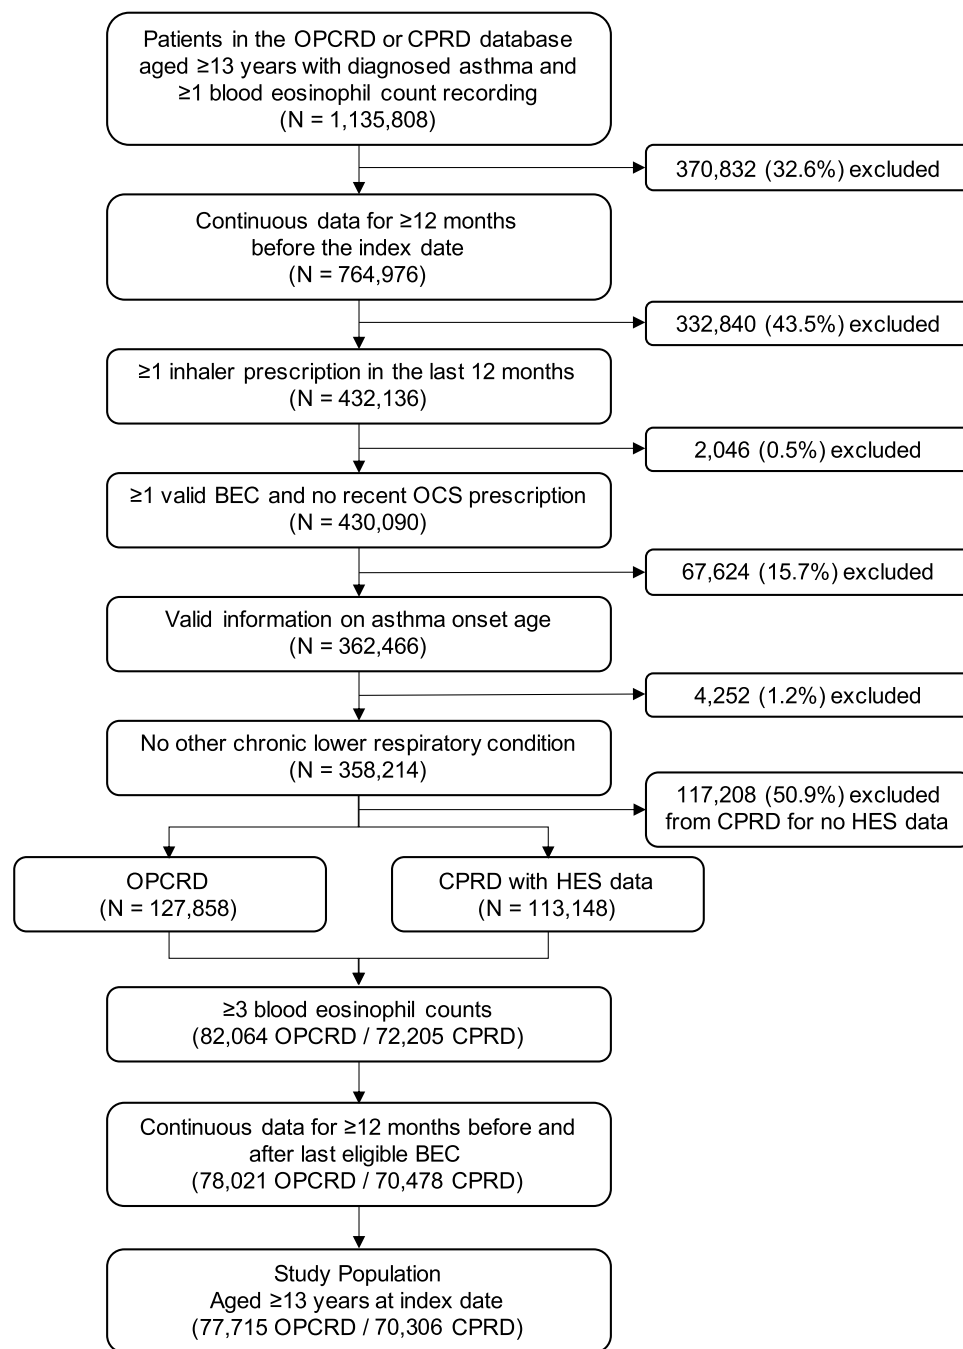

Figure 2 Patient selection criteria.

