25 **Adapting feeding methods for less nitrogen pollution from pig and dairy**
26 **cattle farming: Abatement costs and uncertainties**

27 **Abstract**

28 This study assesses abatement costs of three measures aimed at reducing nitrogen (N)
29 emissions from livestock production: protein-adjusted feeding strategies for pigs, and
30 higher-quality forage for dairy cattle. In a partial cost approach, we quantified the effect of
31 different measures on N losses and production costs. We accounted for emissions of NH₃,
32 N₂O and NO from animal housing, manure storage, manure application, and from soils.
33 Uncertainties related to volatile prices and assumptions about excretion rates and emission
34 factors were assessed in a Monte Carlo simulation. Covering variability of individual input
35 parameters, this uncertainty assessment addresses a fundamental gap in current decision
36 support on N loss reduction measures. For the scenarios investigated, average N abatement
37 costs at farm level were negative and represented net benefits to farmers: In pig husbandry,
38 adapting feeding practices in most individual situations resulted in net benefits, both for
39 three-phase feeding [min -35, max +5, mean -14 €/kg N abated] and optimised single-phase
40 feeding [min -52, max +4, mean -21 €/kg N abated]. In dairy production, N abatement by
41 improved forage quality proved invariably more economic than current practice [min -40,
42 max -11, mean -21 €/kg N abated]. As shown in this study, N abatement costs can serve as a
43 framework for comparing the cost-effectiveness and feasibility of N loss reduction measures
44 within and between livestock production systems. This is in turn critical when informing
45 practitioners and providing policy support on workable strategies for reducing the N
46 footprint of animal husbandry.

48 efficiency (NUE), pig fattening, dairy forage

49 1. Introduction

1
2 50 Human influence on the global nitrogen (N) cycle is substantial, with agriculture as the
3
4
5 51 largest contributor. Reactive N refers to those chemical forms of N that are available to
6
7 52 plants and animals. Variable proportions of the reactive N used as fertiliser for feed crop
8
9
10 53 production are eventually released back into the environment during the storage and
11
12 54 decomposition of animal manures. Inefficient manure management practices and excessive
13
14
15 55 application rates increase emissions of reactive N, with a range of detrimental effects on
16
17 56 ecosystems, human health and global climate (Erisman et al. 2013; Fowler et al. 2013;
18
19
20 57 Galloway et al. 2004; Galloway et al. 2008). In response to these challenges, which apply
21
22
23 58 particularly to intensive, industrialized production systems, a broad range of measures has
24
25 59 been proposed for different agricultural sectors to become more nitrogen-efficient. In arable
26
27
28 60 farming, cover crops and optimised low-N fertilisation have proven effective at reducing N
29
30
31 61 losses (Dalgaard et al. 2014; Döhler et al. 2011; Newell Price et al. 2011; Reis et al. 2015). For
32
33 62 animal husbandry effective N loss reduction has been demonstrated for instance for
34
35
36 63 optimised livestock feeding and for improved manure management (i.e. removal, storage,
37
38 64 and spreading techniques) (Dalgaard et al. 2014; Döhler et al. 2011; Newell Price et al. 2011;
39
40
41 65 Reis et al. 2015; Rotz 2004). Animal nutrition has been highlighted as a priority area for
42
43
44 66 reducing environmental N pollution from livestock production (Aarnink and Verstegen 2007;
45
46 67 Klimont and Brink 2004). Increasing the N use efficiency (NUE) of common husbandry
47
48
49 68 systems by adapting feeding methods is therefore the focus of this paper.

50
51 69 In pig farming, feeding practices can be adapted to minimise N excretion and N losses from
52
53
54 70 manure management by phase feeding, i.e. adjusting feed composition according to the
55
56 71 pig's physiological needs at different growth stages; supplementing diets with limiting amino
57
58
59 72 acids; reducing crude protein intake; and shifting N excretion from urine to faeces by
60
61
62
63
64
65

73 adjusting feed composition (Aarnink and Verstegen 2007; Dourmad and Jondreville 2007;
1
2 74 Jongebreur et al. 2005; Nahm 2002; van Vuuren et al. 2015).

3
4 75 Under production conditions in industrialised countries, reducing N intake by dairy cattle has
5
6
7 76 the potential to decrease N excretion and N losses without compromising milk production
8
9
10 77 (Bittman et al. 2014; Powell 2014). One approach to reducing emissions of reactive N and
11
12 78 greenhouse gases (GHG) from dairy cattle farming is to increase milk yields to an extent that
13
14
15 79 outweighs additional N excretion. This can be achieved by enhancing the energy density of
16
17 80 the feed, e.g. through a higher content of grain-concentrates in compound feeds or higher-
18
19
20 81 quality forage (Gruber et al. 1999; Hörtenhuber et al. 2010; Ryan et al. 2011). However, the
21
22 82 effect of more concentrate might be partially counteracted by additional emissions from
23
24
25 83 soils and fertiliser use in the production of such feeds (Hörtenhuber et al. 2010). This
26
27 84 approach also raises questions regarding animal health as well as ethical concerns, since the
28
29
30 85 capacity of dairy cows to digest concentrates is limited, and using grains as livestock feed
31
32
33 86 rather than for human nutrition is questionable (Ertl et al. 2014; Hörtenhuber et al. 2011). To
34
35 87 address these concerns, Hörtenhuber et al. (2010) proposed to focus efforts on finding
36
37
38 88 alternative ways to improve the nutrient and energy density of forage. One measure which
39
40
41 89 can achieve this, while avoiding the dilemma of grain-based feeds, is to increase the number
42
43 90 of grass cuts per year (Gruber et al. 1999; Gruber and Pötsch 2006).

