Abstract The Neoproterozoic (~723–716 Ma) Franklin Large Igneous Province exposed on Victoria Island in the Canadian Arctic is comprised of a sill-dominated magma plumbing system overlain by the coeval Natkusiak flood basalts. We have investigated three sections, separated by a total of >50 km of distance, of a sill (the Fort Collinson Sill Complex) emplaced just above a prominent sedimentary marker unit. The sill is characterized by a basal olivine-enriched layer (OZ: up to 55 % olivine) and an upper gabbroic unit. The observed diversity of olivine compositions in the OZ implies that bulk-rock MgO versus FeO arrays reflect accumulation of a heterogeneous olivine crystal cargo. We suggest that the OZ was formed as a late olivine slurry replenishment in a partially crystallized gabbroic sill, propagating for over 50 km along strike. This interpretation is consistent with Pb-isotope data, which show that at least three geochemically distinct magmas were emplaced into the Fort Collinson Sill Complex. The OZs exhibit a gradual

westward evolution toward more Fe-rich bulk compositions. This is best explained by progressive mixing of the replenishing olivine slurry with a resident gabbroic mush during westward flow. Pb-isotopic signatures suggest that magmas near the inferred conduit feeder assimilated small amounts (<10 %) of dolostone country rock, which may have locally buffered olivine compositions to high-Fo contents.

Keywords Contamination · Differentiation · Franklin · Olivine · Slurry · Sills

Introduction

To understand the geochemical evolution of basalts, we need to constrain the processes active in the associated magmatic plumbing system. Sill-dominated plumbing systems are prominent in Proterozoic and Phanerozoic continental flood basalt provinces (Baragar 1976; Francis and Walker 1986; Hawkesworth et al. 1995; Chevallier and Woodford 1999; Bédard et al. 2007), oceanic crust formed by seafloor-spreading (Bédard 1991; Lissenberg et al. 2004), oceanic plateau crust (Kerr et al. 1998), and Archean greenstones (Bédard et al. 2009). Documenting lateral changes in bulk-rock and mineral chemistry in the constituent sills of such basaltic plumbing systems would shed light on the mechanisms of magma emplacement in the crust, of magma interaction with host rocks, on igneous differentiation processes, and may enable the reconstruction of magma flow directions (Marsh 2004). In addition to constraining fundamental properties of magmatic systems, this type of information is an important element in the search for Noril'sk-type Ni–Cu–PGE sulfide deposits (Naldrett 1992).

Separation of crystals from melt in magma chambers is frequently assumed to be responsible for the observed geochemical diversity of lavas (Bowen 1928) and also plays a role in the development of layering in fossil magma chambers (Wager and Deer 1939; Irvine 1980, 1987; Naslund and McBirney 1996). Recent discussions have emphasized the importance of remobilization of previously deposited crystal cumulates or crystal slurries, and associated consequences for the magmatic evolution of plutonic systems (Marsh 2013; Neave et al. 2013; Leuthold et al. 2014). It has also been proposed that the abundant phenocrysts seen in some basalts are remobilized cumulates that were flushed out of underlying feeder systems (Larrea et al. 2012; Passmore et al. 2012). Examples of crystal slurry emplacement have been documented in the Ferrar sills of Antarctica (Bédard et al. 2007); the Shiant Isles sills in NW Scotland (Gibb and Henderson 2006); and the Franklin sills on Victoria Island (Hayes et al. 2015). The emplacement of crystal slurries is also pertinent for the construction of large layered intrusions such as the Bushveld Complex (Mondal and Mathez 2007; Roelofse and Ashwal 2012; Wilson 2012). Slurry remobilization is also implicated in the genesis of anomalous concentrations of immiscible sulfide liquids observed in some Ni–Cu–PGE deposits (Naldrett 1992).

An additional factor that can affect melt and crystal evolution is the assimilation of (and reaction with) country rocks. It is widely accepted that mantle-derived melts may undergo modification of their isotopic signatures as a result of crustal assimilation, e.g., Hildreth and Moorbath (1988). Assimilation of carbonate rocks in particular may impact on the liquid line of descent (LLD) of magma by buffering melt Mg/Fe ratios and preferentially stabilizing clinopyroxene on the liquidus (Di Rocco et al. 2012; Mollo and Vona 2014). The impacts of carbonate assimilation have been demonstrated for Merapi Volcano (Chadwick et al. 2007; Troll et al. 2013) and the Colli Albani volcanic district (Gaeta et al. 2009; Di Rocco et al. 2012), but are not as well documented in tholeiitic systems. Assimilation of carbonate rocks by magma can potentially release significant volumes of CO₂ (Iacono Marziano et al. 2007), which may perturb global climate. CO₂ excursions in the geological record have been correlated with the formation of Large Igneous Provinces (LIPs) (Wignall 2001).

The well-preserved and exposed Neoproterozoic Franklin LIP on Victoria Island provides a unique natural laboratory to address many of these issues. The Franklin LIP has a sill-dominated magmatic plumbing system with local fault-mediated shifts in emplacement level that facilitated magma transgression (Bédard et al. 2012). Franklin sills were emplaced primarily into limestones and dolostones, and calc-silicate skarns that formed by magma–carbonate interaction are locally prominent (Nabelek et al. 2013).

Hayes et al. (2015) documented the development of first-order modal layering in a composite Franklin sill as a result of two magmatic pulses. They proposed that the basal olivine-enriched layer of the ~21-m-thick Lower Pyramid Sill (LPS) represents a late olivine slurry replenishment into a resident gabbroic mush. Here, we present data from two other localities situated north of Minto Inlet on Victoria Island (Fig. 1) that we believe represent sections through coeval and possibly correlative sills. The P-sill (PS) is located ~20 km to the ENE of the LPS, while the West Uhuk Sill (WUS) is another ~30 km to the ENE (Fig. 1). Both have olivine-enriched bases and were emplaced at the same stratigraphic level, just above the Fort Collinson Formation marker unit. The WUS is adjacent to a prominent fault-guided magma upflow zone known as the Uhuk Massif (UM; described in Bédard et al. (2012)), which preserves calc-silicate reaction facies at some intrusive contacts (Nabelek et al. 2013). These three olivine-enriched sills (WUS, PS, and LPS) are collectively termed the Fort Collinson Sill Complex (FCSC). We will compare sections through them and document how bulk-rock compositions, mineral chemistry, and isotopic compositions vary along strike.

In this contribution, we propose that the FCSC records a regional scale (>50 km) olivine slurry replenishment event in a previously emplaced sill. The along-strike changes in composition recorded in the FCSC provide constraints on the geochemical and textural impacts of cumulate remobilization and slurry emplacement. We also discuss how small amounts of dolostone assimilation could have increased the Mg/Fe ratio of the magma and buffered the Fo content of equilibrium olivine in some parts of the FCSC.

Regional geology

The Franklin sills

The Franklin LIP is thought to be related to breakup of Rodinia, and geochemically equivalent rocks have been recognized across the Canadian Arctic, to Greenland and Siberia (Heaman et al. 1992; Rainbird 1993; Pehrsson and Buchan 1999; Shellnutt et al. 2004; Ernst et al. 2008; Ariskin et al. 2009; Denyszyn et al. 2009). The Franklin intrusions are dated between 723 and 716 Ma, corresponding to the early stages of the Neoproterozoic Sturtian glaciation (Heaman et al. 1992; Macdonald et al. 2010). Franklin-aged rocks are well preserved in the Minto Inlier of Victoria Island (Fig. 1), where they are hosted by the Shaler Supergroup; a sequence of Neoproterozoic carbonates and subordinate clastic and evaporitic sedimentary rocks that were deposited in the Amundsen Basin (Jefferson 1977; Rainbird et al. 1994, 1996). Shaler rocks are intruded by ~20 gabbroic

Fig. 1 Geological map of the Minto Inlier on Victoria Island adapted from Bédard et al. (2012), with the olivine-enriched sills of the FCSC labeled. WUS West Uhuk Sill, PS P-sill, LPS Lower Pyramid Sill. The inferred location of the feeder system to the FCSC is labeled UM (Uhuk Massif), which corresponds to a NNW-trending Neoproterozoic fault. The locations of other olivine-enriched sills, including Kat's, Dick's, and Uwe's are also shown

