Received 5 January 2021; revised 17 April 2021; editorial decision 7 June 2021; accepted 18 June 2021

Aims

The aim of this study was to determine the frequency of heterozygous truncating *ALPK3* variants (*ALPK3*tv) in patients with hypertrophic cardiomyopathy (HCM) and confirm their pathogenicity using burden testing in independent cohorts and family co-segregation studies.

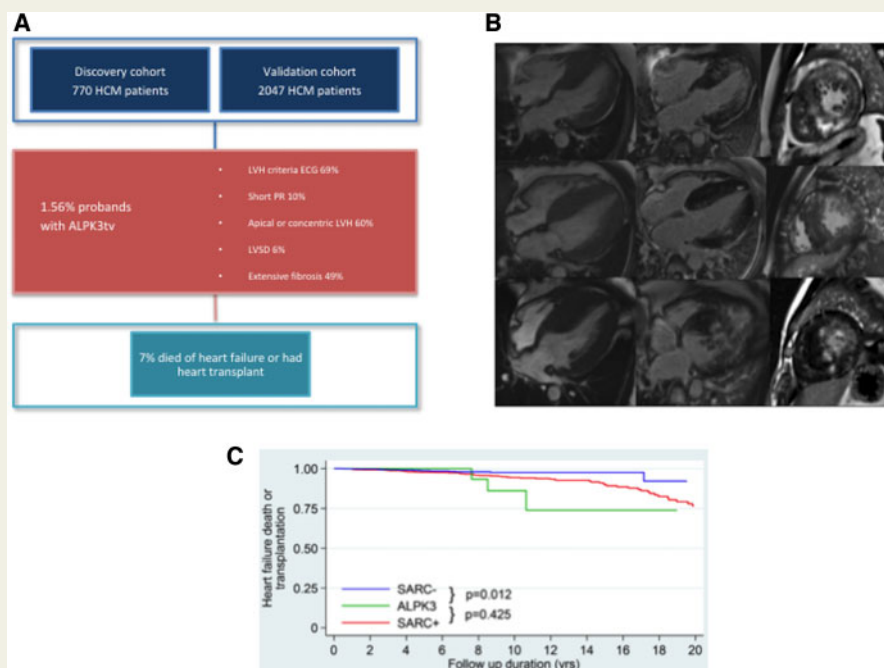

Methods and results

In a discovery cohort of 770 index patients with HCM, 12 (1.56%) were heterozygous for *ALPK3*tv [odds ratio(OR) 16.11, 95% confidence interval (CI) 7.94–30.02, $P=8.05e-11$] compared to the Genome Aggregation Database (gnomAD) population. In a validation cohort of 2047 HCM probands, 32 (1.56%) carried heterozygous *ALPK3*tv (OR 16.17, 95% CI 10.31–24.87, $P<2.2e-16$, compared to gnomAD). Combined logarithm of odds score in seven families with *ALPK3*tv was 2.99. In comparison with a cohort of genotyped patients with HCM ($n=1679$) with and without pathogenic sarcomere gene variants (SP+ and SP-), *ALPK3*tv carriers had a higher prevalence of apical/concentric patterns of hypertrophy (60%, $P<0.001$) and of a short PR interval (10%, $P=0.009$). Age at diagnosis and maximum left ventricular wall thickness were similar to SP- and left ventricular systolic impairment (6%) and non-sustained ventricular tachycardia (31%) at baseline similar to SP+. After 5.3 ± 5.7 years, 4 (9%) patients with *ALPK3*tv died of heart failure or had cardiac transplantation (log-rank $P=0.012$ vs. SP- and $P=0.425$ vs. SP+). Imaging and histopathology showed extensive myocardial fibrosis and myocyte vacuolation.

Conclusions

Heterozygous *ALPK3*tv are pathogenic and segregate with a characteristic HCM phenotype.

Graphical Abstract

Truncating variants in *ALPK3* are a cause of 1–2% of autosomal dominant hypertrophic cardiomyopathy and are associated with a phenotype characterized by extensive fibrosis and a predominantly concentric or apical pattern of left ventricular hypertrophy without left ventricular outflow tract obstruction. (A) Main phenotype characteristics and outcomes. *ALPK3*tv, alpha-protein kinase 3-truncating variants; CK, creatine kinase; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter–defibrillator; LVH, left ventricular hypertrophy; LVSD, left ventricular systolic dysfunction; SCD, sudden cardiac death. (B) Cardiac magnetic resonance imaging showing the prevalent phenotype of severe mid to apical hypertrophy and extensive late gadolinium enhancement in three patients. Left to right: 4-chamber view end-diastole cine image, 4-chamber view late gadolinium enhancement image, short axis late gadolinium enhancement image. (C) Kaplan–Meier analysis comparing incidence of an outcome of heart failure death and transplant between *ALPK3*tv patients, sarcomere positive and sarcomere negative. SARC+: sarcomere positive; SARC-: sarcomere negative.