44
45 91 Using N inefficiently by excess feeding to livestock not only contributes to environmental
46
47
48 92 pollution via increased N excretion; expenses for surplus feed also unnecessarily increase
49
50
51 93 costs to farmers. Feed costs generally account for a large proportion of total costs of animal
52
53 94 production (Finneran et al. 2012; Powell et al. 2013). Many studies focus on possible
54
55
56 95 reductions of negative environmental effects, without consistently considering the economic
57
58
59 96 viability of those measures at farm level (Aarnink and Verstegen 2007; Dourmad and
60
61
62
63
64
65

97 Jondreville 2007; Nahm 2002; Ryan et al. 2011). Other studies analyse economic effects of
1
2 98 different feeding strategies and strive for economic optimisation, but lack detailed
3
4 99 discussion of environmental implications (Finneran et al. 2012; Marston et al. 2011; Niemi et
5
6
7 100 al. 2010; Vibart et al. 2012). Discussions which examine and synthesise both aspects, i.e. the
8
9
10 101 potential environmental benefits and the economic implications of different measures, are
11
12 102 scarce (see e.g. van Vuuren et al. (2015) who review the economics of low-N feeding
13
14
15 103 strategies). Such analyses, however, are vital for setting policy priorities: A given N
16
17 104 abatement measure will appear more attractive to farmers, and will thus more likely be
18
19
20 105 adopted, if there is evidence supporting its economic feasibility and benefits. On the other
21
22 106 hand, if the reduction of N emissions is not profitable for farmers under current conditions,
23
24
25 107 additional policy incentives (e.g. subsidies, support schemes) might be needed to increase
26
27 108 uptake.

29
30 109 The recently completed Austrian research project FarmClim - "Farming for a better climate"
31
32
33 110 (Amon et al. 2014) aimed to identify cost-effective and practical strategies for farmers to
34
35 111 increase the nitrogen-efficiency and to reduce the GHG emissions of their production
36
37
38 112 systems. Measures considered for animal husbandry included phase feeding for pigs,
39
40
41 113 improved dairy cattle diets, and anaerobic digestion of animal manures. For crop production,
42
43 114 increasing the use of legumes in crop rotations, and optimising fertiliser input were
44
45
46 115 addressed. In close collaboration between stakeholders (researchers as well as agricultural
47
48 116 institutions and extension services) agricultural measures were assessed and discussed from
49
50
51 117 different perspectives in a transdisciplinary and participatory process. The livestock part of
52
53 118 FarmClim focussed in particular on the situation of farmers, as a central aim was to provide
54
55
56 119 practical guidance at farm level.

120 The objective of the present paper is to assess farm-level N abatement potentials and costs
121 of three key measures developed for animal husbandry in the FarmClim project (Amon et al.
122 2014): optimised single phase feeding and three-phase feeding for pigs, and higher-quality
123 forage for dairy cattle. A Monte Carlo uncertainty analysis was conducted to account for
124 uncertainties due to volatility in demand and market prices as well as for variability in milk
125 yield, N excretion and N emissions. Reducing the dependency on specific assumptions of
126 input data, this uncertainty analysis enables the consideration of a broader range of
127 production characteristics. We first calculated partial gross margins per unit of product and
128 then derived changes in gross margins between different measures, by comparing additional
129 costs and benefits at farm level. In order to estimate average N abatement costs for each of
130 the measures, we assessed potential reductions in N excretion and in the subsequent
131 volatilisation of NH₃, N₂O and NO.

132 **2. Methods**

133 **2.1. Scope of analysis**

134 This study addresses exemplary, individual pig and dairy farms, aiming to provide
135 information for decision making in practice. Therefore cost analyses focus on private costs
136 and benefits for farmers. Calculating average abatement costs for specific measures, we did
137 not assess abatement potentials for the entire sector of agriculture nationally or
138 internationally. Furthermore, because individual farms are considered as price takers within
139 the market, complex market dynamics, such as the consequences of many farmers changing
140 their activities, were not accounted for within this study. Likewise, sectoral, national or
141 international developments and interactions are neglected. In line with this farm
142 perspective, only those emissions related directly to the farming practice were assessed (i.e.,
143 animal housing and manure management).

144 Based on some assumptions about principal production traits that are in line with EU
145 averages (see below for details), we were able to simulate a wide of range of production
146 situations by independently and simultaneously varying several input variables in a Monte
147 Carlo analysis (e.g. feed and product prices, N excretion rates, N emission factors). Data
148 were sourced from agricultural extension services and guidelines, such as: the Austrian
149 Federal Institute of Agricultural Economics (AWI 2015) for production traits and related
150 costs, national statistical information from Statistics Austria (2014) mainly for input and
151 output prices, and international guidelines for N excretion and emission factors (European
152 Environment Agency (EEA) 2013; IPCC 2006a). Specific data used can be found in Table A.3 in
153 the Annex. Additional input data were taken from the FarmClim project (Amon et al. 2014;
154 Moser et al. 2013), and were further processed as detailed in the subsequent section.

2.2. N abatement through optimised diets: Measures and data

Pigs. Phase feeding systems adjust the diet in several phases, rather than providing feed of
unchanged composition over the entire course of the fattening period. More specifically, the
supply of protein as the main source of dietary N is matched to the changing physiological
needs of the pig, thereby reducing excess supply and excretion of N. As the optimum dietary
protein concentration decreases during the growth of a pig, phase feeding reduces N
emissions without compromising growth performance (i.e. slaughter weight) (Dämmgen et
al. 2011; Pomar et al. 2014; van Vuuren et al. 2015).

Phase feeding systems usually require additional investment in feeding technology. Such
investment is only economically feasible for farms with a sufficiently long-term production
perspective and economies of scale in cost savings. For farms with shorter planning horizons,
optimisation measures that require upfront investment are often disproportionate to profit
margins and hence not an option. That situation is faced by many small farms across Europe;

168 especially family farmers may not know whether their operations will be continued after
169 their retirement. For such farms, a technologically simpler and more attractive option would
170 be to optimise the feed mix in a traditional single-phase feeding system by reducing the
171 overall protein content of the diet. This approach is generally less effective at reducing N
172 losses than phase feeding. Nevertheless, we included optimised single-phase feeding in this
173 analysis as it was the aim of our research to find N abatement methods that would be
174 workable more generally in Europe.

175 For both pig feeding methods, it is important to bear in mind that reduced protein intake
176 necessitates the supplementation of limiting essential amino acids. The resulting costs were
177 included in our calculations.

178 We analysed the following scenarios for pig fattening (Table 1):

- 179 • a single-phase feeding system as the reference case (REF_pig),
- 180 • an optimised single-phase feeding system with reduced dietary crude protein
181 content but supplementation of synthetic amino acids (S1_pig), and
- 182 • a three-phase feeding system with the same feed components as in S1_pig, with a
183 further reduction of crude protein content (S2_pig).

