Abstract: Thermoplastic, polysaccharide-based plastics are environmentally friendly. However, typical shortcomings include lack of water resistance and poor mechanical properties. Nanocomposite manufacturing using pure, highly linear, polysaccharides can overcome such limitations. Cast nanocomposites were fabricated with plant engineered pure amylose (AM), produced in bulk quantity in transgenic barley grain, and cellulose nanofibers (CNF), extracted from agrowaste sugar beet pulp. Morphology, crystallinity, chemical heterogeneity, mechanics, dynamic mechanical, gas and water permeability, and contact angle of the films were investigated. Blending CNF into the AM matrix significantly enhanced the crystallinity, mechanical properties and permeability, whereas glycerol increased elongation at break, mainly by plasticizing the AM. There was significant phase separation between AM and CNF. Dynamic plasticizing and anti-plasticizing effects of both CNF and glycerol were demonstrated by NMR demonstrating high molecular order, but also non-crystalline, and evenly distributed 20 nm-sized glycerol domains. This study demonstrates a new lead in functional polysaccharide-based bioplastic systems.

Keywords: bioplastics; amylose; starch; cellulose nanofibers; composite films

40 **Highlights**

41 - Engineered amylose and waste CNF generate good bioplastics.

42 - CNF enhanced crystallinity, mechanics and permeability.

43 - Cellulose nanofibers and amylose showed domain phase separation.

1 Introduction

Increased plastics pollution in the environment has attained notable attention to find alternative eco-friendly and biobased solutions. Such materials refer to renewable resources, preferably of plant-based and waste stream origins that are biodegradable, or home-compostable and non-toxic (Khalil, Bhat & Ireana Yusra, 2012; Mohanty, Misra & Drzal, 2002; Thakur & Thakur, 2015). However, production of such all-natural bioplastics turns out to be challenging and associated problems mainly related to water sensitivity and brittleness (Follain, Joly, Dole & Bliard, 2005; Sagnelli et al., 2016; Sagnelli et al., 2017b).

Starch, the most important energy resource in plants, and cellulose, a main constituent in the plant cell wall, are two of the most abundant carbohydrates in nature providing raw materials for bioplastics production. Starch is an inexpensive, renewable, biodegradable and non-toxic natural polysaccharide (Dai, Zhang & Cheng, 2019; Gross & Kalra, 2002) typically combined of two major polymers, amylose (AM) and amylopectin, which in their native granular form are packed in concentric growth rings forming semi-crystalline and amorphous layers (Copeland, Blazek, Salman & Tang, 2009). AM is an essentially unbranched (approximately 0.1-0.5% branched) polymer composed of α-(1-4)-linked glucose units that contributes mainly to the amorphous phase (Tester, Karkalas & Qi, 2004) while amylopectin has a more branched structure due to additional α-(1-6) branch points (Blennow et al., 2013; Thakur, Pristijono, Scarlett, Bowyer, Singh & Vuong, 2019). Starch is a native

65   granular assembly structure that is almost fully shattered by hydration during any

66   common manufacturing processes. However, their inherent molecular structures,

67   which differ from one starch type to another, will direct the formation of new diverse

68   semi-crystalline and viscoelastic systems during cooling and aging (Sagnelli et al.,

69   2016). Hence, the semi-crystalline and visco-elastic nature of starch has profound

70   influence on properties and functions of starch-derived bioplastics.

71   Using pure starch systems as raw material for bioplastics entails drawbacks, such

72   as a poor cohesiveness and brittleness (Follain, Joly, Dole & Bliard, 2005). Usually

73   the brittleness can be overcome adding a plasticizer e.g. glycerol, which offers

74   flexibility and elasticity, reduces brittleness of the material (Giosafatto, Di Pierro,

75   Gunning, Mackie, Porta & Mariniello, 2014) and also maintains biodegradability.

76   Blending starch with glycerol reduces inter- and intra-molecular hydrogen bonding

77   interactions thereby increasing the movement and rearrangnet of the glucan chains.

78   The poor cohesiveness of these films could be overcome by blending with compatible

79   polymers providing an entangled system or grafting or crosslinking the starch with

80   highly flexible polymers.

81   Starch, even high-AM starch, has a non-optimal structure for entangled matrices

82   due to the presence of highly branched amylopectin providing too short chain

83   segments for stable double-helical junction zones to be formed. AM could not until

84   now be obtained in bulk quantities at reasonable price. However, the production of

85   pure AM in a transgenic barley grain system (Carciofi et al., 2012) has permitted bulk

86   prodution of AM for e.g. biomaterials purpose. Due mainly to its linear molecular

87   structure, AM is regarded as an optimal raw material for bioplastics purpose (Follain,

88   Joly, Dole & Bliard, 2005) and our previous work has demonstrated that a pure AM

89   can provide significantly improved mechanical strength as compared to normal starch,

90   in extruded materials and its high gelatinization temperature provides high thermal

91   stability comparable to semi-natural bioplastics such as MaterBi® (Sagnelli et al.,

92   2016; Sagnelli et al., 2017a). Biosynthesis directly in the cereal grain can for the first

93   time enable inexpensive bulk production of AM, which hitherto has not been possible

94   due to too high costs for separation of AM from amylopectin.