Keywords ALPK3 • Hypertrophic cardiomyopathy • Genetics

Introduction

Hypertrophic cardiomyopathy (HCM)—defined as left ventricular hypertrophy (LVH) unexplained by abnormal loading conditions—is a myocardial disease affecting 1 in 500 of the general population and is a major cause of sudden cardiac death (SCD), heart failure, and stroke.¹ HCM is most frequently inherited as an autosomal dominant genetic trait caused by pathogenic variants in cardiac sarcomere genes, but the yield of clinical genetic testing is no more than 60%, even in patients with a family history of the disease.² This gap in knowledge exposes individuals and families to uncertainty about their future health and hampers efforts to develop novel disease modifying therapies.

Alpha-protein kinase 3 (ALPK3), located on chromosome 15q25.2, has recently emerged as a possible candidate gene in cardiomyopathy.³ Bi-allelic truncating variants in ALPK3 (ALPK3tv) have been reported in small paediatric case series, presenting with a complex phenotype of dilated cardiomyopathy (DCM) often evolving into HCM with poor systolic function^{3–8} and common variants in ALPK3 have been associated with DCM and more recently HCM in genome-wide approaches.^{9–13} A case report has described a family with HCM caused by a heterozygous ALPK3 variant¹⁴ and ALPK3tv were found to be enriched in a mixed cohort of patients with HCM and DCM.⁸

In this study, we sought to determine the frequency of heterozygous rare ALPK3tv in a discovery cohort of patients with HCM investigated with whole-exome sequencing and to establish their pathogenicity by means of burden testing in independent cohorts and family co-segregation studies. The findings show that heterozygous ALPK3tv cause a severe clinical phenotype in adults with HCM.

Methods

Discovery cohort—study population and genetic analyses

The discovery cohort comprised 770 consecutively evaluated unrelated patients with HCM referred to the Inherited Cardiovascular Disease unit at St. Bartholomew's Hospital, London, UK, and before 2015, to the Inherited Cardiovascular Disease Unit at The Heart Hospital, UCLH, London, UK. The samples used in this study were collected from 2013 to 2018. All patients gave written informed consent, and the study was approved by the regional ethics committee (15/LO/0549). Clinical evaluation was as previously described.^{15,16} HCM was diagnosed according to current European Society of Cardiology guidelines.¹ Patients with previously confirmed HCM phenocopies were excluded from the study.

DNA extraction, library preparation, whole-exome sequencing, variant calling, and annotation were performed as described previously¹⁶; variants identified with a minor allele frequency more than or equal to 0.0001 in the Genome Aggregation Database (gnomAD)¹⁷ (in any population) were removed from further analysis. The analysis of large rearrangements was performed using a read-depth strategy (ExomeDepth).¹⁸ Prioritized variants

were confirmed by conventional automated (Sanger) DNA sequencing.¹⁶

Validation in a multicentre cohort using enrichment analysis and familial co-segregation

From 2018 to 2020, ALPK3 was sequenced using next-generation sequencing in 4904 consecutive unrelated probands with inherited cardiac conditions referred for molecular genetic diagnosis at Health in Code. This cohort encompassed different cardiovascular phenotypes established by each referring centre: HCM ($n = 2047$), DCM ($n = 746$), arrhythmogenic cardiomyopathy (ACM, $n = 435$), non-compaction cardiomyopathy ($n = 313$), restrictive cardiomyopathy ($n = 41$), and undefined cardiomyopathy ($n = 121$). An additional 1059 index cases with no evidence of structural cardiac disease (channelopathies and aortic diseases) were used as controls. The remaining 142 individuals in this cohort had an unestablished phenotype.

Patients were referred mainly from centres in Spain, the UK, Denmark, Russia, Latvia, Brazil, and Argentina. Ethical approval and patient consent was obtained from participating centres.