184 All three scenarios were based on a total feed intake of 254 kg per fattening pig and a
185 slaughter weight of 96 kg (AWI 2015). Thus, whereas the feed composition changes, the pigs'
186 performance level remains constant. The production system was further characterised by a
187 herd size of 450 fattening places with a turnover rate of 2.67, and an N excretion rate of 10.3
188 kg N per fattening place and year (AWI 2015; Umweltbundesamt 2014b). While this is based
189 on Austrian sources to maintain internal consistency, the basic characteristics are in line with
190 average EU values (see table A.1 in the Annex for information on N excretion and slaughter
191 weight).

192 [Insert Table 1 here]

1
2 193 **Dairy cattle.** Forage quality can be improved by cutting grassland more frequently (Gruber et
3
4 194 al. 1999). This results in a lower total dry matter yield of the cut grass, but at the same time
5
6
7 195 increases forage intake, digestibility and protein content (Gruber et al. 1999; Gruber and
8
9
10 196 Pötsch 2006). The higher protein content leads to increases in total N intake and N
11
12 197 excretion, which seems to counteract the intended reduction of N losses at first sight.
13
14
15 198 However, the larger amount of energy provided by higher-quality forage supports higher
16
17 199 milk yields, and thereby reduces N excretion per kg milk produced (Ertl et al. 2014;
18
19
20 200 Steinwider and Guggenberger 2003). For dairy cattle, we analysed two feeding options: a
21
22 201 reference case (REF_milk) with medium-quality forage from three grass cuts per year and a
23
24
25 202 mixture of concentrate feed; and a scenario with high-quality forage (S_milk), where the
26
27 203 frequency of grass cuts was increased to four. This results in a higher intake of grass-silage
28
29
30 204 and hay. Due to the conceptual assumption of a constant share of each forage component in
31
32
33 205 the total diet (i.e., 65% grass silage, 20% maize silage, 15% hay), intake of maize silage is also
34
35 206 increased. In addition, S_milk included the same ration of concentrate feed as REF_milk (see
36
37
38 207 Table 2). In contrast to the pig scenarios, both feed intake and performance (i.e., milk yield)
39
40
41 208 are affected by the measure. We assumed predominantly grass-based diets with limited
42
43 209 supplementation of concentrate feed, and local climatic conditions that allow for frequent
44
45
46 210 grass-cutting and correspondingly high forage quality. We assumed baseline milk yield (6500
47
48 211 kg/cow/year) and N excretion (100 kg N/cow/year) to correspond to the EU-28 average
49
50
51 212 (6538 kg milk/cow/year and 108.07 kg N/cow/year, respectively; see Table A.2 in the Annex
52
53
54 213 for country data). Our calculation of attainable milk yield was based on following
55
56 214 assumptions: From their diet, dairy cattle need to obtain 13 870 MJ worth of net energy for
57
58
59 215 lactation (NEL) for maintenance, and an additional 700 MJ NEL during the preparation phase
60
61
62
63
64
65

216 for lactation. That latter phase hence requires a more energy-dense diet, i.e. one with a
217 larger concentrate component. Any further energy intake is available for milk production,
218 where 3.3 MJ NEL are required for each kg of milk produced (AWI 2015).

219 [Insert Table 2 here]

220 **2.3. Nitrogen abatement**

221 Nitrogen abatement is defined as the total amount of N emissions that can be avoided by
222 implementing a given measure, in comparison to the reference case. To quantify these
223 “avoided losses” of N to the environment, emissions of ammonia (NH₃), nitrous oxide (N₂O)
224 and nitric oxide (NO) were derived from N excretion rates and emission factors. Thus, the
225 terms “N emission” (or “N losses”) and “N abated” in this paper always refer to the sum of
226 emissions of these three N species. Emission sources considered here were animal housing
227 and manure management (storage and application to land including direct emissions from
228 soil) (IPCC 2006a). The analysis hence incorporated the entire chain of N emissions which
229 arise from livestock production and which are directly attributable to individual farms.
230 Upstream effects, e.g. of feed or fuel production, which would typically be included in life
231 cycle analyses (LCA), were not considered in this study.

232 N emissions for both reference cases (REF_pig and REF_milk), as given in Table A.3 in the
233 Annex, were based on excretion rates and emission factors from Austria’s national emission
234 inventory reports (Umweltbundesamt 2014a, 2014b), on a regression model predicting dairy
235 cow excretion (Gruber et al. 1999), and on international guidance documents (European
236 Environment Agency (EEA) 2013, IPCC 2006a, 2006b). Our calculations further assumed the
237 use of a liquid slurry system for manure management in all scenarios.

238 The reduction of ammonia emissions due to adjustments in feeding methods has been
239 assessed in a range of experimental studies (Aarnink and Verstegen 2007; Dämmgen et al.

240 2011; Dourmad and Jondreville 2007; Pomar et al. 2014). Those studies provide a valuable
1
2 241 baseline. However, due to the number of variables and lack of standards for experimental
3
4 242 conditions, results are often only valid for very specific technical and geographical contexts.
5
6
7 243 This unfortunately limits the extent to which those empirical studies can inform policy and
8
9
10 244 practice elsewhere. For the same reasons, our calculations did not draw upon results from
11
12 245 individual experimental studies. We instead took a simplified approach for approximating
13
14
15 246 the change in N excretion:
16
17 247 For pigs, the reduction in N excretion can be derived from simple N balance considerations:
18
19
20 248 When excess N supply in pig fattening diets is reduced (as described above), a given
21
22 249 decrease in protein intake directly translates into a corresponding decrease in N excretion
23
24
25 250 (Kornegay and Harper 1997). N emissions then decline accordingly, as they are calculated as
26
27
28 251 percentages of N excretion.
29
30 252 In dairy systems, estimating N abatement is more complex: When milk yield is increased by
31
32
33 253 raising the protein density of the diet, this inherently also increases N excretion. However, it
34
35 254 is generally assumed that the resulting increase in N emissions is outweighed by the higher
36
37
38 255 milk yields. National inventory reports (Umweltbundesamt 2014b) for instance estimate N
39
40
41 256 emissions with a linear function, where N excretion exclusively depends upon milk yields. In
42
43 257 reality, N excretion however also depends, among other factors, on the protein content of
44
45
46 258 the diet (Gruber and Pötsch 2006; Pötsch 2006). Gruber et al. (1999) have developed a more
47
48
49 259 detailed regression model, which predicts manure N concentrations and N excretion of dairy
50
51 260 cows, based on forage and concentrate intake and on the corresponding crude protein and
52
53
54 261 energy content of the diet. Their model was used here to estimate N excretion more
55
56 262 accurately (Eq.1) (Gruber et al. 1999):

$$Ec_N = -0.6 + 0.106(IF * XP_F) + 1.153(IC * NEL_C) + 0.0605(XP_T * NEL_T) \quad (\text{Eq.1})$$