95   Blends of AM with other natural biopolymers has the potential to further

96   improve mechanical properties, permeability and thermostability without using

97   artificial or mineral oil-based resources. For example, cellulose is a linear homo-

98   polysaccharide consisting of thousands of β-(1$\rightarrow$4)-D-glucopyranose residues.

99   Natural cellulose in plant cell walls is in the form as cellulose microfibrils (3 nm in

100   width and several micrometers long) from several glucopyranose chains, which is a

101   remarkably robust structure that strengthens plant cell walls (McNamara, Morgan &

102   Zimmer, 2015; Somerville et al., 2004). Cellulose nanofibers (CNF) are 5 - 60 nm

103   wide and 0.1 - 2 µm long structures can be derived from plant biomass as first

104   demonstrated by Turbak et al. (Turbak, Snyder & Sandberg, 1983) and Herrick et al.

105   (Herrick, Casebier, Hamilton & Sandberg, 1983). Depending on the pre-treatment

106   method, various types of nano-scale cellulose (nanocellulose) can be obtained.

107   Nevertheless, CNF is usually preferred as reinforcing agent in composite materials

108   due to its high aspect (length to width) ratio (Klemm et al., 2018; Saïd Azizi Samir,

109   Alloin, Paillet & Dufresne, 2004). Hydrogen-bonding between several neighboring

110   cellulose chains generate densely packed CNF that possess high strength, stiffness,

111   low density and biodegradability (Moon, Martini, Nairn, Simonsen & Youngblood,

112   2011). Therefore, CNF can be used to improve the mechanical and barrier properties

113   of bio-composites (Vilarinho, Sanches Silva, Vaz & Farinha, 2018). Recently, CNF

114   derived from agricultural side streams consisting mainly of primary cell walls, has

115   generated special interest due to facile and cleaner preparation methods compared to

116   using wood as raw material (Perzon et al., 2019; Holland et al., 2019). Protocols for

117   preparing CNF from vegetable pulp typically consists of alkaline treatment to strip off

118   non-cellulosic polysaccharides, followed by oxidation of phenolic compounds and

119   finally high-shear homogenization. CNF have successfully been derived from sugar

120   beet, potato tuber, and carrot using this method (Dinand, Chanzy & Vignon, 1996;

121   Dufresne, Dupeyre & Vignon, 2000; Siqueira, Oksman, Tadokoro & Mathew, 2016).

122   Indeed, the abundance of pulp originating from industrial production of commodities

123   such as starch, sugar, pectin etc. constitutes a sustainable source of CNF.

124   Blending starch (but not pure AM) with CNF have demonstrated some superior

125   properties of such blends, possibly partly due to strong interaction between the α- and

126   β-glucosidic polysaccharides. CNF can be extracted from different commodities such

127   as cassava, corn and maize and produced by harsh chemo-physical treatments and

128   chemical modification (Chen, Liu & Chen, 2019), However, composites of 1:99 ratio

129   CNF:starch suffered from poor dispersion resuling in breaking of the films. Studies on

130   the reinforcement of cassava starch with CNF plasticized with a mixture of sorbitol

131   and glycerol (Teixeira, Pasquini, Curvelo, Corradini, Belgacem & Dufresne, 2009),

132   showed that the elastic modulus increased with 5 wt. % of CNF. However, at 10 and

133   20 % of CNF, significant reduction in elasticity occurred, suggesting that plasticizer

134   used could delay the stress transfer between the CNF and the matrix.

135   The present work reports the first attempt of the preparation and characterization

136   of nanocomposite films based on pure AM derived from bioengineered grain, CNF

137   derived from waste sugar beet pulp and glycerol as plasticizer. We hypothesized that

138   pure AM directly derived from a transgenic plant blended with secondary cell wall

139   CNF from waste sugarbeet pulp provides a bulk solution for production of durable

140   AM-based flexible bioplastics. Hence, the main novelty is the use of entirely new raw

141   materials 1. AM directly produced as a virtually pure substance directly in a cereal

142   grain and 2. CNF extracted for pulp providing unique functionality. It is the first time

143   these two raw materials combindly have been tested for bioplastics purpose. Such

144   AM-CNF cast composite films provided high mechanical stress at break, high

145   Young's modulus, decreased water contact angles and water vapor and oxygen

146   permeability at high CNF content. This study demonstrates some unique properties of

147   nanocomposites fabricated by cast of reinforcing, waste-derived CNF and all-natural

148   bulk-produced AM for biobased bioplastics.

149

2 Experimental

2.1 Materials

Sugar beet pulp was kindly provided as an agro-industrial side stream by Nordic

Sugar A/S. CNF (85%) was extracted as previously described (Perzon et al., 2019).

AM (99%) was prepared as described from a starch branching enzyme RNA

interference suppressor barley line (Carciofi, Blennow, Nielsen, Holm & Hebelstrup,

2012). All chemicals were provided by Sigma-Aldrich (St. Louis, MO, USA).