Sequencing, variant filtering, and classification were conducted as previously described.¹⁹ Coding exons and intronic boundaries of 261 genes related to inherited cardiovascular diseases and SCD (see [Supplementary material online, Table S1](#)) were captured using a custom probe library (SureSelect Target Enrichment Kit for Illumina paired-end multiplexed sequencing method, Agilent Technologies, Santa Clara, CA, USA) and sequenced using the HiSeq 1500 platform (Illumina, San Diego, CA, USA) following Illumina protocols. The read depth of every nucleotide of genes related to the referring phenotype (including ALPK3) was >30 fold (mean 250× to 400×). Exons that did not fulfil this standard were additionally sequenced using the Sanger method. Predicted loss-of-function variants (frameshift, nonsense, and consensus splice site variants) in the latest reported ALPK3 isoform (NM_020778.5; NP_065829.4) were selected for further analysis. Bioinformatics analysis was performed by means of a custom pipeline including software for variant calling, genotyping, and annotation.

The statistical significance of the ALPK3 variant enrichment in cases vs. controls was tested using Fisher's exact statistics. The enrichment analysis was performed in the entire validation cohort (regardless of whether the patients were finally recruited or not) to avoid inclusion bias.

To check for technical artefacts in the enrichment analysis, we have evaluated their comparability through the quantification of the burden of rare synonymous variants in ALPK3tv between every compared group and no statistical differences were observed (results presented in the [Supplementary material online](#)).

HCM probands carrying candidate variants in ALPK3 and none in other genes were invited to participate in segregation studies. Clinical and genetic familial cascade screening was performed following written informed consent in those who agreed to participate. All the participating families belonged to the validation cohort.

We calculated two-point logarithm of the odds (LOD) scores for seven informative families with HCM ([Figure 1](#) and [Supplementary material online, Table S2](#)) by using the PARAMLINK package for R software, computed with the settings $\theta = 0$, phenocopy rate = 0.002 (prevalence of the disease in the general population) and indicated disease penetrance (0.80 and 0.95).²⁰ An indeterminate status was assigned to

Figure 1 Pedigrees for the families in which co-segregation analyses were performed. (A) Proband #36 (p.Glu1146Glyfs*12); (B) proband #23 (p.Trp1563*); (C) proband #37 (p.Glu1179Argfs*93); (D) proband #18 (p.Pro45Alafs*37); (E) proband #32 (p.Pro45Alafs*37); (F) proband #43 (p.Glu1098*); and (G) proband #38 (p.Lys184*). Arrows indicate the probands. Filled symbols, affected. N: not affected. Squares: males. Circles: females. Vertical bar inside symbol: ALPK3tv carrier. WT; wall thickness; LVNC; left ventricular non-compaction.

family members ≤ 45 years of age who did not meet clinical criteria for HCM and to family members with confounding cardiac diagnoses.

Kaplan–Meier curves for age at diagnosis were depicted with the information on both cohorts (validation and discovery) and were computed by means of the ‘survfit’ function in R. In *Figures 2 and 3*, we represent all individuals harbouring ALPK3tv variants (both probands and relatives).

Clinical characteristics and outcomes of patients with ALPK3tv in comparison to genotyped patients with HCM

Patients with ALPK3tv (probands and affected relatives from discovery and validation cohorts) with available follow-up data were compared to adult patients (≥ 18 years of age) with HCM with an available genotype and follow-up data, evaluated between 1986 and 2019.

Variants were classified as pathogenic, likely pathogenic, unknown significance, or likely benign/benign using the current criteria of the American College of Medical Genetics and Genomics.²¹ Patients with ≥ 1

pathogenic or likely pathogenic variant were designated as sarcomere positive, while those with no pathogenic or likely pathogenic variants were designated as sarcomere negative.

A detailed description of this cohort and definitions of the phenotype parameters analysed are provided in the [Supplementary material online, Methods](#).

Means for age at diagnosis, maximal wall thickness, and left atrial diameter were compared with one-way ANOVA and Tukey HSD or Games–Howell *post hoc* analysis, as appropriate. The frequency of categorical variables (male sex, ECG parameters, left ventricular systolic dysfunction defined as left ventricular ejection fraction $< 50\%$ and non-sustained ventricular tachycardia) was compared by Chi-square or Fisher’s exact test, as appropriate. Survival analysis for heart failure death and transplant was carried out using the Kaplan–Meier method and groups were compared using the log-rank test.