Abbreviations: BEC, blood eosinophil count; CPRD, Clinical Practice Research Datalink; HES, Hospital Episode Statistics; OCS, oral corticosteroid; OPCR, Optimum Patient Care Research Database.

However, moderate to severe asthma (GINA step 3–5) was more common in the intermittently (59.0%) or persistently high (61.2%) groups than in the never high group (54.0%). Consistent with the inclusion criteria, the majority of patients in all groups were receiving ICS. The proportion of patients not receiving ICS decreased from 19.9% in the never high group to 17.2% in the intermittently high group

and 14.9% in the persistently high group. Less excessive SABA use (>300 µg mean daily salbutamol equivalent) was observed in the never high group (30.0%) vs the intermittently (35.0%) or persistently high (36.6%) groups. Maintenance OCS use was not meaningfully different between treatment groups, but the number of patients with a mean daily dose >7.5 mg was higher in the

Figure 3 Distribution of longitudinal eosinophil patterns by the number of blood eosinophil measurements available. The proportion of patients classified as persistently high, intermittently high, or never high are shown by total number of blood eosinophil count (BEC) measurements available.

intermittent group (1.2%) than in the persistent (0.6%) and never high groups (0.7%).

Asthma Control During the Outcome Year

A greater percentage of patients with ≥ 1 BEC >300 cells/ μ L (persistently high, 26.0%; intermittently high, 25.7%) experienced ≥ 1 severe asthma exacerbation during the outcome year compared with the never high group (21.7%; Table 4). Other measures of asthma control were not appreciably different among blood eosinophil pattern groups. Full asthma control was achieved by 22.3%, 24.3%, and 23.6% of patients in the persistently high, intermittently high, and never high groups, respectively.

After adjustment for confounders, patients in the persistently high and intermittently high groups had similarly elevated severe exacerbation risk compared with the never high group (Table 5). A history of nasal polyps, older age, anxiety or depression, rate of BEC measurements per year, and overall number of measurements available were independent predictors of increased severe exacerbation risk ($P < 0.001$ for all comparisons). Smoking status significantly modified the association between blood eosinophil patterns and severe exacerbation risk ($P < 0.001$; Figure 4). Patients who never smoked and had persistently high BECs had a 47% greater risk of severe exacerbations compared with never smokers in the never high group. The increase in the intermittently high group was 27%

relative to the never high group. For ex-smokers, a similar increase in risk was found in the persistently high and intermittently high groups (32% and 28%, respectively). Current smokers had a diminished, but significant, increase in severe exacerbation risk associated with persistently or intermittently high BECs.

Health Care Resource Utilization During the Outcome Year

The mean number of all-cause general practitioner consultations was greater in the intermittently high group vs the never high or persistently high groups (SMD = 15.1%); this trend was not observed for respiratory condition-related visits (Table 6). Hospital admissions due to asthma or a respiratory condition as the primary diagnosis were rare events and not meaningfully different among groups. Within the small population of patients with an asthma-related hospital admission, those with persistently high BECs had a shorter mean length of stay (4.7 ± 7.6 days) than the never high (8.0 ± 12.2 days; SMD = 32.8%) and intermittently high patients (6.9 ± 11.2 days; SMD = 23.1%). Similar results were found for inpatient admissions with a respiratory condition as the primary diagnosis.