2.2 Methods

2.2.1 Extraction of AM

Barley flour was mixed at a ratio of 1:10 with a solution containing 1 mM

dithiotreitol (DTT) and 0.5% SDS (sodium dodecyl sulphate). The suspension was

homogenized at 5700 rpm using a Silverson L5A homogenizer with the largest slit

size for 10 min and then at 8300 rpm for 20 min. The AM granules were sedimented

at 4 ºC over night or until the supernatant was visually clear. The supernatant was

carefully discarded, and the AM-containing sediment washed with MilliQ water three

times and sieved through a 100 μm mesh. The AM was collected and washed again

with MilliQ water. A white layer consisting of AM granules (Figure S1) was collected

and dried at room temperature. Purity and molecular characteristics are documented

elsewhere (Shaik et al., 2014,2016; Goldstein et al., 2016).

170

2.2.2 Gelatinisation profile of AM

To establish the dissolution characteristics of amylose at thos conditions (high temperature) as the dissolution method used to produce the bioplastics films, the gelatinisation profile of AM was monitored using a rheometer (Anton Paar, Ireland, MCR102) equipped with a leak-proof pressure cell and a Rapid Visco Analyzer (RVA) vane geometry (Anton Paar, Ireland, ST24-4V-2D). A 10% w/w suspension of AM was prepared in triplicate. The experiment was performed using the following program: mixing at 960 rpm for 90 s at 50 °C, pasting at 170 rpm, by a temperature ramp from 50 °C to 145 °C at a rate of 2 °C/min, an isotherm at 145 °C for 30 min, a cooling ramp from 145 °C to 50 °C at a rate of 3 °C/min.

2.2.3 Extraction of cellulose nanofibers

Cellulose nanofibers were prepared from sugar beet pulp as described elsewhere (Perzon et al., 2019). Briefly, 20 g (dry weight) of sugar beet was added to 2500 mL distilled water (dH_2O) and homogenized to pulp (particle sizes around 1 mm) with a Silverson L5A homogenizer (East Longmeadow, MA, USA) at 5600 rpm for 10 min and thereafter at 8300 rpm for 20 min using a slotted disintegrating head. The pulp was subsequently washed with 5000 mL of dH_2O though a 38 μm sieve and then suspended in 500 mL 0.5 M NaOH, stirred at 80 ºC for 2 h, and washed until neutral with dH_2O. To remove lignin and tannins, the NaOH-treated pulp was submerged in 500 mL bleach solution (1% $NaClO_2$ and pH 5.0), stirred at 70 ºC for 2 h, and washed

192 with dH$_2$O. After obtaining the dry weight of the remaining suspension of cellulose

193 fibers, it was diluted to 1.00% (w/w) in 200 mL dH$_2$O. The cellulose fibers (200 mL)

194 were circulated in a high-shear homogenizer (microfluidizer materials processor

195 M110-P, Newton, MA, USA) with orifices of 200 and 400 μm under 500 bar pressure

196 for 18 min to produce nanofibers. The nanofibers were stored at 4 °C until further use

197 (Figure S1).

198

199 *2.2.4 Casting of composites films*

200   The different nanocomposite formulations of AM and CNF with different

201 glycerol content were prepared as previously published with minor modification

202 (Sagnelli et al., 2017b). The CNF:AM were 0:100, 25:75, 50:50, 100:0 (w/w %). All

203 constituents (1% each of CNF and AM and different glycerol concentrations) were

204 heated while stirring for 30 min at 140 °C using a high-pressure glass reactor. The

205 solutions were cooled to approximately 70 °C, degassed in vacuum and immediately

206 cast in Teflon-coated petri dishes. The films were dried at 50 °C in a ventilated oven

207 overnight or until completely dry and transparent (Figure S2). All the samples are

208 named to indicate the percentages of the different components where CNF and AM

209 constitutes 100% and the amounts of glycerol indicated additionally, as for example

210 15/25/75 for a sample containing 15 % glycerol, 25% CNF and 75% AM. All pure

211 components and composite films were placed in a sealed desiccator containing

212 saturated potassium chloride (RH 85, 20 °C) to balance the moisture before analysis.

213

2.2.5 Confocal Laser Scanning Microscopy (CLSM)

The films were analyzed by CLSM (Leica SP5-X, Leica Microsystems, IL,

USA) equipped with x20 water immersion objectives. Pontamine Fast Scarlet 4BS

(PFS 4BS) and safranin O (Sigma-Aldrich) were used as fluorophores for CNF and

AM, respectively. The excitation fluorescence were 488 nm and 488 nm and emitted

fluorescence were recorded between 560 - 605 nm and 530 - 550 nm, respectively, for

PFS and safranin O. Images analysis was performed with LAS AF X 2.6 software

(Leica Microsystems, IL, USA).

2.2.6 Field Emission Scanning Electron Microscopy (FE-SEM)

FE-SEM images were acquired with a Quanta 3D FEG (FEI Company, The
Netherlands). The films were cut into squares (1×1 cm), attached to a metal plate,
and coated with a 2 nm colloidal gold layer before analysis. The cross section
morphology, film specimens were cryo-fractured by immersion in liquid nitrogen and
then mounted on aluminum stubs perpendicularly to their surface then sputtered with
gold prior to analysis.

2.2.7 Water contact angles (Θw)

Water contact angles (Θw) of films were performed at room temperature with a

KSV Cam 200 (KSV Instruments Ltd, Helsinki, Finland). Measurments the were

performed after 10 sec from the contact to the film and no variation was recorded after

that time. Left and right values were recorded and an average was calculated. Angle

236   pictures were recorded by using the built-in software (CAM200, KSV instruments).