Histopathology analysis

Cardiac tissue was available and re-analysed from two patients who had a septal myectomy. Tissue was formalin-fixed and processed to

Figure 2 Kaplan–Meier estimates for age at diagnosis of HCM in probands and relatives with alpha-protein kinase 3-truncating variants (ALPK3tv). The analysis included non-affected relatives. “Time” represents age in years.

paraffin wax. Sections were cut at 4 μ m and stained with haematoxylin and eosin, Masson trichrome, and periodic acid-Schiff (PAS) stains. Immunohistochemistry was performed for desmin and plakoglobin. We additionally report the clinical findings for a skeletal muscle biopsy (left quadriceps) and cardiac muscle biopsy (myectomy) for two other patients (Supplementary material online, Table S3), for whom tissue was not available to re-analyse.

Results

The discovery cohort comprised 770 patients with HCM, aged 49.3 ± 15.9 years at diagnosis (median 51.6); 515 (67%) were male; 378 out of 589 where ethnicity was stated (64%) were white; 246 (32%) had rare variants in eight sarcomeric genes robustly associated with HCM (*MYH7*, *MYBPC3*, *TNNT2*, *TNNI3*, *MYL2*, *MYL3*, *TPM1*, *ACTC1*). Twenty-one patients carried multiple rare sarcomere variants.

ALPK3-truncating variants

Supplementary material online, Table S3 summarizes the genetic characteristics of patients with ALPK3tv. Figure 4 represents the distribution of ALPK3tv along the gene.

Discovery cohort

In the discovery cohort, 12 patients (1.56%) were heterozygous carriers of an ALPK3tv. All these variants were confirmed with Sanger sequencing. These variants were enriched when compared to the prevalence of truncating variants in the gnomAD population (12/770 HCM-discovery cohort vs. 74/75431 gnomAD) with an odds ratio (OR) of 16.11 [95% confidence interval (CI): 7.94–30.02; $P = 8.05 \times 10^{-11}$]. No copy-number variants in ALPK3 were detected. Three patients were found to harbour variants of uncertain significance (VUS) in sarcomere genes (Supplementary material online, Table S3): one patient with an *MYH7* missense variant

Figure 3 Scatter plot of age vs. maximum left ventricular wall thickness in ALPK3tv carriers. This graph was based on information available on all heterozygous carriers from both cohorts (validation and discovery, probands and relatives). The maximum left ventricular wall thickness was taken from magnetic resonance (or echocardiography results when magnetic resonance study was not performed). A positive correlation between maximum left ventricular wall thickness and age is seen for females. MLVWT, maximum left ventricular wall thickness.