263 where: EC_N = excretion of N per cow (g/day); IF = intake of forage (kg DM); IC = intake of concentrate (kg DM);
1 264 XP_F , XP_T = crude protein concentration of forage and total ration (g/kg DM); NEL_C , NEL_T = energy concentration
2
3 265 of the concentrate and total ration (MJ/kg DM)
4
5

6 266 **2.4. Cost calculation**

7
8
9 267 When comparing the economic feasibility of different management practices, the most
10
11 268 relevant changes in costs and benefits are those that directly result from the implementation
12
13 269 of the measures in question. Standard costs of equipment, etc., can thus be omitted if they
14
15 270 are constant (Rejesus and Hornbaker 1999; Ryan 2005). This simplifies the calculation and
16
17 271 eliminates a source of bias and uncertainty, without compromising the validity and
18
19 272 explanatory power of the results. While this partial cost approach has been criticised
20
21 273 (Finneran et al. 2012), it is appropriate for the study at hand, as the purpose here was to
22
23 274 assess costs and benefits of N abatement in relation to a certain reference situation, rather
24
25 275 than determine general farm profitability, for which full cost accounting would have been
26
27 276 required. In this vein, we did not quantify opportunity, follow-up or indirect costs and
28
29 277 interactions, which are important elements for overall farm profitability assessments, but
30
31 278 are not generally considered in gross margin calculations.
32
33
34
35
36
37

38 279 To reflect the private costs and benefits of different N abatement measures at farm level, we
39
40 280 calculated partial gross margins (PGM) per unit of product, i.e. per kg meat or milk, for each
41
42 281 feeding scenario. PGM was defined as revenues minus costs of production per unit sold.
43
44 282 (*N.B.*: Costs must be directly related to the abatement measure). Partial gross margins hence
45
46 283 represent the revenues available for covering the remaining costs which were unaffected by
47
48 284 the measure, and to generate profit. The following costs were included: costs of the feed
49
50 285 components, investment in phase feeding systems for S2_pig, and additional costs due to
51
52 286 more frequent cutting for S_milk. These latter costs have been incorporated in the costs of
53
54 287 forage provision and encompass seeds, fertilizer, crop protection, variable machinery costs,
55
56
57
58
59
60
61
62
63

65

288 and labour costs. Revenues came from selling pork and milk at market prices. We ignored
 289 potential grants, subsidies, and any costs not practically related to the N abatement
 290 measures. Table A.3 in the Annex lists the specific data and references used, and equations 2
 291 and 3 outline the calculation of gross margins for pig and milk production, respectively.

$$\pi_{pig} = \frac{1}{W} (p_{pig} * W - \sum p_{fi} * F_i - c_{invest}) \quad (Eq.2)$$

292 Where: π_{pig} = partial gross margin per kg pork [€/kg]; W = slaughter weight of pig [kg]; p_{pig} = price of pork
 293 [€/kg]; p_{fi} = price of feed component i [€/kg]; F_i = intake of feed component i [kg/pig/year]; c_{invest} = investment
 294 cost, including costs of capital and depreciation per pig [€/pig/year].

$$\pi_{milk} = \frac{1}{M} (p_{milk} * M - \sum p_{fi} * F_i) \quad (Eq.3)$$

295 Where: π_{milk} = partial gross margin per kg milk [€/kg]; M = milk yield [kg/cow/year]; p_{milk} = price of milk [€/kg];
 296 p_{fi} = price of feed component i [€/kg]; F_i = intake of feed component i [kg/cow/year];

297
 298 To derive average N abatement costs (AC), we calculated the differences in N losses and
 299 partial gross margins between the respective scenario and the reference case. Average
 300 abatement costs were then expressed as the difference in partial gross margin per kg N
 301 abated, compared to REF (equation 4). In this step, all costs and subsidies related to
 302 production in general (rather than to the specific measures) would cancel out; we therefore
 303 considered a detailed assessment of these aspects unnecessary. Commonly used in relevant
 304 literature for assessing individual abatement options (Bittman et al. 2014; Rößler et al. 2012;
 305 Van Vuuren et al. 2015), this measure of average on-farm abatement costs considers the
 306 implementation of one specific measure as a fixed “package” that results in a certain
 307 amount of emission reduction, rather than assuming that farmers gradually adjust their
 308 abatement efforts. In contrast, marginal abatement costs, which are the costs of abating one
 309 additional unit of emissions starting from a certain level, are used in national or sector
 310 economic analyses and to inform policymaking. For instance, marginal abatement cost

311 curves can help to determine economically optimal levels of abatement, and are used for
1
2 312 merit order ranking of different abatement measures (De Cara and Jayet 2011; Eory et al.
3
4 313 2013).

5
6
7 314 To account for interactions and co-benefits of simultaneously reducing NH₃, N₂O, and even
8
9 315 NO, the measure of abatement costs basically refers to the sum of these N species.
10
11 316 However, for reasons of comparability with other studies, separate AC for NH₃, N₂O and NO
12
13 317 are indicated additionally. As the costs cannot reliably be attributed to different N species,
14
15 318 these AC were derived by allocating all costs of the measures to each type of N emissions
16
17 319 and thus contain considerable double counting of costs.

$$AC_i = \frac{\pi_i - \pi_{REF}}{N_{LOSS_i} - N_{LOSS_{REF}}} \quad (Eq.4)$$

21
22
23
24
25
26 320 Where: AC_i = abatement cost for scenario i [€/kg N]; π_{i, REF} = partial gross margin in scenario i and the reference
27
28 321 case, respectively ([€/kg pork] and [€/kg milk], respectively); N_{LOSS_{i, REF}} = N losses in scenario i and the
29
30 322 reference case, respectively ([kg N/kg pork] and [kg N/kg milk], respectively).