237   All measurements were recorded in duplicates.

238

239   *2.2.8 Attenuated total reflectance Fourier-transform infrared (ATR-FTIR)*

240   *spectroscopy*

241   ATR-FTIR spectra were acquired with an attenuated total reflection

242   spectrophotometer (Agilent Technologies Cary 630 FTIR, Santa Clara CA, USA)

243   equipped with reflection ATR unit. Spectra were acquired with a resolution of 4 cm^{-1},

244   in the range 4000 - 650 cm^{-1} by acquiring 32 interferograms. Spectra were analyzed

245   with the open access software SpectraGryph1.2.

246

247   *2.2.9 Wide angle X-ray scattering (WAXS)*

248   Following moisture equlilibration (RH 85, 20 $^{\circ}$C) collection of data was

249   performed using a Panalytical Xpert Pro (Nottingham, UK) instrument. The samples

250   were tested in the WAXS (wide-angle X-ray scattering) mode and the intensity given

251   according to $q = 4\pi \sin\theta/\lambda$, where λ is the wavelength and 2θ is the scattering angle set

252   from 5° to 35°. The exposure time was 400 s/step with a step increment of

253   (0.0131303°) (Sagnelli et al., 2019). For calculation of the crystallinity, the peak

254   analyser tool of Origin2020b PRO was used. In particular a baseline was obtained to

255   remove the amorphous phase to consider only the crystalline phase. Peaks were fitted

256   and integrated to obtain the crystalline contribution. The total area (amorphous +

257   crystalline) was measured following integration the whole spectra. Subtraction

258   between the integrated areas provided the amorphous contribution.

259

260   *2.2.10 Mechanical properties*

261   The films were cut into rectangular strips of length = 100 mm and width = 8 mm,

262   Film thickness, as measured by a micrometer screw gauge, varied as a function of the

263   composition. The tensile tests were performed using an Instron machine model 5569

264   (MTS, USA) equipped with a 5 kN tensile load cell. The distance between clamps

265   was 60 mm and the crosshead speed were set at 10 mm min^{-1}. The elongation and

266   tensile stress at break were measured at 18 °C and 50% humidity. Each analysis was

267   performed at least in pentaplicate (Follain, Joly, Dole & Bliard, 2005). Young´s

268   modulus was calculated as follows: E=FL0/ADL. with F = force L0 Length A=

269   thickness DL= difference between L0 and Lfin (Lfin the length before the

270   deformation starts.

271

272   *2.2.11 Dynamic mechanical analysis with temperature and humidity control*

273   Dynamic mechanical analysis (DMA, Triton technology, 2101405) with a

274   temperature gradient was performed in tension mode with a displacement of 0.005

275   mm and frequencies of 1 and 10 Hz. A standard heating rate of 3 °C min^{-1} was used

276   and a ramp from −50 to 120 °C. The experiments were performed on prototypes with

277   a length of 10 mm. The glass transition temperature was estimated by comparing the

278   derivative function of the storage modulus and the tan delta (tanδ) peak (Sagnelli et

279   al., 2019; Figure S3).

280

281   *2.2.12 Nuclear magnetic resonance magic-angle spinning (NMR MAS)*

282   Conventional solid-state NMR MAS experiments on ^{1}H were performed on a Bruker

283   Avance III 600 MHz spectrometer, equipped with a triple resonance 1.3 mm fast-

284   MAS (magic angle spinning) probe operating at ambient temperature. Zirconia rotors

285   were used for all experiments, and spinning frequencies were set to 60.0 kHz and

286   regulated to ± 2 Hz. [1]H chemical shifts were referenced externally to the [1]H

287   resonances of adamantane set at 1.8 ppm. Relaxation times were measured by using a

288   standard saturation recovery sequence, consisting in a saturation block of multiple 90°

289   pulses, followed by an increasing recovery time and a final 90° and acquisition. One-

290   dimensional ^{1}H spectra were acquired with the use of a spin-echo sequence in order to

291   remove the background signal from the probe. It consisted in a 90° - delay –180°

292   sequence and the signal is detected after a second echo delay. Ultrafast magic angle

293   spinning [1]H – [1]H two-dimensional exchange spectra were recorded with increasing

294   mixing times, and the changes in peak intensities were used to monitor the transfer of

295   magnetization between the domains by spin diffusion. The sequence used was a

296   standard NOESY sequence, suitable for identifying signals from protons in close

297   proximity (Jennings et al., 2016; Ntountaniotis et al., 2014).

298

299 *2.2.13 Permeability to gases*

300 Water vapor permeability (WVP), carbon dioxide (CO_2) and oxygen (O_2)

301 permeabilities were evaluated as described (Mariniello, Giosafatto, Di Pierro,

302 Sorrentino & Porta, 2010; Sagnelli et al., 2017b). The films were placed in a

303 desiccator for two days at 85 % RH in order to secure that all the samples reached the

304 same level of humidity since also water may act as plasticizer and therefore may

305 influence the barrier properties. The films were cut into 5 cm^2 squares and the

306 experiment was performed at 25 °C under 85% RH in duplicate.