Discussion

Results from this large observational cohort highlight the role of eosinophil elevations as a prognostic marker of asthma exacerbation risk. Among patients with at least 3 BEC measures, those with at least 1 elevated BEC (ie, BEC >300 cells/ μ L), regardless of whether the elevation was persistent or intermittent, were at greater risk for severe asthma exacerbations compared with patients with no BECs >300 cells/ μ L. Moreover, risk was increased to a similar degree in patients with persistently or intermittently high BECs. These findings imply that a single high eosinophil measurement is sufficient to identify patients with elevated risk of severe asthma exacerbations.

In this data set, persistently high BEC was present in 13.6% of patients, whereas either persistently or intermittently high BEC was detected in 54.1% of the study population. These data are consistent with a prior longitudinal study of sequential sputum samples taken during routine clinic visits in which 29% of children with mild to moderate asthma had elevated eosinophil counts in all samples and 24% had a mixture of sputum samples that were eosinophilic and non-eosinophilic.²² In previous studies where a single measurement was used to categorize eosinophil elevations,^{13,21} the

proportion of patients with high BEC (≥ 300 cells/ μ L) was lower (33% to 43%), likely reflecting the decreased detection of BEC elevations when only 1 measurement was used versus the minimum of 3 measurements required in the current study. The comparable increase in the risk of severe exacerbations in the intermittently high and persistently high BEC groups observed in our study underscores the need to identify patients in both groups.

Despite the similar risk of severe exacerbations in the persistently high and intermittently high BEC groups, there were notable areas of divergence. Compared with the intermittently high group, patients in the persistently high group had a greater prevalence of nasal polyps (5.1% vs 10.8%), a condition known to be associated with eosinophil elevations³⁴ and an independent predictor of severe asthma exacerbation risk in our analysis. For patients who

never smoked, persistently high BEC was associated with a significantly greater risk of severe exacerbations compared with the intermittently high group. Risk of severe exacerbations was also greater in the persistently high and intermittently high groups relative to the never high group in current and former smokers, although the magnitude of risk increase was similar in the persistently high and

intermittently high groups. In a prior analysis of CPRD data, an association was detected between a high BEC recorded within 1 year before hospital admission for asthma and increased risk of rehospitalization during the subsequent year in nonsmokers but not in current smokers.¹⁹ These data suggest that smoking may modify the relationship between BEC elevations and exacerbation

risk. It is interesting to note that the proportion of patients who were current or former smokers in this study is similar between CPRD and OPCRD but greater than in previous UK studies,^{19,21} which may reflect the

requirement for having at least 3 BEC measurements. Patients with asthma who were current or former smokers may have more check-up visits and, thus, more blood eosinophil measurements performed. Further research is

needed to understand the interactions between smoking, BEC elevations, and exacerbation risk.

Unlike exacerbation rates, no appreciable differences in other measures of asthma control were observed among blood eosinophil pattern groups. Notably, less than one-quarter of patients across eosinophil groups achieved full asthma control during the outcome year. Differences in asthma treatment during the baseline year were minimal. Interestingly, 22% to 26% of patients were prescribed OCS, a small percent at moderate or high doses (mean daily dose >5 mg), despite the associated risk for acute and chronic adverse events.^{6,35} These data add to the large body of literature indicating that a considerable proportion of patients in clinical practice have suboptimal asthma symptom control, many of whom would benefit from referral to a specialist for evaluation and management.^{36,37}

In general, HCRU did not appreciably differ among patients in the 3 eosinophil elevation pattern groups. For patients with an asthma-related hospitalization, the length of stay was shorter for patients with persistent BEC elevations, particularly in comparison with patients in the never high group. This observation suggests that persistently high BECs may represent a distinct subset of patients within the eosinophilic endotype in whom eosinophilia dominates the etiology and, hence, respond rapidly to currently available eosinophil-targeted therapies. It should be noted, however, that the persistently high group had a lower comorbidity burden compared with the intermittently high group, which has been shown to affect asthma-related hospital length of stay.³⁸ Evaluation of treatment response in patients with differing eosinophil elevation patterns is warranted to better understand this patient subgroup.