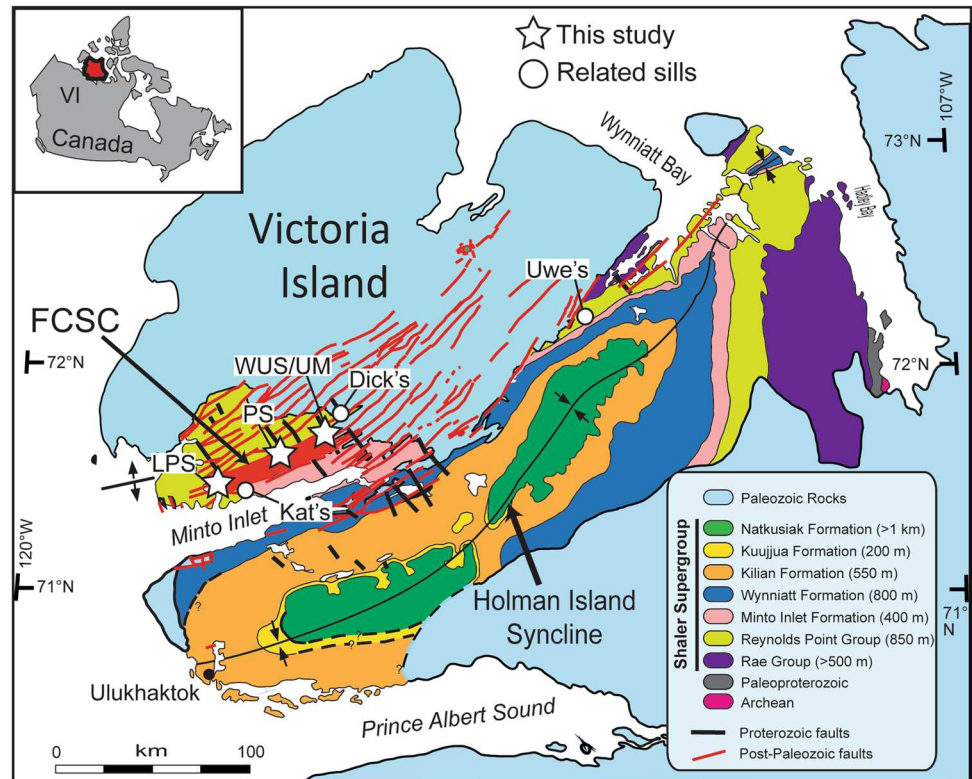

Fig. 2 Field photograph of the UM feeder system (looking west). The olivine-enriched East Uhuk Sill (EUS) jogs up-section into the WUS, with minor olivine-enriched (Og) transgressive sills between the two main sills. The WUS extends toward the west, to the PS and LPS

sills, which are generally 20–60 m in thickness (Jefferson et al. 1994; Hulbert et al. 2005). Good exposure allows some of the sills to be traced for tens of kilometers along strike (Fig. 2). In places, sills are connected to gabbroic feeder-dyke networks that generally trend NW–SE (Bédard et al. 2012). The Shaler Supergroup rocks are overlain by the Natkusiak flood basalts, the extrusive component of the Franklin LIP (Baragar 1976). Two main magma populations are identified in the Franklin LIP. Light-rare-earth element

(LREE)-enriched magmas form a thin basal lava sequence (Williamson et al. 2013). These are succeeded by voluminous tholeiitic sheet flows that have lower LREE/HREE (Dostal et al. 1986). Crosscutting relationships and diagnostic geochemical signatures allow correlation between the sills and lavas. Sills that formed from LREE-enriched magmas (corresponding to the basal lavas) are largely restricted to the lower (~2–4 km depth) part of the stratigraphy. We refer to these as Type-1 sills. Many have olivine cumulate-enriched layers near their base, including the sills constituting the FCSC. Younger, Type-2 intrusions, which have doleritic or clinopyroxene–plagioclase–phyric textures, occur throughout the Shaler Supergroup and are geochemically similar to the younger sheet flow unit of the Natkusiak flood basalts (Beard et al. submitted).

Fort Collinson Sill Complex

The FCSC, comprising the WUS, the PS, and the LPS, outcrops in the Collingwood Hills region of the Minto Inlier, just north of Minto Inlet (Fig. 1). The FCSC was emplaced ~3 km stratigraphically beneath the coeval Natkusiak flood basalts. Previous work has documented the field relationships at the Uhuk Massif (Bédard et al. 2012), showing that the Uhuk Massif (UM) is a magma upflow zone that extends toward the west as a conformable sill-like body, the WUS (Fig. 2). The WUS was emplaced into the dolostone-dominated Jago Bay Formation, only ~10 m

above the contact with the underlying Fort Collinson Formation, which is dominated by quartz arenites. The WUS is ~40 m thick, has sharp chilled lower and upper contacts, and contains a ~12-m-thick olivine-enriched layer in its lower section that we refer to as the Olivine Zone (OZ). About 30 km to the WSW, we sampled a section through another olivine-rich sill (PS) that is located at exactly the same stratigraphic level as the WUS. No chilled margins are exposed at the PS, which has a slightly thinner OZ (~10 m thick) in comparison with the WUS. About 20 km to the WSW of the PS is the ~21-m-thick LPS, which, again, is at the same stratigraphic position as the WUS and PS. Both chilled margins are exposed at the LPS, which has an OZ that is ~7 m thick. The petrology and mineral chemistry of the LPS were described in detail by Hayes et al. (2015) who argued, on the basis of textural and mineral–chemical data, that the LPS OZ is a hybrid rock that formed by mixing between a late olivine slurry and a resident gabbroic mush.

Analytical methods

We analyzed 71 samples from the FCSC (30 from WUS and adjoining UM, 15 from PS, and 26 from LPS) for bulk-rock major and trace elements at the INRS-ETE laboratories in Québec City, Canada. Some of the WUS and UM data originate from previous field campaigns by the Geological Survey of Canada (Bédard et al. in prep). Rock samples were initially trimmed and then reduced with a steel jaw crusher before being powdered with a planetary agate mortar. Sample fusion was operated on a Claisse fluxer using LiBO_2 and LiBr . The HNO_3 – HCl sinter technique was employed to circumvent potential problems associated with high field-strength elements (HFSE) and rare-earth elements (REEs) in refractory minerals. The major elements and Ba, Sr, Sc, V, Co, Cr, Cu, Ni, and Zn compositions were determined by inductively coupled plasma–atomic emission spectrometry (ICP–OES). Trace elements were determined by inductively coupled plasma–mass spectrometry (ICP–MS) using a method similar to that described by Varfalvy et al. (1997). Full details of the detection limits and the accuracy and precision of the data are summarized in Leclerc et al. (2011). A suite of samples from the LPS were analyzed using the ICP laboratories at Cardiff University in the United Kingdom. The samples were prepared into solutions for ICP–MS and ICP–OES analyses using the lithium metaborate fusion method described in McDonald and Viljoen (2006). All bulk-rock chemical data are available in Appendix Table 1 in ESM.

In situ mineral chemical analyses were performed using a Cameca SX-100 electron microprobe at the University of Laval in Québec City, Canada. The probe was fitted with

five wavelength-dispersive spectrometers. Accelerating voltage was 15 kV, beam current was 20 nA, and olivine was analyzed with a focused beam (1 μm diameter) with counting times of 20 s on peak levels and 10 s on background levels. The full olivine dataset for the WUS and PS is provided in Appendix Table 2 in ESM. The LPS olivine dataset and the electron microprobe method are provided in Hayes et al. (2015).

Samples selected for Pb-isotope analyses were prepared at the Pacific Centre for Isotopic and Geochemical Research (PCIGR) at the University of British Columbia, Vancouver. The dataset and details of methods used can be found in Beard et al. (submitted). Samples selected for S-isotope analyses were prepared and analyzed at McGill University, Montréal. The dataset are included in Appendix Table 3 in ESM, and the details of methods can be found in Hryciuk et al. (submitted).