307

308 **3 Results and discussion**

309 *3.1 Solubilisation profile of AM*

310   Prior to the production of the bio-nanocomposites, the solubilisation behavior of

311 AM in a high-pressure rheometer was tested. We recorded three different

312 solubilisation transitions for 10% w/w AM/water suspensions. The first transition was

313 detected at 87 ℃, indicating that the granules were starting to swell and take up water

314 (Fig. 1). The main transition was detected at 97 °C indicating the solubilisation and

315 gelatinization of the granules (Fig. 1). The last transition was detected at 140 °C

316 showing the solubilisation of AM/lipid complexes (Fig. 1). These data agree with

317 solubilisation profiles for AM measured by differential scanning calorimetry (Sagnelli

318 et al., 2016). As guided by the last transition, we set the temperature for gelatinization

319 of the AM in the suspensions to 140 °C to secure complete dissolution of all

320 crystallites prior of the casting phase.

321
322

323   Fig. 1. Gelatinization profile of 10% AM suspensions recorded in an air-tight high-

324   pressure cell. A: the main gelatinization transitions. B Gelation phase.

325

326   *3.2 Surface and internal structures of films*

327   FE-SEM surface analysis of films produced from AM and CNF specimens at

328   different ratios showed that the topography and the cross section changed significantly

329   with increasing CNF content. Additional detailed information of the surface alterations

330   as compared to previous studies on composite CNF starch systems [35-37] were

331   revealed. The 0/0/100 (pure AM) film surface showed numerous pleated structures (Fig.

332   2a). CNF blended to 25 % resulted in a smoother surface indicating an interaction

333   between the two polysaccharides where the CNF are located internally and coated by

334   AM (Fig. 2b). When CNF content was raised to 50 % and 100 % fiber-like structures

335   became visible on the surface of the films (Fig. 2c, d). The films plasticized with

336   glycerol showed no significant differences as compared to the non-plasticized films

337   (not shown). The coating of the nanofibers with the starch matrix indicate that the

338   nanofibers were physically reinforced in the network, which demonstrates that the two

339   polymers are compatible. No voids or pores were observed in the film, which indicated

340   a strong adhesion between the nanofibers and the starch successively reinforcing the

341   matrix and enhancing the mechanical strength.

342

343   FE-SEM images of the cross section of cryo-fractured surfaces of the composite films

344   (Fig. 2) showed that the pure AM film presented a smooth dense fractured surface that

345   is typical of a brittle material (Fig. 2e). High homogenous distribution of CNF at 25%,

346   which lead to strong interfacial adhesion (Fig. 2f). Both surface and cross section

347   became more non-homogeneous with increased concentration of CNF to 50% that

348   revealing low interfacial adhesion between nanofibers and matrix (Fig. 2g). The pure

349   CNF film showed uniform layers of fibers (Fig. 2h). Only few cracks and

350   deformations within the starch matrix indicates even distribution of the polymeric

351   structures in the matrix.
353

354 Fig. 2. FE-SEM of AM/CNF pure and composite films. (a,e) surface and cross section

355 for 0/0/100; (b,f) surface and cross section for 0/25/75; (c,g) surface and cross

356 section for 0/50/50; (d,h) surface and cross section for 0/100/0. Arrows indicate

357 fissure surfaces. Scale bars represent 3μm for the surfaces (left) and 50 μm for the

358 cross sections (right).

359

360   The internal structure of the films was analyzed by CLSM (Chen, Yu, Simon,

361 Petinakis, Dean & Chen, 2009) using two different fluorophores, safranin O and PFS

362 4BS (Anderson, Carroll, Akhmetova & Somerville, 2010; Dürrenberger, Handschin,

363 Conde-Petit & Escher, 2001) permitting identification of AM and cellulose domains,

364 respectively (Fig. 3). The pure AM and CNF films displayed virtually homogeneous

365 internal phases as evaluated by the safranin O and PFS 4BS staining, respectively. No

366 cross-contamination with AM or cellulose of these pure films was detected as

367 deduced from the virtual absence of green fluorescence in the pure AM system and

368 very little red fluorescence in the pure CNF system. Phase partitioning between CNF

369 and AM was readily detected in the 0/25/75 and 0/50/50 films as separated bright and

370 dark fields representing safranin O-stained AM and PFS 4BS stained CNF domains.

371 These results clearly suggest a partial phase separation between AM and CNF. The

372 same phenomenon was observed for nanocomposites of starch and betaglucans

373 (Sagnelli et al., 2017b). Phase separation can be an effect of the slow fabrication

374 (casting) process and not due to the special features of the AM and CNF used in the

375 study as compared to other similar raw materials.

376

381 μm.

382

383 *3.3 Water contact angles of films*

384 The water contact angle (Θ_w) is defined as the angle formed by the intersection

385 of the tangent lines of the liquid and surfaces of the solid at the three-phase boundary

386 (generally liquid, solid and air) (Wong, Gastineau, Gregorski, Tillin & Pavlath, 1992).