36 324 **2.5. Uncertainty analysis**

37
38
39 325 The parameters and assumptions first used to develop deterministic baselines (see section
40
41 326 2.4) are in reality linked with uncertainties, such as price fluctuations and variation in
42
43 327 livestock performance and physiological characteristics (milk yield, N excretion).
44
45 328 Furthermore, the uncertainty of N emission factors needs to be accounted for, as the exact
46
47 329 amount of N emitted depends on a broad set of influencing factors and management
48
49 330 practices.

50
51
52 331 To take these uncertainty aspects into consideration, we conducted a Monte Carlo
53
54 332 uncertainty analysis. Monte Carlo analysis is a stochastic technique that uses random
55
56 333 numbers and probability statistics to evaluate uncertain outcomes. More specifically, a
57
58
59
60
61
62
63
64
65

334 randomly selected set of input values for uncertain parameters is fed into the simulation to
1
2 335 derive related outputs. This procedure is repeated for numerous iterations (in our case
3
4 336 10 000), and finally allows to estimate output uncertainty by mapping the results as new
5
6
7 337 output-probability distribution functions (Benke et al. 2007; Bergsdal et al. 2007). By
8
9
10 338 introducing statistical distributions for uncertain and variable input parameters, Monte Carlo
11
12 339 analysis reduces the dependency on single point estimates and assumptions (Bergsdal et al.
13
14
15 340 2007; Evans et al. 2007). To define these probability distribution functions (pdf's) for the
16
17 341 market prices of pork, milk, barley, wheat, soybean meal and rapeseed meal, monthly prices
18
19
20 342 from 2000 to 2010 were adjusted by the price index of animal and plant-based agricultural
21
22 343 products, respectively (LKÖ 2013). This correction removed the deterministic element of the
23
24
25 344 variation in prices, i.e. inflation, and only considered stochastic variation (see also Finneran
26
27
28 345 et al. (2012), who used a more complex approach). Most of the price distributions did not
29
30 346 meet all criteria for normal distribution. We therefore modelled the prices with continuous
31
32
33 347 triangular distributions, based on the minimum, maximum and mode values of the index-
34
35 348 adjusted monthly prices. A continuous triangular probability distribution was also assumed
36
37
38 349 for the other stochastic variables (other feed components, investment cost, forage quality,
39
40
41 350 milk yield, N excretion and emission factors), where no larger data sets or longer time series
42
43 351 were available. Using triangular distributions to estimate probabilities under such data
44
45
46 352 constraints is common practice (Evans et al. 2007), and has also been used for estimating
47
48
49 353 emission factors (Lovett et al. 2008; Zehetmeier et al. 2014). The specific probability
50
51 354 distribution functions used in our analysis, and the corresponding data sources, are
52
53 355 summarised in Table A.3 in the Annex.

56 356 **Correlations.** Correlations need to be defined in order to avoid illogical and unrealistic
57
58
59 357 combinations of the randomly selected input values, which would distort the results. This

358 serves to ensure that differences in model outputs between scenarios can be attributed to
1
2 359 the examined N abatement measures, and not to randomly introduced biases through the
3
4 360 simulation. For example, a cow with the physiological potential for a relatively high milk yield
5
6
7 361 in the reference case must not be compared to a cow with a relatively low potential in the
8
9
10 362 scenario. Due to large data sets available, specific mutual correlations could be determined
11
12 363 between the prices of the feed inputs barley, soy, rape, wheat and plant oil, as well as pig
13
14
15 364 and milk prices; all correlations with a significance level of 0.01 were used. For other
16
17 365 variables, where testable data series were unavailable, correlations were purely based on
18
19
20 366 logical connections. This applied to: N excretion rates for pig and dairy (correlation between
21
22 367 reference case and scenarios), provision costs of grass and hay and attainable milk yield
23
24
25 368 (reference case and scenario). All correlations used for the simulation can be found in Table
26
27
28 369 A.4 in the Annex.

31 370 **3. Results**

32
33
34 371 The baseline calculations drew on literature data and yielded deterministic estimates of
35
36 372 partial gross margins and N abatement. The uncertainty analysis, by contrast, generated
37
38
39 373 estimates of the probability to arrive at a particular outcome, i.e. at a given profit margin or
40
41
42 374 N loss. When presented as a cumulative distribution, probabilities can be specified for a
43
44 375 given outcome, e.g. how likely it is for a certain margin or N loss to be exceeded.

45
46 376 **Partial gross margins (PGM).** For both pig and dairy farming, the proposed N abatement
47
48
49 377 measures increased PGM compared to both reference scenarios. For pigs, optimised single-
50
51
52 378 phase and three-phase feeding surpassed the baseline of 1.19 €/kg meat by 3.4 and 4.2
53
54 379 percent, at 1.23 and 1.24 €/kg, respectively. In milk production, improved forage quality
55
56
57 380 yielded a PGM of 0.28 €/kg, exceeding the baseline of 0.25 €/kg milk by 12 percent.

381 The cumulative probabilities of partial gross margins show that, even when allowing for
1
2 382 considerable uncertainty in production costs and markets, the proposed abatement
3
4 383 measures are economically preferable to the reference cases, and that farmers are highly
5
6
7 384 likely to benefit from implementing them (Fig. 1). For the two pig feeding scenarios, PGM is
8
9
10 385 almost identical; the probability is only 0.43 for S1_pig and 0.42 for S2_pig, respectively, that
11
12 386 the gross margin is smaller than the baseline value of 1.19 €/kg meat. In the REF case, this
13
14
15 387 probability is 0.51 (in a slightly skewed pdf with a median below the mean value). The PGM
16
17 388 for improving dairy forage quality (S_milk) has a probability of only 0.26 to be below the
18
19
20 389 baseline value of 0.25 €/kg milk; this is more likely to happen for the REF scenario, with a
21
22 390 probability of 0.51.

25 391 These results indicate that all considered measures make economic sense. Feeding
26
27 392 adjustments for pigs reduce the expensive protein components in the diet, which outweighs
28
29
30 393 the costs of investment and additional feed components such as synthetic amino acids and
31
32
33 394 plant oil. Higher milk yields of dairy cows compensate for increased feed provision costs
34
35 395 when enhancing forage quality.