Identifying a patient's asthma endotype has significant relevance to clinical practice. As the accumulated evidence suggests, eosinophil elevations indicate increased risk for asthma exacerbations and adverse outcomes,^{13–19} thus distinguishing a patient population in need of further monitoring and intervention. Patients with eosinophil elevations may also be candidates for biologic therapies targeting interleukin 5 or the interleukin-5 receptor. In clinical practice, however, measurement of BECs has not been incorporated as a universal facet of asthma management. Indeed, a prior analysis of data from OPCR and CPRD found that only 52% of patients with asthma had BECs recorded in the EMR.¹⁵ Regular assessment of asthma endotype, including measurement of biomarker

concentrations, is needed to improve implementation of individualized, targeted asthma management.

A major strength of this study was that it utilized a large data set in a first-of-its-kind analysis of longitudinal, repeated blood eosinophil measurements, which allowed for evaluation of the heretofore unexamined relationship between eosinophil elevation patterns and exacerbations. There are several limitations that affect the interpretation of these analyses. Full blood count measurements are not routinely performed (every 1 to 2 years) and are generally requested for a specific medical reason; therefore, ascertainment bias in the types of patients for whom BEC data were available cannot be excluded, and the study population may not be fully representative of the broader population of patients with asthma. In the OPCR data set, for example, 43% of patients with a diagnostic code for asthma were not eligible for inclusion in the analysis due to lack of a BEC measurement. Comparable statistics were not available for the CPRD data set. Both the OPCR and CPRD data sets comprise information collected for clinical and routine use rather than specifically for research purposes. Although extensive quality control and validity checks are conducted on the practice level, the validity and completeness of individual patient records may be limited. Among the possible influences on BECs, we cannot exclude the potential effect of ICS, which was used by the majority of patients in each BEC category. Interestingly, 85% of patients were receiving ICS in the persistently high group, suggesting that ICS use is insufficient to lower BECs to ≤ 300 cells/ μL for these patients. We also did not evaluate the prevalence of eosinophilic esophagitis among BEC groups, despite its association with asthma, because of the diagnostic challenges and rarity of the condition. A variable that was not available for analysis in the data sets was the time of day of BEC measurement. Circadian variations have been observed for BECs.^{39,40} The magnitude of daily variation is modest; therefore, the number of instances where the time of day made the difference between a value above or below 300 cells/ μL is likely small. Moreover, geometric mean BECs at the index date were 125.9 ± 2.0 cells/ μL in the never high group and 501.2 ± 1.6 cells/ μL in the persistently high group, indicating that measurements in these groups were generally not close to the 300 cells/ μL threshold. The group most likely to be affected were patients in the intermittently high group, for whom variability in measurement is expected.

Conclusion

These data validate the use of blood eosinophil measurements to characterize a patient population at increased risk for severe asthma exacerbations. The consistency in risk elevation between the persistently high and intermittently high groups suggests that in patients with a single or multiple BEC measurements, 1 or more elevated BEC is sufficient to characterize a patient as having eosinophilic asthma, thus affirming the validity of categorizing patients in clinical practice, clinical trials, and real-world studies using the highest recorded BEC. Conversely, a single eosinophil measurement ≤ 300 cells/ μL cannot rule out the potential of having eosinophilic asthma. For these patients, additional measurement of BECs in clinical practice is needed to increase the identification and appropriate management of patients with eosinophilic asthma.

Journal of Asthma and Allergy

Dovepress

Publish your work in this journal

The Journal of Asthma and Allergy is an international, peer-reviewed open-access journal publishing original research, reports, editorials and commentaries on the following topics: Asthma; Pulmonary physiology; Asthma related clinical health; Clinical immunology and the immunological basis of disease; Pharmacological interventions and

new therapies. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/journal-of-asthma-and-allergy-journal>