387 The water contact angle provides information related to the degree of

388 hydrophilic/hydrophobic nature of a surface, and is indicative of the surface

389 wettability as well as the strength of the molecular interaction among liquid, solid, and

390   air phases (Gutiérrez, Ollier & Alvarez, 2018). The water contact angle increases with

391   increased surface hydrophobicity. Polysaccharides typically show relatively high Θ_w,

392   which is suggested to be related to strong intermolecular hydrogen bonding among the

393   hydroxyl groups of the polysaccharide backbone with the surface of films

394   (Karbowiak, Debeaufort, Champion & Voilley, 2006; Ojagh, Rezaei, Razavi &

395   Hosseini, 2010).

396   The Θ_w values of the composite films were affected in various degrees by the

397   AM:CNF ratios and glycerol (Table 1). Without glycerol, CNF decreased the Θ_w

398   value suggesting strong positive effect of CNF on the surface wettability. The water

399   contact angles of 0/50/50 and 0/100/0 were lower than 65°, indicating the CNF

400   decreased intermolecular hydrogen bonding in the polysaccharide composite matrix.

401   Pure AM and 0/25/75 (75% AM) films showed water contact angles $\geqslant 65°$

402   suggesting low wettability of these composites. Addition of 15% glycerol to the AM

403   film showed little effect. However, when both CNF and glycerol were included, the

404   water contact angle increased, suggesting glycerol-induced increase in intramolecular

405   bonding in the composite.

406   With a high (25%) glycerol concentration, the AM films showed a notable

407   increase in Θ_w suggesting the presence of strong intermolecular hydrogen bonding

408   between glycerol and AM in the AM matrix and the presence of specific AM-glycerol

409   structures (Karbowiak, Debeaufort, Champion & Voilley, 2006). On the other hand,

410   high glycerol concentration in the AM/CNF composites showed a significant

411   variability in Θ_w. Among the 25% glycerol samples, we observed an unexpectedly

412   low contact angle (46°) for the 25% glycerol sample (25/25/75, Table 1), which we

413   suggest is due to a decrease of the intermolecular hydrogen bonding network. These

414   effects could not be readily explained and might be caused by a wide variety of

415   different amorphous and crystalline phases in the films. Especially, glycerol, due to

416   the anti-plasticizing effect of the glycerol, may affect the distribution of AM and CNF

417   in the films, inducing formation of aggregates at the surface of films leading to

418   increased water contact angles.

419

420   Table 1. The moisture, crystallinity and contact angle of AM/CNF pure and composite

421   films.

Composition	Moisture (%)	Crystallinity (%)	Contact angle (degrees)
0/0/100	12.08	14	87.0±1.0
0/25/75	13.67	18	67.0±1.0
0/50/50	9.58	23	58.0±1.0
0/100/0	7.23	40	55.0±1.0
15/0/100	12.87	15	90.0±1.0
15/25/75	16.15	12	87.0±1.0
15/50/50	13.12	34	74.0±1.0

25/100/0	14.34	55	60.0±1.0

422

423   *3.4 Fourier-transform infrared spectroscopy (FTIR)*

424   FTIR was conducted in order to test if new chemical bonds or physical

425   interactions (mainly H-bonding) were formed during the processes. The ATR FTIR

426   spectra (Figure S4) showed O–H stretching, corresponding to a broad band between

427   3600 - 3200 cm^{-1}, due to an extensive H-bonding network among the OH of AM

428   glycerol and cellulose. The C–H stretching was observed at 2900 cm^{-1}. The

429   appearance of an absorption band at 1650 cm^{-1} is attributed to the water adsorbed, due

430   to the hygroscopic nature of polysaccharides. The peaks at 1050 to 950 cm^{-1}, related

431   to the C–O–C stretching showed a slight shift towards higher wave number for the

432   CNF-containing films demonstrating an additive effect of CNF. Otherwise, all the

433   spectra were very similar and hence, we conclude that no new covalent bonds formed

434   between AM and CNF, as previously reported for CNF-starch composites (Liu &

435   Budtova, 2012). As deduced from FTIR glycerol had only minor effects on the

436   bonding network of the films (Figure S4).

437

438   *3.5 Crystalline structures*

439   AM/CNF pure and composite films were found to possess well-defined

440   crystalline structures as deduced by wide angle X-ray scattering (WAXS) (Table 1

441   and Fig. 4). The AM films exhibited a typical V-type polymorph mainly formed by

442   single-helices (Xu, Tan, Chen, Li & Xie, 2019) as demonstrated by diffraction peaks

443   at 2θ of 5.5°, 16.0°, 17.0° and 20.0°. CNF film displayed characteristic diffraction

444   peaks at 2θ of 16.2° and 22.3°, which represent a typical Type-I crystalline structure

445   (Lu, Lin, Tang, Wang, Chen & Huang, 2015), showing that the purification and melt

446   processing of CNF had little effects on its crystalline structures. The crystallinity of

447   the films increased with CNF content. Interestingly, the diffractograms did not seem

448   to be entirely additive for AM and CNF and for the 50% and 100% CNF the cellulose

449   crystalline polymorph dominated as were virtually the same indicating very

450   amorphous AM. Glycerol did not have any significant effect on crystallinity for any

451   of the film formulations except for the 50% CNF, which had an unexpectedly high

452   crystallinity (Table 1). A 2-fold higher crystallinity as compared to the films without

453   glycerol was found indicating that glycerol has weaker interaction with CNF than

454   with AM creating an imbalance in the composites when the amount of CNF exceed a

455   certain limit. This can increase the relative amount of glycerol interacting with the

456   AM-phase of the nanocomposite allowing more moisture absorption and the overall

457   crystallinity. This was confirmed by the small change of crystallinity for pure CNF