Results

Petrography

The sills constituting the FCSC exhibit near-identical internal stratigraphies, albeit with differences in layer thicknesses. From bottom to top, they have an olivine-phyric (~5 %) Lower Chilled Margin (LCM); an olivine-phyric (~10 %) Lower Border Zone (LBZ); an Olivine Zone (OZ) composed of olivine-melagabbro to feldspathic peridotite with olivine modes up to ~55 %; a clinopyroxene-rich cumulate gabbro zone (CPZ), which is most prominent at the LPS; a doleritic gabbro zone (DZ) comprised of sub-ophitic clinopyroxene and plagioclase with a minor (<10 %) cumulate component; an aphyric Upper Border Zone (UBZ); an olivine-phyric (~5 %) Upper Chilled Margin (UCM). The key features of each layer are summarized in an idealized FCSC stratigraphic log (Fig. 3). We will now describe the key features of each layer of the FCSC following the nomenclature of Irvine (1982) and then discuss along-strike sill-to-sill variations.

Where it is visible, the thin (~5 cm) LCM contains 5 % euhedral (0.5–2 mm) olivine phenocrysts in a very-fine-grained groundmass (0.1 mm) of plagioclase and clinopyroxene dendrites. Small chromite microphenocrysts occur both as inclusions in olivine and in the groundmass. In the WUS LCM, hopper olivine is also present (Fig. 4a). The UCM is exposed at both the LPS and WUS and also contains 5 % olivine phenocrysts (or its pseudomorphs) in a very-fine-grained groundmass (0.1 mm). Amygdules (1–2 mm) filled with secondary chlorite, biotite, and quartz are present in the UCM.

The LPS LCM grades up into a ~1 m-thick LBZ, where euhedral (1–2 mm) olivine phenocrysts are embedded in

Fig. 3 A schematic log through the FCSC, showing key features of each layer. Both Lower and Upper Chilled Margins (LCM and UCM, respectively) contain olivine phenocrysts (*a*, *a'* ~5 %). The chilled margins grade into Lower and Upper Border Zones (LBZ and UBZ, respectively) characterized by plagioclase and clinopyroxene dendrites (*b*, *b'* with local nucleation on the surfaces of olivine phenocrysts). The olivine zone (OZ) is characterized by high olivine modes (up to 55 %) with primitive olivine primocrysts, pyroxene-poikilitic textures (*c*), and anhedral olivine-clinopyroxene textures. The OZ also contains hopper olivines (*d*). The clinopyroxene zone (CPZ) is characterized by abundant (40–50 %) sector-zoned clinopyroxene in an olivine-poor (5–10 %) gabbroic matrix (*e*). The doleritic zone (DZ) consists of sub-ophitic plagioclase and clinopyroxene (*f*) with minor olivine, sometimes pseudomorphed by orthopyroxene. The *top part* of the DZ is characterized by acicular pyroxenes (*g*) and an increase in late-stage accessory phases (quartz, alkali feldspar, hornblende, and biotite)

a matrix composed of plagioclase and clinopyroxene dendrites (1–2 mm). The LBZ at the WUS and PS is generally similar, although the slightly thicker (~5 m) WUS LBZ also contains olivine with hopper morphologies (Fig. 4b). At the PS and WUS, the dendrite-textured basal LBZ grades up into an upper LBZ facies with a gabbroic-textured groundmass (Fig. 4c). Some olivine primocrysts appear to have been fractured and veined by groundmass plagioclase. Clinopyroxene oikocrysts contain inclusions of olivine, chromite, and euhedral plagioclase laths. Minor groundmass orthopyroxene is also observed.

The LPS UCM grades down to an UBZ that is free of olivine phenocrysts, and which is composed of plagioclase and clinopyroxene dendrites. Hayes et al. (2015) suggested that the absence of phenocrysts was due to crystal settling of olivine, such that the propagating upper crystallization front was no longer able to capture fast-settling phenocrysts after about 10–15 cm of growth. The WUS has a very thin UBZ, whereas the uppermost facies are missing from the PS as a result of erosion. The UBZ at the WUS grades down rapidly into varitextured DZ gabbros, some markedly pegmatitic with acicular pyroxene morphologies.

The LPS LBZ grades up into a ~7-m-thick OZ composed of olivine orthocumulate melagabbro to feldspathic peridotite with 40–55 % modal olivine. The OZ is slightly thicker (~9–10 m) at the PS and thicker again (~12 m) at the WUS. Hayes et al. (2015) subdivided the LPS OZ into lower, middle, and upper facies, based on olivine morphologies. The LPS lower OZ contains euhedral (1–2 mm) olivine primocrysts and finer-grained (0.5–1 mm) olivine that are enveloped by clinopyroxene oikocrysts and interstitial plagioclase. The LPS middle OZ has fewer olivine primocrysts and is dominated by anhedral olivine that is intergrown with clinopyroxene (Fig. 4d). The LPS upper OZ mostly contains hopper olivine (Fig. 4e), with subordinate primocrystic and groundmass olivine. Upper OZ clinopyroxene is commonly euhedral and does not contain olivine chadacrysts.

In the PS and WUS, the divisions into lower OZ, middle OZ, and upper OZ are less clear than at the LPS. In the WUS OZ, hopper olivine can be seen at various levels rather than being restricted to the upper OZ (Fig. 4f). Near the base of the PS and WUS OZ, clinopyroxene occurs both as oikocrysts (Fig. 4g) and as euhedral “cumulus” grains, some with internal “fairy rings” of chromite microphenocrysts. Higher in the PS and WUS OZ, subordinate orthopyroxene occurs as oikocrysts, as euhedral prisms or is intergrown with clinopyroxene. Some olivine inclusions in clinopyroxene oikocrysts have hopper shapes and contain clinopyroxene inclusions (Fig. 4h). Plagioclase occurs as subhedral inclusions in clinopyroxene oikocrysts, as interstitial grains and as fine groundmass laths.

Overlying the LPS OZ is a thin (~1 m) CPZ, which is dominated by euhedral sector-zoned clinopyroxene (40–50 %). Equivalents of the CPZ were observed at the PS interlayered with olivine-rich cumulates. CPZ-type rocks were not identified in our section through the poorly exposed OZ/DZ transition at the WUS. In the PS, the euhedral sector-zoned clinopyroxene commonly has sieved internal zones and may have alternating normal and reversed zones (in terms of Mg#). The matrix of the PS CPZ preserves hopper olivine that is cemented by plagioclase.

Fig. 4 Photomicrographs (all in crossed-nicols) of olivine morphologies and textural relationships in the FCSC. **a** The olivine-phyric WUS LCM with the lower contact with the Jago Bay Formation visible. Olivine phenocrysts (Olph) and hopper olivines (Hol) are shown, residing in a very-fine-grained groundmass (Gm). **b** The WUS LBZ contains both phenocrystic and hopper olivine that reside in a fine-grained matrix of clinopyroxene (Cpx) and plagioclase dendrites (Pld). **c** The PS LBZ showing a euhedral olivine phenocryst residing in a dendritic matrix. **d** The LPS OZ (specifically the middle OZ) showing both olivine primocrysts and amoeboid olivines that are overgrown by clinopyroxene. **e** The LPS OZ (specifically the upper OZ) showing hopper olivines that are intergrown with interstitial plagioclase (Plg). **f** The WUS OZ showing hopper olivine (Hol), olivine chadacrysts (Olc) enclosed in poikilitic clinopyroxene (Pcpx) and groundmass olivines (Olg) residing in interstitial plagioclase. **g** The WUS OZ showing euhedral olivine primocrysts (Olpr) and a coarse poikilitic clinopyroxene enclosing abundant olivine chadacrysts. **h** The PS OZ showing a hopper olivine that is overgrown by clinopyroxene

Above the LPS CPZ is a ~9- to 10-m-thick DZ, which mostly consists of sub-ophitic clinopyroxene and plagioclase. Orthopyroxene (~10 %) in the LPS DZ may be pseudomorphous after olivine. The habit of clinopyroxene changes gradually from blocky prismatic crystals at the base of the LPS DZ to acicular elongated prisms in the upper LPS DZ. The PS DZ and WUS DZ show a general similarity to the LPS DZ, but with some differences. At the WUS, the DZ

is markedly thicker (~27 m) than at the LPS. The basal DZ at the WUS and PS contains 10 % euhedral olivine (1–3 mm) in a gabbroic matrix (1–2 mm) with only minor Fe–Ti oxides (1–2 %) and granophyric patches. Some clinopyroxene grains are equant to euhedral, with optically distinct cores reminiscent of CPZ clinopyroxene. Plagioclase is generally anhedral, with a few coarser (1–2 mm) euhedral (cumulus?) laths that may have spongy internal zones. In the PS, this

Example OZs from the LPS, PS, WUS are shown, as well as the LCMs of the LPS and WUS. The average FCSC chill composition is also shown. See Appendix Table 1 in ESM for the full dataset

basal olivine-bearing DZ facies is thin and grades up rapidly into a varitextured doleritic gabbro that contains abundant Fe–Ti oxides and shows marked variations in grain size through the development of pegmatoidal patches. The basal WUS DZ described above is succeeded by a thick, doleritic-textured gabbro with acicular clinopyroxene habits. Approximately 12 m below the upper contact, the proportion of Fe–Ti oxides and sulfides in this gabbro increases markedly (to ~10 %), as does the amount of granophyre (to ~10 %) and hornblende (~5 %). The uppermost portions of the WUS DZ resemble the upper varitextured gabbroic facies seen at the PS, with abundant pegmatoidal patches and acicular pyroxene habits. We interpreted the increase in these accessory phases in the upper DZ at the LPS to represent an evolved residue (sandwich horizon) that formed by in situ fractional crystallization (Hayes et al. 2015).