38 396 **N losses.** Comparing the likely N losses of the reference cases with those of the scenarios
39
40 397 (Fig. 2) shows that the proposed feeding methods reduce N losses in most cases, and thus
41
42
43 398 effectively abate N emissions (NH₃, N₂O and NO). Under all simulated production conditions,
44
45
46 399 phase feeding for pigs (S2_pigs) is likely to abate more N emissions than the optimised single
47
48 400 feed mix (S1_pig) (Fig. 2a). Higher-quality forage for dairy cows increases the total amount of
49
50
51 401 N excretion and emissions per cow. These losses are however outweighed by an increase in
52
53 402 milk yields, thereby increasing overall nitrogen-efficiency (Fig. 2b).

56 403 [Insert Fig 1 here]

59 404 [Insert Fig 2 here]

405 **Abatement costs (AC)** are negative under nearly all simulated production conditions (Table 3
1
2 406 and Fig. 3). For both pig scenarios, the probability of a negative AC is close to 1. In other
3
4 407 words, the chance that an individual farmer is burdened with actual costs when
5
6
7 408 implementing the measures is 0.1% in S2_pig, and even less in S1_pig. Both AC distributions
8
9
10 409 have a similar degree of dispersion, and are between -52 and +4 €/kg N, for S1_pig and
11
12 410 between -35 and +5 €/kg N for S2_pig (Table 3). Thus, while S1_pig offers a slight economic
13
14 411 advantage, S2_pig is more effective at reducing N losses (see above). Investment costs do
15
16
17 412 not play a decisive role here. They range from 0.52 €/pig in the baseline calculation (based
18
19
20 413 on initial investments of € 7500) to a maximum of 2.09 €/pig (based on an investment of
21
22 414 30,000 €). The maximum investment would still only reduce the PGM from 1.24 to 1.22 €/kg
23
24
25 415 meat, considering a depreciation time of 15 years.

26
27 416 For milk production, the situation is even more evident as the Monte Carlo analysis shows
28
29
30 417 no cases with abatement costs above 0, and the AC probability distribution is less strongly
31
32
33 418 dispersed than the respective distributions of the pig measures. Thus, it is very likely that the
34
35 419 implementation of the measures is beneficial for each individual farmer. Abatement costs
36
37
38 420 are of the same order of magnitude as for the pig measures (mean -21 €/kg N, Table 3). The
39
40
41 421 economic feasibility of the dairy measure clearly depends on the increase in milk yield that is
42
43 422 required to offset both the additional feeding costs and the additional N excretion per cow.
44
45
46 423 With an average milk yield increase of 463 kg/cow/year (min 197, max 866, SD 113), the
47
48
49 424 same gross margin per cow as in the reference can be maintained.

50
51 425 At first sight, S1_pig might seem preferable to S2_pig, due to its higher cost savings per kg N
52
53
54 426 abated. However, it is also important to consider absolute differences at farm level, as is
55
56 427 demonstrated by the baseline calculations: S1_pig generates roughly 5000 € of additional
57
58
59 428 gross margin and abates 250 kg N, whereas S2_pig generates an additional 6600 € and
60
61
62
63
64
65

429 abates 440 kg N. A farmer aiming to maximise profits would opt for S2_pig, which offers
1
2 430 both more economic benefits and more N abatement.

3
4 431 As NH₃ abatement accounts for the largest share (95% of N abated), NH₃-N abatement costs
5
6
7 432 almost correspond to AC_{total}. Conversely, although N₂O and NO abatement appears
8
9
10 433 extremely beneficial for farmers in this way of presentation, it has to be considered that the
11
12 434 total amount of avoided emissions is small.

13
14
15 435 [Insert Table 3 here]

16
17 436 [Insert Fig 3 here]

20 21 437 **4. Discussion**

22
23 438 Our results clearly demonstrate that measures to increase the N use efficiency of livestock
24
25
26 439 production can simultaneously confer both economic and environmental benefit. Even
27
28
29 440 without consideration of environmental benefits, the economic benefits presented here
30
31
32 441 provide a reliable incentive for farmers to implement the measures. The link between these
33
34 442 objectives, and the obvious incentive to minimise N losses, is the economic value of N in
35
36
37 443 animal nutrition. At the farm level, this is reflected in negative average N abatement costs
38
39 444 for the proposed N-efficient feeding methods (mean values of -21.2 €/kg N abated for
40
41
42 445 S1_pig, -13.6 for S2_pig, -21.0 for S_milk); adopting these methods would reliably increase
43
44 446 farmers' margins, even in the face of considerable uncertainties in production costs and
45
46
47 447 product markets. Although the existence of negative abatement costs (i.e., "win-win"
48
49
50 448 situations) for certain measures is well known, adoption rates are not always as high as
51
52 449 would be expected (Glenk et al. 2014; MacLeod et al. 2010). We discuss this in more detail
53
54
55 450 below.

56
57 451 Our estimates of economic gains are higher than those by Bittman et al. (2014) who
58
59
60 452 estimated NH₃ abatement costs of low-protein feeding strategies between -2 and +2 € per kg

453 NH₃-N saved. However, due to large differences in costs and emissions, both between
1
2 454 European countries and between animal categories, that estimate remains fairly rough –
3
4 455 especially as the authors did not define a specific reference situation. Rößler et al. (2012)
5
6
7 456 calculated abatement costs for pig feeding measures in Germany in a range of -11.4 to -
8
9
10 457 16.5 € per kg NH₃-N saved, depending on the reference case and size of the farm, which is
11
12 458 close to the results presented here (values have been converted from €/kg NH₃ to €/kg NH₃-
13
14
15 459 N by multiplying by a factor of 17/14). Van Vuuren et al. (2015) estimated changes in pig
16
17 460 production costs between -2.4 and +7.3 € per kg NH₃-N reduced, and costs of up to +75.3 €
18
19
20 461 per kg NH₃-N when not supplementing synthetic amino acids. The authors found that, similar
21
22 462 to pigs, low-N feeding strategies for dairy cows may induce net benefits or costs (abatement
23
24
25 463 costs of -1.70 to +7.3 € per kg NH₃-N) (van Vuuren et al. 2015). However, in contrast to the
26
27
28 464 present study, those studies only accounted for ammonia abatement. While NH₃ contributes
29
30 465 the largest share of gaseous agricultural N emissions, N₂O and NO emissions from manure
31
32
33 466 management and soils should also be considered for a more complete analysis. The data
34
35 467 from such assessments can then also be used to identify trade-offs and synergies between
36
37
38 468 mitigating N pollution and climate change. For instance, increasing milk yields has not only
39
40
41 469 been recognised as an effective measure to abate N but also to reduce methane emissions
42
43 470 from dairy production (Yan et al. 2010).