458   films and by the water contact angle of 50/% CNF films that does not follow the trend

459   when 25% of glycerol was added.
460

461   Fig. 4. WAXS diffractograms of AM/CNF pure and composite films without glycerol.

462

463   *3.6 Mechanical properties*

464   The deformation behavior of AM/CNF pure and composite films as

465 characterized by tensile tests and calculation of the parameters strain at break, stress at

466 break and Young's modulus showed that the films were influenced by all three

467 components AM, CNF and glycerol (Fig. 5). The presence of glycerol decreased the

468 stiffness and strength of the films and increased elasticity. In particular, when we

469 intended to plasticize the AM films with 15 % of glycerol an anti-plasticization effect

470 was observed as demonstrated by decreased strain at break. This effect has been

471 previously recorded for thermoplastic starch (TPS) materials (Lourdin, Bizot &

472 Colonna, 1997). Interestingly, the addition of 25 % CNF reverted the anti-

473 plasticization showing a 5-fold increase in the strain at break, which is a typical effect

474   for nanocomposites. The strain at break decreased with increased CNF and for the

475   pure CNF, strain at break increased only 2-fold confirming the lower affinity of CNF

476   to glycerol. At higher concentration of glycerol, the strain at break increased

477   significantly with the concentration of CNF in the composites.

478   Increased CNF:AM ratio resulted in higher stress at break for the films without

479   glycerol, demonstrating that CNF had a significant strengthening effect on the

480   composites. In the presence of glycerol there was a drop in the strength of all the films

481   (Fig. 5B). At 15% glycerol, the stress at break of the samples was not significantly

482   different for any of the films. However, the Young´s modulus of these films increased

483   with increasing CNF content. When glycerol content was increased to 25%, the

484   strength of AM and composites films showed a notable decrease. However, the pure

485   CNF films showed indifferent strength, virtually independent of the glycerol content

486   demonstrating that CNF has a great potential as filler and reinforcer. As deduced from

487   the combined high stress and strain at break, the CNF films showed high cohesiveness

488   even with high concentration of glycerol.

489

490
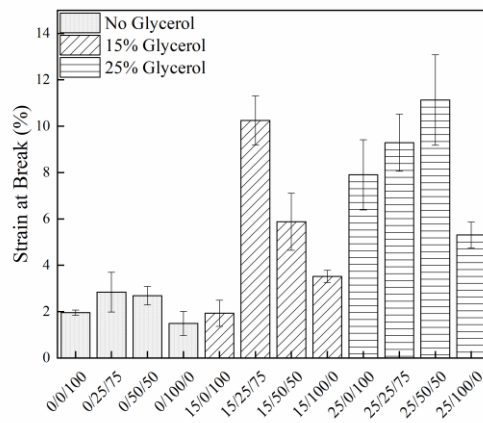

491
492

493   Fig. 5. Mechanical properties of AM/CNF pure and composite films. Top: strain at

494   break, Middle: stress at break, Bottom: Young's modulus.

495

496   *3.7 Effects of temperature on dynamic visco-elasticity*

497   The visco-elastic properties of the films were analyzed with a dynamic

498   mechanical analyzer (DMA) using tension mode and temperature gradients to

499   estimate the glass transition temperature and calculating the tanδ peak (Sagnelli et al.,

500   2017b). There was a general trend that the presence of CNF and glycerol decreased

501   the T_g of the films (Figure S5). However, just as shown for the strain at break, a weak

502   anti-plasticization effect was observed at 15% glycerol for the films with high AM

503   content. This effect has been previously recorded for high AM films (Lourdin, Bizot

504   & Colonna, 1997). Generally, at 25% glycerol T_g was decreased demonstrating a

505   notable plasticized system where the polymers chains have flexibility in the

506   plasticizer-rich phases.

507

508   *3.8 Solid-state NMR*

509   Solid-state NMR spectroscopy was used to evaluate the domain size of the

510   different component on the whole sample. [1]H ultrafast-MAS solid-state NMR

511   experiments were performed on AM/CNF pure and composite films. NMR relaxation

512   measurements are sensitive to the crystalline nature of the materials, high degree of

513   crystallinity induce a strong network of dipole-dipole interactions which results in fast

514   spin-lattice relaxation times (T_1). Relaxation was monitored over a range of 100 s for

515   each sample and the extracted relaxation times were fast (order of magnitude of a few

516   seconds) and characterized by a mono-exponential behavior. This, together with the

517   fact that all the chemical sites show the same relaxation behavior, suggests that the

518   domains present in the composites were relatively small (nm scale) and intimately

519   distributed. The relaxation times decreased with the increase of the glycerol content of

520   the films. Moreover, the relaxation times decreased as CNF was increased in the films

521   and this effect was most noticeable in absence of glycerol (Fig. 6). The addition of

522   glycerol substantially modified the relaxation behaviour of all the films by decreasing

523   the relaxation, compatible with a plasticizing effect of the glycerol.