Bulk-rock chemistry

The chilled margin compositions of the WUS and LPS are very similar (10.9 vs. 10.7 wt% MgO, respectively; Table 1). Meter-scale dykes emplaced near the contacts of the UM also have similar compositions (Appendix Table 1 in ESM). We calculated an average FCSC chill composition of 10.3 wt% MgO (Table 1) from 10 samples (chills, thin sills, and dykes). This chill composition was used by Hayes et al. (2015) as a starting composition for PELE (Boudreau 1999) fractional crystallization modeling, which will be used to anchor some of the models in the discussion section below.

Many of the OZ rocks from the FCSC show MgO-enrichment and Al₂O₃-depletion trends, indicating that they

contain cumulus olivine (Table 1). The OZ rocks have MgO contents between 18 and 27 wt%, Al₂O₃ between 6 and 10 wt%, and Ni contents up to 720 ppm (Table 1). The CPZ rocks have high CaO contents, with values between 12 and 14 wt%, and high Cr and Sc (1,500 and 52 ppm, respectively), indicating a cumulate clinopyroxene component. The major-element chemistry of DZ rocks is very similar in all three sections of the FCSC, with MgO contents ranging between 6 and 10 wt%. FCSC DZ rocks show clear trends of increasing FeO_T and TiO₂ and decreasing Al₂O₃ as MgO decreases, which imply fractionation along a multiphase cotectic (Fig. 5). Many DZ rocks have high Al₂O₃ contents (11–15 wt%) and Sr contents (250 ppm), and some show positive Eu anomalies on MORB-normalized spidergrams (not shown), implying a plagioclase cumulate component, consistent with plagioclase crystal habits. WUS DZ rocks typically have higher CaO (wt%) and Sr (ppm) contents than the LPS DZ.

The similarity of igneous stratigraphy, petrography, and major element compositions at the WUS, PS, and LPS indicates very similar differentiation paths of a common (or at least very similar) magma. The most notable difference between the three sills is that the OZ rocks show a systematic shift toward more Fe-rich bulk compositions toward the west (Fig. 5; Table 1), which will be discussed below.

Olivine chemistry

Olivine chemical data (Table 2) provides in situ compositional constraints on the crystals and melts involved in the formation of OZ rocks in the FCSC. An array of different

Olivine primocrysts are also common in the WUS OZ and PS OZ, with core compositions up to Fo₉₀ being observed at the PS. Olivine chadacrysts enclosed by clinopyroxene oikocrysts have Fo_{83–78} compositions, similar to the LPS range. Groundmass olivines at the WUS and PS range to lower Fo contents (Fo_{80–77} and Fo_{83–68}, respectively). The Fo contents of hopper olivines at the WUS and PS sites are very similar to those of the LPS OZ, but at the WUS and PS, they are mostly normally zoned.

Pb- and S-isotopes

Discrimination plots of ²⁰⁸Pb/²⁰⁴Pb versus ²⁰⁶Pb/²⁰⁴Pb and ²⁰⁷Pb/²⁰⁴Pb versus ²⁰⁶Pb/²⁰⁴Pb are presented in Fig. 6. The WUS and LPS are plotted (we do not have Pb-isotope data for the PS), along with other olivine-enriched sills (Kat’s, Dick’s, and Uwe’s) from the Minto Inlier, some of which may be correlative with the FCSC. The WUS OZ and DZ are close to isotopic equilibrium in both Pb-isotope plots, consistent with derivation from the same magma. In contrast, the LPS OZ and DZ are isotopically distinct in both Pb-isotope plots, indicating that these layers were derived from discrete magmas. This observation supports the replenishment model developed in Hayes et al. (2015). Dick’s and Uwe’s OZ and DZ are also in Pb-isotope disequilibrium, indicating these are also composite sills. Kat’s sill (~5 km SE of the LPS: Fig. 1) may be an offshoot of the FCSC as it is also located just above the Fort Collinson Formation. Isotopically, Kat’s sill is similar to the WUS, with an OZ and DZ that are in approximate isotopic equilibrium.

S-isotope data for the PS and LPS are presented in Fig. 7 and Table 3. The PS and LPS exhibit similar δ³⁴S profiles, with contrasting ranges for their OZ and DZ rocks. The LPS exhibits more of a “step-change” between OZ and DZ. In general, OZ rocks have δ³⁴S values ranging between +3 and +5 ‰, while the DZ rocks have a greater range in δ³⁴S values between +3 and +8 ‰. The apparent decoupling between the OZ and DZ shown by the S-isotopes is consistent with the Pb-isotope disequilibrium observed in the LPS. Values of +3 to +4 ‰ are common for the Franklin magmas and are suggestive of a slightly anomalous melt source composition (Hryciuk et al. submitted), whereas the range to higher δ³⁴S seen in the DZ rocks suggests these facies incorporated a sedimentary crustal component.

Discussion

Are the three FCSC sills a single, composite sill?

The WUS, PS, and LPS are all exposed at the same stratigraphic horizon, immediately above the upper contact of

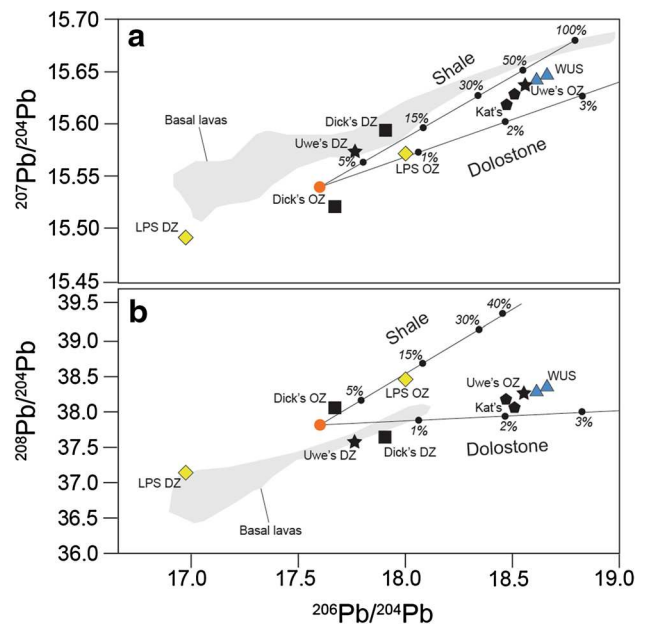

Fig. 6 Pb-isotope discrimination plots with OZ and DZ rocks of the FCSC shown, along with other possibly correlative sills (Dick’s, Kat’s, and Uwe’s). **a** ²⁰⁷Pb/²⁰⁴Pb versus ²⁰⁶Pb/²⁰⁴Pb and **b** ²⁰⁸Pb/²⁰⁴Pb versus ²⁰⁶Pb/²⁰⁴Pb. The compositional field of the basal lava unit of the Natkusiak flood basalts is plotted (gray field) showing Pb-isotope compositions that partly overlap with those of the Type-1 olivine-enriched Franklin sills. Assimilation trajectories for dolostone and shale are shown with the starting composition (red circle) set as the average Type-1 Franklin magma composition

the Fort Collinson Formation marker unit. They share a similar internal stratigraphy with analogous first-order bimodal layering (OZ/DZ) with comparable petrographic features (Fig. 4), chilled margin compositions (Table 1), and olivine compositions (Table 2). Additionally, the LPS and PS show a roughly similar split between the S-isotope signatures of the OZ versus the DZ (Fig. 7). Dykes at the UM branch toward the west [see Fig. 6 in Bédard et al. (2012)], suggesting westward sill propagation. The thickness of the OZ decreases systematically from 12 m at the WUS to 7 m at the LPS, as does the total sill thickness from 40 m at the WUS to 20 m at the LPS. These relationships suggest that the WUS, PS, and LPS represent a single, laterally extensive sill (>50 km) that propagated westward from a feeder zone at the UM. Hayes et al. (2015) presented mineral–chemical and textural data, indicating that the LPS OZ is a hybrid rock that was produced when a primitive olivine slurry was emplaced into a resident gabbroic mush. The OZ at the PS and WUS shows similar textural characteristics and olivine compositions to those observed in the LPS OZ, and we infer from this that they formed in a similar manner. S-isotope data (Fig. 7) support the distinct origins of the OZ and DZ and seem to preclude a simple fractional crystallization relationship between the two layers at the PS and LPS.