45
46 471 **Sensitivities.** In modelling N abatement costs, algorithms govern the effect of a given
47
48 472 uncertainty in the input parameters on the uncertainty of the corresponding outputs. When
49
50
51 473 interpreting simulation results, the following characteristics determine the influence of an
52
53 474 input term to the overall outputs: (i) for multiplicative terms, input uncertainty is directly
54
55
56 475 transferred to the output, such that factors with larger uncertainty contribute to overall
57
58
59 476 uncertainty directly depending on their relative magnitude (i.e., in %). With most input

477 factors having been assigned similar uncertainty factors (see Table A.3) these influences are
1
2 478 similar for most parameters. In the algorithms used in this study, terms are mostly linked up
3
4 479 by multiplication. (ii) Abatement cost calculation compares results of a given scenario with
5
6
7 480 that of the reference case. Both elements are derived using a very similar approach and
8
9
10 481 identical inputs, so that a differentiation of contributing factors is not possible. (iii) As
11
12 482 investment costs per pig are small, their uncertainty does not markedly affect the results.
13
14
15 483 Similarly, the uncertainties of meat/milk prices are much smaller than those of prices for
16
17 484 feed ingredients and mixtures, and thus of lower importance for the uncertainty of results.
18
19
20 485 In consequence, the uncertainties in feed prices and N excretion (implemented as
21
22 486 multiplicative terms) have the greatest effect on the overall output uncertainties. Due to the
23
24
25 487 importance of correlation between the individual input parameters, it is not possible to
26
27
28 488 further differentiate these parameters and their specific impact on the overall results.

30 489 **Economic rationale and decision-making.** A set of assumptions has been used to construct
31
32
33 490 specific measures and simulate the financial and environmental effects of their
34
35 491 implementation. The assumption here was that farmers will make a “yes or no”-decision
36
37
38 492 based on whether the proposed measure is economically beneficial for their operation.
39
40
41 493 Other approaches (such as linear programming or nonlinear optimisation) mostly come from
42
43 494 economics and aim to maximise profitability or return of capital by optimising production
44
45
46 495 parameters under given constraints and market conditions (Morel et al. 2012; Niemi et al.
47
48 496 2010). Economic risks related to market price fluctuations and uncertainties might help
49
50
51 497 explain why (risk-averse) farmers hesitate to implement measures which follow this
52
53
54 498 rationale (Finneran et al. 2012). It is therefore important to look beyond purely economic
55
56 499 factors and realise that farmers act in a complex socio-ecological system: Although they
57
58
59 500 need to maintain their farms’ profitability and thus adopt an economic rationale to some

501 extent, farms are more than just businesses; their production possibilities, and their actual
1
2 502 production and income are highly dependent on natural resources, geographic location,
3
4 503 weather and climate, and they face many risks and variabilities. Furthermore, besides food
5
6
7 504 production, agriculture fulfils multiple functions and responsibilities, such as the
8
9
10 505 maintenance of cultural landscape, biodiversity and ecosystem functions (Rossing et al.
11
12 506 2007). In this sense, Feola and Binder (2010) emphasise the need to consider the complex,
13
14
15 507 multi-scale and multi-level nature of agricultural systems when formulating pertinent
16
17 508 concepts and integrative models. Achieving economic objectives is most likely not the
18
19
20 509 farmers' only motivation and cause for action, as is shown by sometimes low adoption rates
21
22 510 despite negative abatement costs for certain measures (Glenk et al. 2014). This points to the
23
24
25 511 existence of non-financial barriers and motivating factors that drive farmers' behaviour, such
26
27
28 512 as age, education and experience of the farmers as well as social aspects including attitudes
29
30 513 and perceptions, social norms and context, imitation of others, or role models (Barnes and
31
32
33 514 Toma 2011; Feola and Binder 2010; Glenk et al. 2014). Furthermore, consumer demand or
34
35 515 farm specific constraints such as the suitability and availability of surrounding land, labour
36
37
38 516 constraints or access to technology can play a role (Glenk et al. 2014). A growing body of
39
40
41 517 literature examines such behavioural aspects of decision-making processes, in several cases
42
43 518 applying agent-based modelling (Feola and Binder 2010; Reise et al. 2012; Skevas et al.
44
45
46 519 2012). Nevertheless, economic viability and profitability of N abatement measures, as
47
48
49 520 assessed in the present study, appear as important starting points. They are necessary for
50
51 521 developing sustainable emission reduction strategies, but probably insufficient as sole
52
53
54 522 incentive for farmers to take action and adopt new (feeding) practices. Further research into
55
56 523 farmers' decision-making and perception of N reduction measures will thus be indispensable
57
58
59 524 to enhance implementation.

525 **5. Conclusion**

1
2 526 Integrating economic and environmental aspects, we assessed the potential of three
3
4
5 527 different animal feeding measures to make livestock farming more N-efficient – two
6
7 528 measures for fattening pigs, and one for dairy cattle. Results show that those measures are
8
9
10 529 economically beneficial for farmers and at the same time effectively reduce N losses to the
11
12 530 environment. Optimised single-phase feeding and three-phase feeding for pigs reduce
13
14
15 531 expensive protein components in the diet, which outweighs the costs connected with the
16
17 532 two measures. Improving the quality of dairy forage distinctly increases milk yields and
18
19
20 533 thereby compensates for increased N excretion and forage provision costs. The dairy
21
22 534 measure and the optimised single-phase feeding for pigs can be adopted by farmers without
23
24
25 535 needing to commit to long-term investment costs. As N loss is lower and partial gross
26
27
28 536 margins higher for all cases for the three-phase feeding for pigs, extension services and
29
30 537 policy should advise those farmers who know that their farming operation will be continued
31
32
33 538 to invest in this technology. This is particularly relevant when the farmer is already planning
34
35
36 539 to add or modify pig housing, as feeding equipment could be installed more cheaply in
37
38 540 conjunction with other construction measures.