524
525

526   Fig. 6. 1H Spin-lattice relaxation times as a function of CNF and glycerol contents.

527

528   Ultrafast-MAS ^{1}H spin-echo experiments were performed at 60.0 kHz to

529   characterize the chemical environments of the films. All the spectra show an aliphatic

530   region between 0 and 2 ppm indicating small amount of impurities. Spectra for the

531   films without glycerol were not resolved enough to differentiate between the different

532   chemical sites. Even though the resolution did not fully resolve each chemical

533   environment of the protons it was clear that AM showed a spectrum with a relative

534   sharp peak centered at approx. 4 ppm, characterized by two small shoulders, one at

535 3.5 ppm and the second one at approximately 6.0 ppm (Fig. 7A). The CNF spectrum

536 instead showed only one broad resonance at 4 ppm. However, the lack of resolution

537 for the pure spectra makes the structural analysis and the peak assignment impossible.

538 On the other hand, the effect of the addition of glycerol (Fig. 7B,C,D) is easily

539 noticeable by the appearance of two sharp and intense glycerol resonances, at 3.7 and

540 4.8 ppm respectively, which substantially overlapped with the AM/CNF unresolved

541 protons.
542

543

544

545 Fig. 7. 1H solid-state NMR MAS Hahn-echo spectra. A: 0/0/100 (dotted line), 0/50/50

546 (solid line) and 0/100/0 (dashed line); B: 0/0/100 (dotted line), 15/0/100 (solid line)

547 and 25/0/100 (dashed line); C: 0/50/50 (dotted line), 15/50/50 (solid line) and

548 25/50/50 (dashed line); D: 0/100/0 (dotted line), 15/100/0 (solid line) and 25/100/0

549 (dashed line).

550

551   To obtain additional data on the average domain size, solid-state NMR ^{1}H – ^{1}H

552   spin diffusion measurements were carried out. The NOESY proton-exchange

553   experiment (Fig. 8), performed at a different mixing times in the range 1 to 300 ms,

554   showed the presence of cross-peaks demonstrating that there is a substantial fast

555   magnetization exchange transferring the polarization between the different domains of

556   the matrix. This suggests that the relative domain size in the samples are small, which

557   is compatible with the previous observation that only a single mono-exponential

558   relaxation behavior is present for all peaks. However, since the glycerol signals

559   obscure the AM/CNF chemical shifts and due to the similarity of the two pure AM

560   and CNF films, calculation of the copolymeric blocks are not precise. However, from

561   the resolved glycerol peak signal it is possible to estimate the upper limit for the

562   glycerol domain size according to (Pili et al., 2018) $< r^2 > = 6Dt$, setting the spin

563   diffusion coefficient to the order of magnitude of 10^{-16} m^{2}s^{-1} and t to T_1, an upper limit

564   of 20 nm can be assumed for the domain size of the glycerol. These data are

565   compatible with the CLSM results (Fig. 3) in which the phase separation involves

566   only AM and cellulose.

567
Fig. 8. 1H - 1H NOESY exchange for the 25/100/0 sample.

569

3.9 Gas permeability

Water vapor (WVP), carbon dioxide (CO_2) and oxygen (O_2) permeability

measurements were carried out on films without glycerol (Table 2). AM films

(0/0/100) were too fragile to be tested for O_2 and CO_2. WVP decreased with increased

CNF; the pure AM films showed a 7-fold higher WVP than the CNF films. Such

effects have been discussed (Ferrer et al. , 2017) in terms of the dense network

structure that is formed by CNF as we documented by SEM providing a more tortuous

diffusion path for gases. Furthermore, the WVP of all the composite films were far

lower than the majority of petroleum-based materials (Ferrer, Pal & Hubbe, 2017).

The same effects of CNF were seen for O_2 and CO_2, especially for the O_2 permeability

showing a 3-fold decrease as compared to the AM-rich composites. The reduced O_2

permeability can be advantageous for packaging purposes.

582

583

584   Table 2. Barrier properties of AM/CNF pure and composite films.

Composition	Thickness (μm)	Permeability (cm^3 mm kPa/m^2 24h)		
		O_2	CO_2	H_2O

585   * Not determined due to fragility.

586

4 Conclusions

588   Composite transparent films were fabricated by casting of pure plant engineered

589   AM from transgenic barley grain and waste-derived primary cell wall CNF. The

590   presence of 25% CNF resulted in a smooth composite while increased CNF had

591   rougher surface, fiber-like surface structures and increased wettability. Phase

592   partitioning between AM and CNF was identified using CLSM indicating only partial

593   interaction between the two polymers. Crystallinity, mechanical strength and stiffness

594   were increased by CNF. All composites showed increased elasticity (strain at break)

595   as compared to the pure polysaccharide prototypes demonstrating that even minor

596   AM-CNF interactions have major effect on mechanical properties. An anti-

597   plasticizing effect in the AM film was observed at 15% glycerol but this was reversed

598 in the presence of 25% CNF. Solid-state NMR relaxation times were suppressed by

599 both CNF and glycerol demonstrating plasticizing effects of these constituents. Spin-

600 echo ^{1}H data substantiated the presence of high molecular, but non-crystalline,

601 ordered domains in the AM matrix. The glycerol domains within the pure and

602 composite films were in the range of 20 nm and distributed in close proximity to each

603 other. The permeability to O_2 and water were substantially reduced with increasing

604 concentration of CNF. This study demonstrate novel agrowaste and plant engineered

605 polysaccharide raw materials for the development of all-natural and fully home-

606 compostable composite blends as an alternative to (partially) synthetic bioplastics to

607 reduce plastics pollution.