Pb-isotopic compositions support the conclusion from S-isotopes that the LPS OZ and DZ originated from different magmas (Fig. 6). Upstream at the WUS, the DZ and OZ are close to Pb-, Sr-, Nd-, and Hf-isotopic equilibrium and have similar trace-element compositions, (Beard et al.

submitted). Therefore, the OZ–DZ couple at the WUS appears to have developed by internal differentiation of the same magma. Despite these chemical similarities, the two facies of the WUS are very different in terms of S-isotopic compositions (unpublished data). We suggest that the magmas at the WUS either experienced open-system processes with an extremely heterogeneous host stratigraphy as they migrated through the crust, or that magmas originated in an extremely heterogeneous source mantle and were not homogenized *en route*, or both. Thus, the LPS OZ magma acquired radiogenic isotope signatures that are distinct from those in the LPS DZ and which also differ from those in the WUS. We will now examine the Fe–Mg systematics of the FCSC, so as to determine the compositions of crystals and melts involved in intra-sill differentiation. We will reconsider the isotopic constraints afterward when we develop the FCSC emplacement model.

Crystal–melt Fe–Mg constraints: a heterogeneous olivine crystal cargo?

The Fe–Mg relationships help us to constrain the composition of crystals and melt involved in the formation and differentiation of the sills constituting the FCSC. Figure 8 shows the average FCSC chill composition, together with analyses of DZ and OZ rocks from the FCSC sills we have sampled. We have also plotted the LLD pathway predicted from PELE (Boudreau 1999) for the average FCSC chill composition and labeled the point where plagioclase and clinopyroxene join olivine (Fo_{84}) on the liquidus. This model LLD pathway overlaps the compositions of DZ rocks from the FCSC, supporting the notion that these DZ rocks are cotectic precipitates derived from fractional crystallization of a tholeiitic melt similar to the average FCSC chill composition.

The petrography (Fig. 4) and MgO-enrichment trends of the FCSC OZ rocks imply olivine accumulation; yet, the OZ arrays in the FCSC sills (WUS, PS, and LPS) define three distinct trends (Fig. 5). In principle, each individual OZ bulk-rock analysis should represent a two-component mixture of cumulus olivine and trapped melt, now mostly represented by clinopyroxene and plagioclase. The modal proportion of olivine in these rocks ranges between 20 and 55 % (Fig. 8), of which most is indeed “cumulus” textured. A least squares regression trend was fitted to each OZ array, defining both the composition of (bulk) olivine that accumulated from the melt (Cawthorn et al. 1992) and the composition of the dominant entrapped basaltic melt (Fig. 8). The WUS OZ array intersects the average FCSC chill composition (10.3 wt% MgO) and projects toward an olivine composition of Fo_{87} . The PS OZ array projects toward a more evolved basaltic melt composition (9 wt% MgO) and a more evolved olivine composition of Fo_{86} . The

Fig. 8 FeO*–MgO systematics of the FCSC with bulk-rock compositional fields as well as the constraints provided by the olivine compositional data and their inverse melt compositions. The histogram attached to the olivine Fo–Fa join shows the distribution of primocrystic, chadacrystic, and groundmass olivine compositions observed in the FCSC OZ from all three sills belonging to the FCSC

LPS OZ array projects toward a still more evolved basaltic melt composition (8 wt% MgO) and a still more evolved olivine composition of Fo₈₅. If we force the regression of the LPS OZ through the average FCSC chill composition (shown in Fig. 5), then the bulk-extract olivine compositions that are required to satisfy the bulk-rock mass balance for the PS and LPS OZ rocks are much more Fe-rich (~Fo₈₃) than the dominant primocrystic olivines (~Fo₈₆) that these rocks contain. Although the bulk-rock Fe–Mg systematics imply that the olivine cumulates in the FCSC were derived from increasingly more Fe-rich melts toward the west, the observed compositions of olivine in these rocks do not show systematic Fe-enrichment toward the west and only approximately match the required crystal “cumulates” (Fig. 8; Table 2). Clearly, the diversity of olivine compositions (histograms on the Fo–Fa join: Fig. 8) observed within each sill’s OZ does not fit an idealized equilibrium crystal–extract model (Cawthorn et al. 1992; Wilson 2012) and implies that the OZ cumulate arrays reflect an average cumulate formed from a heterogeneous olivine crystal cargo.

Can progressive magma fractionation explain the along-strike Fe-enrichment trend?

The westward Fe-enrichment trend in the FCSC OZ (Fig. 5) could perhaps be interpreted as a result of olivine fractionation during flow. However, the data show that olivine primocrysts and chadacrysts have almost identical compositions in the three OZ sections (Table 2). The absence of a systematic trend toward more evolved olivine compositions toward the western end of the FCSC OZ is inconsistent with a simple syn-flow fractional crystallization hypothesis. The Fe–Mg systematics imply that the

WUS OZ formed from an accumulation of primitive olivine crystals originating from a melt almost identical in composition to the average FCSC chill composition (Fig. 8). Such a melt (10.3 wt% MgO) would be saturated only in olivine (+minor chromite). Therefore, the WUS OZ could plausibly be interpreted to have formed by partial separation of olivine from a melt similar in composition to the average FCSC chill (cf. Cawthorn et al. 1992). In contrast, the LPS OZ array implies the extraction of less forsteritic olivines from a more evolved melt composition (8 wt% MgO), which would have been very close to cosaturation in pyroxene and plagioclase (Fig. 8). Consequently, this melt should not have been able to create a 7-m-thick sequence of olivine cumulates in the LPS, suggesting that the LPS OZ contains “excess” olivine. One might have inferred that the LCM of the LPS (being only ~1 m below the LPS OZ) should have been the melt from which the LPS OZ crystallized. However, the misfit between the entrapped melt composition predicted from the LPS OZ array (Fig. 8) and the LPS LCM (Table 1) implies that the melts from which the LPS OZ was extracted had a different and more complex origin. We will now demonstrate that the along-strike Fe-enrichment trend is best explained by mixing between a late olivine slurry replenishment and a resident gabbroic mush.

Mixing between an olivine slurry and a resident gabbroic mush

Hayes et al. (2015) argued that the LPS OZ is a hybrid rock that formed from a mixture of an evolved component similar in composition to the DZ and an injected magma charged with olivine. This inference is supported by isotopic data (Figs. 6, 7), which indicate that the LPS OZ and

DZ are not strictly consanguineous. We will now show that the OZ in the other sills constituting the FCSC is formed by the same process and then argue that an olivine slurry replenishment propagated >50 km in this thin sill. First, we will constrain the compositions of the components involved in mixing, and then, we will quantify their proportions in the mixture, using the Fe–Mg diagram.