40
41 541 A Monte Carlo uncertainty analysis revealed that the generally positive conclusion not only
42
43 542 holds for a point-estimate based on specific assumptions, but is also robust to possible
44
45
46 543 market fluctuations, different physiological conditions of the livestock and variability in
47
48
49 544 emission factors. Thus, the results are not limited to one specific single case based on static
50
51 545 assumptions. The simulation results further confirm the effectiveness and wide applicability
52
53
54 546 of the proposed N abatement measures, despite production conditions placing some
55
56 547 restrictions on the choices available. By investigating measures related to both pig and dairy
57
58
59 548 production in one study, we illustrated that N abatement costs (or, in this case, abatement

549 benefits) can be comparable between husbandry systems. This also clearly shows that there
1
2 550 is scope for simultaneous action in several fields. The approach used in this study can be
3
4 551 applied to a range of situations, where the feasibility and effectiveness of implementing
5
6
7 552 proposed measures in agriculture needs to be assessed, and communicated. Enhancing the
8
9
10 553 adoption of these measures, however, will require more insights into farmers' decision-
11
12 554 making behaviour and potential non-financial barriers to implementation as a prerequisite
13
14
15 555 to develop specific policies. In the further debate on this topic, closer attention should be
16
17 556 paid to specific background conditions under which farmers operate, such as the EU
18
19
20 557 Common Agricultural Policy (CAP) and related grants and subsidies. Those policy instruments
21
22 558 can provide further leverage for the introduction of agricultural measures and help bridge
23
24
25 559 the science-policy gap, even in cases where measures are not *per se* profitable under current
26
27
28 560 market conditions, but desired and valued politically. Ultimately, evidence-based guidance
29
30
31 561 for individual farms needs to be part of a broader strategy to minimise external costs and to
32
33 562 maximise environmental benefits for society as a whole.

764 **Tables**765 **Table 1: Pig phase feeding – Scenario assumptions**

Pigs: phase feeding	Reference scenario (REF_pig)	Scenario 1 (S1_pig)	Scenario 2 (S2_pig)
	Single-phase feeding	Optimised single-phase feeding	3-phase feeding
Feed components [kg/fattening pig]			
<i>Barley</i>	63.5	127	127
<i>Soybean meal 44% XP</i>	50.8	40.64	31.07
<i>Wheat</i>	132.08	78.232	88.84
<i>Minerals</i>	7.62	5.08	4.74
<i>Plant oil</i>	0	2.54	1.83
<i>L-Lysine HCL</i>	0	0.508	0.508
Total [kg/fattening pig]	254	254	254
Average crude protein content [%]	19.0%	17.7%	16.6%
Additional investment [€] (depreciated over 15 years)	-	-	7500
Slaughter weight [kg/fattening pig]	96		
Fattening places per farm	450		
Turnover rate	2.67		
N excretion [kg N/fattening pig]	3.86	3.29	2.85
Sources	Feed components: AWI 2015 (REF); Roth et al. 2011 (S1, S2) Protein contents: Dämmgen et al. 2011 Other production traits: AWI 2015 N excretion: Umweltbundesamt 2014b (REF), calc. (S1, S2)		

766

767

768 **Table 2: Dairy cattle forage quality – Scenario assumptions**

Dairy: forage quality	Reference scenario (REF_milk)		Scenario (S_milk)	
Forage quality	Medium		High	
Forage	Intake [dt DM/cow/year]	Quality [MJ NEL/kg DM]	Intake [dt DM/cow/year]	Quality [MJ NEL/kg DM]
<i>Grass-silage</i>	26.1	5.9	35.6	6.3
<i>Maize-silage</i>	8.0	6.7	11.0	6.7
<i>Hay</i>	6.0	5.2	8.2	5.5
Concentrate feed	intake [kg DM/cow/year]	quality [MJ NEL/kg DM]	intake [kg DM/cow/year]	quality [MJ NEL/kg DM]
<i>Barley</i>	452.6	8.07	452.6	8.07
<i>Soybean meal</i>	302.95	8.60	302.95	8.60
<i>Rapeseed meal</i>	302.95	7.20	302.95	7.20
<i>Dairy compound feed</i>	452.6	8.05	452.6	8.05
Total energy intake [MJ NEL/cow/year]	35 991		46 355	
Milk yield total [kg/cow/year]	6491		9632	
Milk for calves [kg/cow/year]	300		300	
Milk yield available for sale [kg/cow/year]	6191		9332	
N excretion [kg N/animal*year]	98.82		119.74	
Sources	Feed intake: FarmClim (Moser et al 2013), AWI 2015 Feed quality: AWI 2015; Hörtenhuber et al. 2010; DLG 2015, Resch 2007 Milk yield: calculated based on AWI 2015 N excretion: calc. based on Gruber et al. 1999

771 **Table 3: Abatement costs of the analysed measures.**

	Pig		Milk
	S1	S2	S
Total abatement cost (AC_total)			
Baseline value [€/kg N abated]	-20.05	-15.08	-18.17
Stochastic simulation [€/kg N abated]			
Mean	-21.16	-13.56	-21.01
Minimum	-51.64	-35.01	-40.17
Maximum	4.30	4.91	-11.45
Standard deviation (SD)	6.72	4.90	3.56
NH₃-N abatement cost (AC_NH₃)			
Baseline value [€/kg NH ₃ -N abated]	-21.13	-15.89	-19.09
Stochastic simulation [€/kg NH ₃ -N abated]			
Mean	-22.58	-14.47	-22.26
Minimum	-55.23	-37.39	-43.63
Maximum	4.55	5.32	-12.13
Standard deviation (SD)	7.21	5.26	3.85
N₂O-N abatement cost (AC_N₂O)			
Baseline value [€/kg N ₂ O-N abated]	-673.15	-506.24	-661.83
Stochastic simulation [€/kg N ₂ O-N abated]			
Mean	-597.96	-383.05	-701.21
Minimum	-1863.33	-1360.43	-1863.29
Maximum	144.42	126.68	-279.64
Standard deviation (SD)	235.18	165.47	206.56
NO-N abatement cost (AC_NO)			
Baseline value [€/kg NO-N abated]	-927.44	-697.47	-895.16
Stochastic simulation [€/kg NO-N abated]			
Mean	-910.07	-582.99	-958.79
Minimum	-3081.34	-2167.51	-2619.88
Maximum	166.44	131.81	-379.83
Standard deviation (SD)	388.62	269.97	301.94