Component 1: Resident gabbroic mush

Hayes et al. (2015) argued that the LPS contained a partly crystallized gabbroic mush at the time of olivine slurry replenishment. The composition of the gabbroic mush at this juncture was constrained by comparing the PELE LLD of the average FCSC chill with the melt composition calculated to be in equilibrium with evolved olivine cores located in the LPS OZ. These cores were interpreted to be xenocrystic, being derived from the host gabbro mush. In fact, the composition of evolved xenocrystic olivine cores is very similar across the FCSC, ranging between Fo_{77–75}. Hayes et al. (2015) calculated from Fe–Mg olivine–melt equilibria that these olivine xenocrysts were in equilibrium with melts of ~6 wt% MgO. The LLD for fractional crystallization of the average FCSC chill is plotted on Fig. 8. At 6 wt% MgO, the PELE model predicts that 40 % of the melt has solidified, containing 11 % olivine, 16 % plagioclase, and 13 % clinopyroxene. The location of this resident mush mixing pole is labeled as Gab75, and it lies approximately in the middle of the FCSC DZ compositional field (Fig. 9a, b). Olivine cores as evolved as Fo₇₃ are present in the LPS upper OZ, suggesting that more evolved gabbroic material was ingested, and we label this more evolved resident mush as Gab73 (Fig. 9c). We also define a third possible resident mush mixing pole that would correspond to the most evolved possible FCSC DZ compositions as SdH (Sandwich Horizon: Fig. 9c).

Component 2: Olivine slurry

The olivine primocrysts (Fo_{88–82}) in the LPS OZ were interpreted to have been derived from an olivine slurry that was injected into an evolved resident gabbroic mush Hayes et al. (2015). The WUS OZ array links the average FCSC chill composition to olivine compositions (Fo₈₇) that are similar to the olivine primocrysts found within these rocks. Therefore, the WUS OZ appears to represent a mixture of a melt similar to the average FCSC chill and forsteritic olivine. In order to be mobile, such an olivine slurry must have contained at least 50 % melt (Marsh 1981; Paterson 2009); so it seems plausible to suggest that the lower-MgO, melt-rich part of the WUS OZ may approximate the olivine slurry-mixing component. We use the average WUS OZ composition (OS87a: Fig. 9a) as one potential olivine

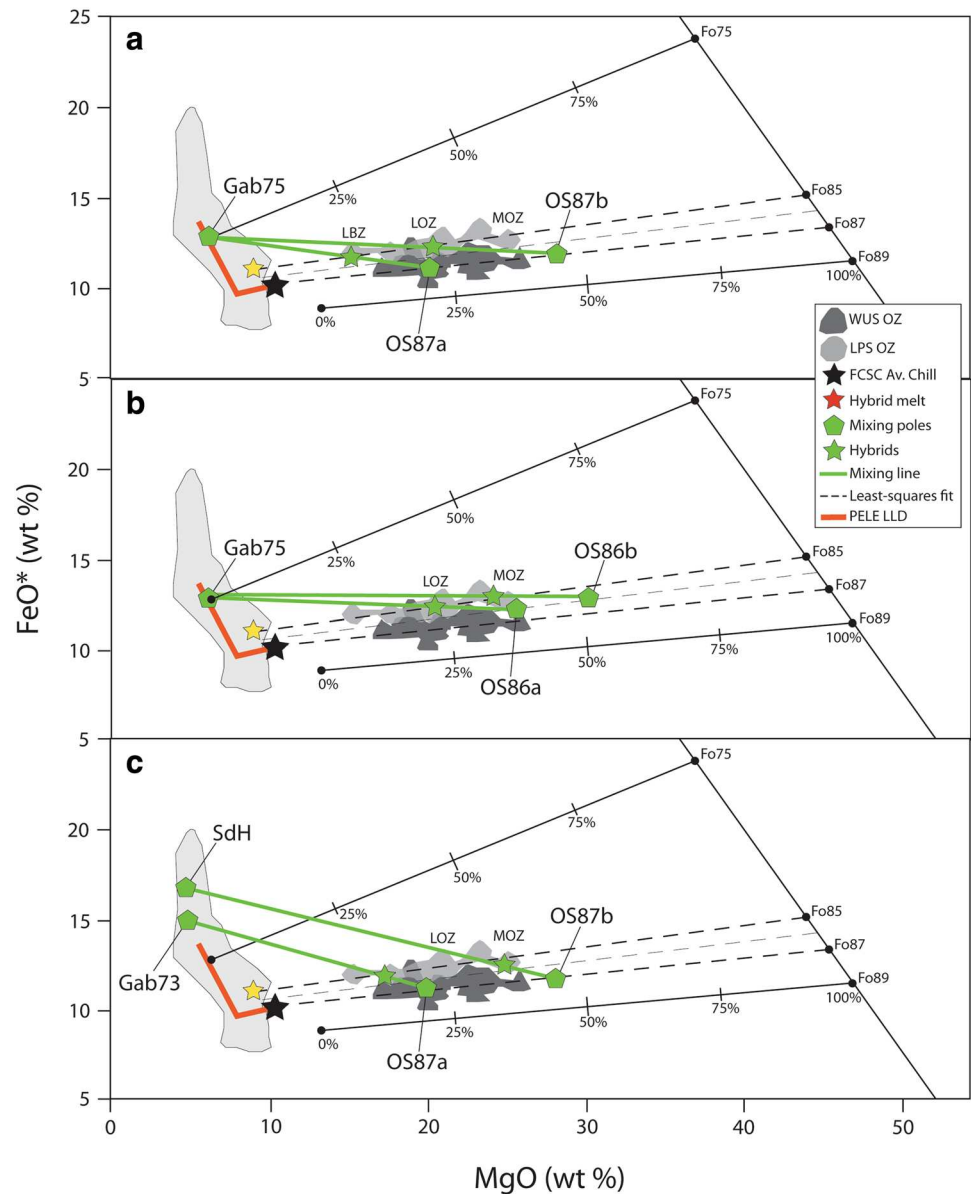

slurry-mixing pole. This composition (OS87a) corresponds to 20 % olivine (Fo₈₇) in a primitive carrier melt (13 wt% MgO). The composition of this primitive carrier melt was determined by calculating the melt in equilibrium with Fo₈₇ olivine using the Fe = Mg olivine–melt exchange coefficient ($K_d = 0.34$) of Matzen et al. (2011) with all Fe as FeO. This calculated carrier melt is more primitive than the FCSC chill, indicating that the melts in equilibrium with this olivine were unfractionated and that the melt at the end of the WUS OZ array defined in Fig. 8 is not in equilibrium with the projected olivine composition. However, given the large spread of olivine primocryst compositions in the FCSC OZ (Fig. 8), it is likely that the olivine slurry was compositionally heterogeneous. The median of olivine primocryst core compositions from the FCSC OZ is Fo₈₆ (see histograms on Fig. 8). This second potential olivine slurry-mixing pole (OS86a: Fig. 9b, c) would contain 30 % olivine (Fo₈₆) and a carrier melt with 12 wt% MgO, also calculated using the olivine–melt Fe = Mg exchange coefficient of Matzen et al. (2011). More olivine-rich slurry-mixing poles can also be defined. One, which contains 45 % olivine, is on the WUS array (OS87b) and another with 55 % olivine is on the Fo₈₆ tieline (OS86b: Fig. 9c).

Mixing calculations

Mixing the Gab75 and OS87a components in a proportion of 70:30 creates a hybrid olivine-charged magma that falls on the LPS OZ array (Fig. 9a). Mass balance implies that this hybrid magma would contain ~15 % olivine primocrysts, primarily inherited from the OS87a component, and would have bulk MgO values between ~15 and 17 wt%. These hybrid magmas could then unmix to generate the LPS OZ array. Such olivine/liquid unmixing was argued to play an important role in the development of the LPS OZ (Hayes et al. 2015). The same mixing line (Fig. 9a) passes through the PS OZ array, suggesting that the PS OZ might have formed in the same way with a slightly (~5 %) higher proportion of olivine slurry in the mixture. This pattern is consistent for the PS OZ in all the mixing calculations presented below. It is possible to produce a more MgO-rich 1-stage hybrid that could match the more olivine-rich facies of the OZ (19–21 wt% MgO or lower OZ). To do so, the olivine slurry would need to contain a higher proportion of olivine (e.g., OS87b). Mixing OS87b (containing 45–50 % olivine), with Gab75, can potentially produce these more MgO-rich compositions as one event, without the need for post-hybridization unmixing (Fig. 9a).

Mixing Gab75 with the OS86a mixing pole in a proportion of 75:25 also generates a more MgO-rich hybrid (Fig. 9b). Mass balance implies that this hybrid magma would contain 20–25 % olivine primocrysts, primarily inherited from the OS86a component, and would have bulk

Fig. 9 Various FeO–MgO mixing models using different mixing poles. **a** OS87a containing ~20 % olivine (Fo₈₇) mixed with Gab75 (with ~6 wt% MgO), and OS87b containing ~45 % olivine (Fo₈₇) mixed with Gab75. **b** OS86a containing ~40 % olivine (Fo₈₆) mixed with Gab75, and OS87b with >50 % olivine (Fo₈₆) mixed with Gab75. **c** OS87a mixed with Gab73 (with ~5 wt% MgO) and OS87b mixed with SdH (with ~4 wt% MgO)

MgO values between ~19 and 21 wt%. The most bulk-MgO-rich OZ compositions along the LPS array contain up to 25 wt% MgO. The more MgO-rich hybrid magmas defined above could have unmixed to produce these higher MgO bulk-rock compositions. On the other hand, if the high-MgO compositions were formed in one event, then a more olivine-rich slurry would be needed. An 80:20 mix of Gab75 and OS86b (which contains >50 % olivine) can produce such hybrid magmas. However, we believe this last model is unrealistic because the high proportion of olivine in the slurry would probably inhibit flow and mixing (Marsh 1981; Paterson 2009). Alternatively, instead of high olivine modes in the slurry, the resident gabbroic mush may have been more evolved than Gab75. Mixing Gab73 with OS87a in a proportion of 80:20 can produce hybrid

magmas with ~19–21 wt% MgO (Fig. 9c). This is a 5 % reduction in the proportion of olivine slurry required, compared to models that use the Gab75 mixing pole.

What these mixing models show is that it is easy to reproduce the more evolved (low MgO) part of the LPS OZ array by some variant of this mixing process, but that it is difficult to generate the more primitive parts of the LPS OZ array (e.g., LPS middle OZ with ~25 wt% MgO) by a 1-stage mixing process unless a very high proportion (>50 %) of olivine is present in the recharging olivine slurry (e.g., OS86b). If we only consider “reasonable” olivine modes in the olivine slurry (e.g., OS87b), then the more primitive part of the LPS OZ array can only be attained in a single stage if the resident gabbroic mush had a SdH composition, with mixtures of 80:20 (SdH/OS87b).

However, it seems implausible that the invading olivine slurry could have ingested large volumes of solely late-stage evolved magmas that only constitute a small (~5 %) proportion of Type-1 sills. We therefore favor a scenario whereby the MgO-rich part of the OZ arrays form when the hybrid magmas unmixed, which we discuss next.

Post-hybridization unmixing and the formation of high-MgO olivine cumulates

The propagation of a primitive olivine slurry and its hybridization with a resident gabbroic mush can produce hybrid magmas that explain the formation of the FCSC OZ. The apparent westward decrease in the proportion of the olivine-rich component in the mixture from which the different OZs accumulated suggests that the olivine slurry progressively hybridized with an evolved resident gabbroic mush as it migrated through the sill. This progressive hybridization scenario accounts for the downstream bulk Fe-enrichment trend seen in the FCSC OZ. The resultant hybrid magmas would then have unmixed (crystal–liquid separation) to produce the high-MgO cumulate arrays displayed in Fig. 9. In the LPS, the olivine slurry seems best preserved in the lower OZ, which contains high-Fo primocrystic olivine. We infer that the high-MgO rocks (~25 wt% MgO) from the LPS middle OZ best preserve the hybridization/unmixing stage. The LPS middle OZ contains the highest olivine modes (Fig. 8) and is predominantly composed of anhedral olivine that is intergrown with clinopyroxene (Fig. 4d, f, h), with only few (~5 %) euhedral olivine primocrysts. These LPS middle OZ olivine compositions (Fo_{83-81}) are more evolved than the euhedral olivine primocrysts that characterize the olivine slurry. Based on these textural and compositional constraints, Hayes et al. (2015) proposed that the LPS middle OZ crystallized directly from a hybrid produced as suggested above. To test this scenario, we ran an assimilation–fractional–crystallization (AFC) model in PELE, to see whether the mixing process described above produces “excess” olivine crystallization and so could account for the lower olivine Fo contents and higher olivine modes (~55 %) and by extension, the higher MgO (~25 wt% MgO) contents observed in the LPS middle OZ. We simulated in PELE, an olivine slurry (containing 30 % olivine and 70 % melt) that assimilates a gabbroic mush (corresponding to an average FCSC DZ composition). The output from this model shows that ~5 % more olivine crystallization is produced prior to the cotectic. Olivine Fo contents are also buffered at Fo_{82} , compared to closed-system models where Fo decreases rapidly with crystallization. These olivine compositions are similar to the composition of olivines observed in the LPS middle OZ. The AFC model results (Appendix Table 3 in ESM) support the

hypothesis that the LPS middle OZ rocks are crystallized from a hybrid magma (Fig. 9).

Pb- and S-isotopic constraints for the petrogenesis of the FCSC

A record of multiple, isotopically distinct magmas in the FCSC

The spread of Pb-isotope compositions indicates that many different magmas were involved in the generation of the olivine-enriched Franklin sills (Fig. 6). The distribution of Pb-isotope compositions can in part be explained by the assimilation of Shaler Supergroup crustal rocks. Because the WUS OZ/DZ have similar trace-element compositions with enriched Pb concentrations and distinctive radiogenic $^{206}\text{Pb}/^{204}\text{Pb}$ and $^{207}\text{Pb}/^{204}\text{Pb}$ -isotope compositions, we suggest they shared a similar melt source composition and contamination history. What is pertinent here is that the LPS OZ and LPS DZ have different Pb- and S-isotope signatures (Fig. 6), consistent with the composite intrusion model presented in Hayes et al. (2015). In Pb-isotope plots, mixing lines between two geochemical reservoirs are straight lines. As the LPS OZ plots above a tie line between the WUS OZ/DZ and the LPS DZ, a simple mixture of these two magmas cannot explain its isotopic signature (Fig. 6b), in apparent contradiction with the hybridization model we favor (Fig. 9). If the FCSC does indeed represent a single sill system, then either the olivine slurry replenishment event was internally heterogeneous, or there were two isotopically distinct olivine slurry replenishment events in the FCSC.

We suggest that the igneous rocks preserved at the WUS represent a vigorous late replenishment event, which we suspect pushed previously emplaced magmas downstream toward the LPS. Pb-isotope compositions suggest that relative to the average Type-1 magma, this final pulse assimilated small amounts (<10 %) of dolostone (Beard et al. submitted). The Franklin intrusions of the Minto Inlier are hosted by a predominantly carbonate/dolostone sedimentary sequence (Thomson et al. 2014), and calc-silicate reaction products are locally prominent (Nabelek et al. 2013). Bédard et al. (2012) report field and thin-section evidence of dolostone assimilation in the UM. In this context, the gradual shifts in OZ Fe/Mg in the FCSC that we attribute to downstream hybridization (Fig. 9) are superimposed on a secular variation in the geochemical/isotopic signatures of the incoming primitive magmas.

The potential effects of dolostone assimilation on the FCSC magma(s)

As stated above, Pb-isotope variations in the FCSC can be explained by small amounts (<10 %) of dolostone

Fig. 10 Forsterite (Fo) in olivine versus temperature diagram showing the LLD of the average FCSC magma during fractional crystallization (FC) and AFC. Dolostone is the contaminant, which has been added to the magma in varying proportions per fractionation step. Models are included in Appendix Table 5 in ESM

assimilation (Beard et al. submitted). We investigated the potential impacts of dolostone assimilation on melt and mineral chemistry using PELE. We used the average FCSC chill as our starting composition (10.3 wt% MgO) and added a dolostone contaminant to the magma (0.2, 0.4, 0.5, and 1 g of contaminant added per fractionation step). The composition of the contaminant was taken as the average of 26 dolostone bulk-rock analyses from sedimentary rocks of the Minto Inlier (Appendix Table 4 in ESM). The addition of this high-MgO (~20 wt%) and low-FeO (<1 wt%) dolostone contaminant to the magma has major impacts on the LLD, when compared to regular fractional crystallization. Prior to olivine saturation, abundant CO₂ gas is released, and the AFC models with the most dolostone contaminant predict an increase in melt MgO content up to 11.7 wt% and decrease the melt FeO/MgO ratio. Primitive olivine (up to Fo₈₉) crystallizes at temperatures of ~1,260 °C, earlier than in closed-system models for this melt composition (Fig. 10). Between 1,260 and 1,200 °C, ~7 % olivine crystallizes and 7 % CO₂-rich gas is released. In contrast to fractionation models without dolostone assimilation where olivine Fo contents decrease rapidly (Fig. 10), assimilation of MgO-rich dolostone buffers olivine Fo contents at values of ~Fo_{88–87} in the 1,260–1,200 °C interval (Fig. 10). Clinopyroxene begins to crystallize earlier in the dolostone-AFC models compared to the closed-system model due to the high CaO contents (24–47 wt%) of the dolostone contaminant, with up to ~20 % clinopyroxene being extracted before the arrival of plagioclase. In contrast, both clinopyroxene and plagioclase join olivine on the liquidus nearly simultaneously in closed-system models.

The modeled effects of dolostone assimilation on the FCSC magma are very similar to those observed experimentally (Iacono Marziano et al. 2008; Mollo and Vona 2014) and resemble products of volcanic systems where assimilation of host carbonates occurred (Chadwick et al. 2007; Di Rocco et al. 2012; Troll et al. 2013). Dolostone assimilation in the FCSC magma could help explain the high-Fo compositions of olivine cores in the WUS OZ. Additionally, the effects of volatile and gas budgets within crystal mushes have been shown to affect their viscosity. CO₂ produced from dolostone assimilation may have reduced the viscosity of propagating crystal-rich magmas and thus facilitated hybridization (Pistone et al. 2013).

Differentiation model for the FCSC magmatic plumbing system

The evidence we have presented is consistent with a model whereby the FCSC OZ formed from a late injection of olivine-enriched magma that mixed with a resident, partly consolidated gabbroic mush. This olivine slurry was sourced from upstream in the FCSC, possibly from the UM feeder system. Multiple isotopic signatures are recorded within the FCSC. One potential explanation for this is that the olivine slurry replenishment was internally isotopically heterogeneous upon emplacement. The LPS DZ isotopic signature (Fig. 6) would represent the earliest pulse of magma into the FCSC and seem to record minor amounts of Archean basement or sedimentary rock contamination (Beard et al. submitted). This first event was then injected by an isotopically distinct olivine slurry. The isotopic signature of this second pulse is consistent with small amounts of dolostone assimilation (Fig. 6). In contrast, ~10 % dolostone assimilation appears to best explain the observed Pb-isotope compositions of the last major batch of magma emplaced into the FCSC (Beard et al. submitted) at the WUS (Fig. 6), where magma differentiated into an OZ/DZ couple after emplacement. The simplest explanation for these near-random shifts in radiogenic isotope composition is that they reflect differences in the types of host rock encountered and assimilated in transit. The field evidence suggests to us that contamination mostly occurred during transport of magma through fault-guided conduits populated by cataclastic breccias (Bédard et al. 2012). Even though magmas being injected into the system were isotopically heterogeneous, the extent of contamination was small, such that similar textural and petrological facies were developed at the WUS, PS, and LPS.

Olivine slurry replenishment appears to have been widespread in the Franklin plumbing system, since Type-1 olivine-enriched sills (Kat's, Dick's, and Uwe's sills) are common at the stratigraphic level where the FCSC was

Fig. 11 Schematic diagram illustrating the formation of the FCSC and the basal lava sequence of the Natkusiak flood basalts (NFB). *a* Deep (>3 km) holding sills or feeder conduits are fed by fresh batches of primitive melt from isotopically distinct mantle sources; *b* after initial residual magmas escape from the holding system, primitive olivine cumulates with equilibrium melts are left behind, and then are remobilized by melt replenishment events; *c* remobilized olivine slurries ascend along Neoproterozoic faults (arrows with squiggly contacts), where they assimilate brecciated dolostone; *d* olivine slurries are emplaced into the FCSC, which already hosts a partly crystallized gabbroic mush derived from an earlier magma pulse; *e* residual melts to the sills erupt at the surface if structures facilitate melt escape. The erupted melt forms the basal Natkusiak Fm lavas. If melts affected by dolostone assimilation were erupted, then significant quantities of CO₂ may have been released from degassing lava. *BI* Boot Inlet Formation, *FC* Fort Collinson Formation, *JB* Jago Bay Formation

emplaced. Kat's sill is similar to the WUS in that it shows isotopic equilibrium between OZ and DZ, as well as having isotopic signatures very similar to those of the WUS. Kat's sill is located just to the south of the FCSC (Fig. 1) and may represent another branch of the WUS-forming pulse. In contrast, Dick's and Uwe's sills both show OZ/DZ isotopic disequilibrium. These two sills would record different, non-unique sources and/or differentiation paths. As the OZ of Uwe's sill has similar radiogenic isotope and trace-element ratios to rocks from the WUS and Kat's sill, the magma from which Uwe's OZ accumulated may also have been affected by dolostone assimilation.

We present a model for the development of the FCSC olivine-enriched rocks in Fig. 11. The geochemical effects of olivine slurry replenishment and mixing with a resident gabbroic mush described above have implications for other systems where slurry emplacement has been inferred (e.g., Gibb and Henderson (2006); Bédard et al. (2007); Marsh (2013)). The isotopic constraints imply that the emplacement dynamics of these heterogeneous olivine slurry replenishment events are similar to the "braided sills"

differentiation model of the Torres Del Paine Mafic Complex in Patagonia (Leuthold et al. 2014). Our assimilation-replenishment scenario is also analogous to the Roelofse and Ashwal (2012) model proposed for the formation of the Main Zone of the Bushveld Complex. In their model, crustal contamination of crystal mushes occurred in sub-compartments of an underlying feeder system. A similar scenario may have operated beneath the FCSC at >3 km depth in the Franklin plumbing system. Olivine slurry replenishment may have also operated in other sills associated with rift-related LIPs, e.g., Palisades sill, Husch (1990), which is part of the Central Atlantic Magmatic Province. Ultimately, our documentation of lateral variations in the compositions of the olivine-enriched sills of the Minto Inlier provides insight into magma/crystal slurry flow directions. These have important implications for the evolution of magmatic plumbing systems, intra-sill mixing, and the search for economic Ni–S deposits.

Conclusion

The FCSC of the Franklin LIP extends for >50 km along strike, and its constituent sills are characterized by basal olivine-enriched layers (OZ) and capping gabbros (DZ). We investigated three sections through the FCSC. At its eastern end is the WUS, in the center is the P-sill (PS) and at its western end is the LPS. The FCSC OZ rocks exhibit a gradual westward shift toward more Fe-rich bulk compositions. Olivine cumulate arrays on Fe–Mg plots were used to define bulk crystal extracts and equilibrium melts. The predicted equilibrium PS and LPS olivine compositions only approximately match the olivine cargo they contain, however, suggesting excess olivine was added. We propose that the primitive olivine primocrysts within the FCSC OZ were derived from a replenishing olivine slurry, which was emplaced into and mixed with a partly crystalline gabbroic mush. Downstream propagation and hybridization between these two components can explain the westward Fe-enrichment trend in the FCSC OZ. Radiogenic isotope data suggest that there were at least three geochemically distinct pulses of magma in the FCSC. Isotopic signatures in the WUS can be explained by small amounts of dolostone assimilation, which buffers the melt Mg/Fe ratio enabling crystallization of the higher-Fo olivine that characterizes the WUS. In addition, clinopyroxene is preferentially stabilized on the liquidus ahead of plagioclase, and significant quantities of CO₂ are released during dolostone assimilation. The similarities between the FCSC and other olivine-enriched Franklin sills suggest that olivine slurry replenishment events are common, and that the olivine-rich slurries were able to propagate >50 km along strike in a thin sill.

Acknowledgments This study was supported by the Geomapping for Energy and Minerals (GEM) program, led by the Geological Survey of Canada. We greatly acknowledge all of the geologists involved in the mapping of Victoria Island during two summers in 2010 and 2011. Mapping and sampling by everyone involved contributed to the Victoria Island geochemical database. We particularly thank Dick Naslund and Kathryn Steigerwaldt for sampling the WUS section. We also thank Boswell Wing, Matthew Hryciuk, Marc Choquette, Iain McDonald, Ley Wooley, and Tony Oldroyd for their help with sample preparation and data collection. Comments by John MacLennan and Michel Houlé improved earlier versions. We are grateful for the thoughtful reviews of Othmar Müntener, Bruce Marsh, and an anonymous reviewer. Hayes was supported by a Natural Environment Research Centre (NERC) research studentship (Grant Number NE/152787X/1). This is NRCAN/ESS contribution 20140231.