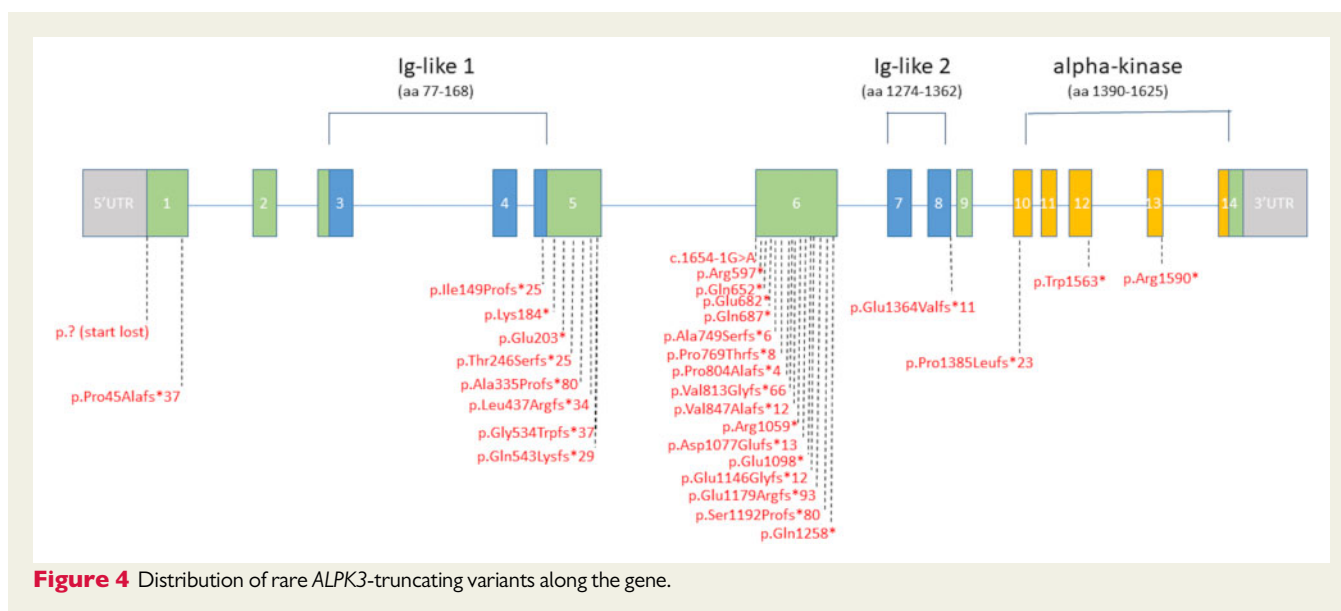

(#10) and two patients with an *MYBPC3* missense variant (#1; #11). No proband was found to carry a second rare missense ALPK3 variant.

Validation cohort

In the validation cohort, a total of 24 ALPK3tv were identified in 36 probands in simple heterozygosity, out of 4904 (0.86%) consecutive unrelated index cases who were sequenced with a genetic library including this gene. HCM was the diagnosis in 32 out of the 36 probands. The remaining 4 cases had other phenotypes: DCM ($n = 1$), ACM ($n = 1$), restrictive cardiomyopathy ($n = 1$) and Brugada syndrome ($n = 1$). From these 36 identified patients, 30 were finally recruited to this study, diagnosed with HCM ($n = 29$) and ACM ($n = 1$). One patient was homozygous for the truncating ALPK3 variant p.Trp1563* (c.4689delG); this case was not included in the enrichment analysis (where only heterozygous variants were analysed).

The prevalence of ALPK3tv found in simple heterozygosity was significantly higher in the HCM cohort (32/2047; 1.56%) than in disease control subjects/non-cardiomyopathy controls (1/1059; 0.09%), non-HCM cases (4/2857; 0.14%) and gnomAD database (74/75431; 0.1%), with an OR of 16.8 (95% CI: 2.79–682.77; $P = 2.375 \times 10^{-5}$), 11.32 (95% CI: 4.01–44.09; $P = 8.01 \times 10^{-9}$), and 16.17 (95% CI: 10.31–24.87; $P = 2.2 \times 10^{-16}$), respectively.

Two of the HCM patients with ALPK3tv in simple heterozygosity in the validation cohort were found to carry a second variant in a sarcomeric gene in digenic heterozygosity (Supplementary material online, Table S3) [*MYBPC3* VUS (p.Pro677Ser) (# 17), *MYH7* pathogenic variant (p.Arg869Cys) (# 39)]. One

case diagnosed with restrictive physiology was also a carrier of a *FLNC* variant (p.Gly2011Arg) (# 30). The remaining cases had no other candidate variant as a potential cause for their phenotype.

Recurrent variants

Four variants were particularly frequent in the discovery and validation cohorts combined: p.Arg1059* (five probands from different geographic origins, including the UK, Spain, and Latvia), p.Glu1179Argfs*93 (three probands, all from Spain), p.Trp1563* (c.4689delG, three probands, from Spain, including one patient homozygous for this variant).

Three (# 8, # 13, # 14) of the five patients harbouring the variant p.Arg1059* also had a missense variant, p.Arg86Trp. This fact, along with their similar frequencies in the gnomAD population, suggests that these two variants are in linkage disequilibrium and part of a haplotype; the effect of the nonsense variant usually prevails in these cases.

Clinical characterization of HCM patients with heterozygous *ALPK3*tv and comparison with a genotyped HCM cohort

Table 1 and Supplementary material online, Tables S3–S5 summarize the clinical characteristics of the 51 patients (probands and relatives) with *ALPK3*tv from both discovery and validation cohorts. In Table 1, the phenotype and outcomes are compared with sarcomere positive and sarcomere negative patients.

Demographic, ECG, and imaging characteristics

The age at diagnosis (56 ± 15.9 years) and sex distribution (69% males) of HCM patients with *ALPK3*tv were similar to sarcomere-negative and higher than sarcomere-positive patients.

From the initial WES discovery cohort, 6 out of 12 patients were white and 5 South Asian. We have stratified the enrichment

analysis in the discovery cohort by ethnicity as follows: for European (non-Finnish), 6/378 (1.59%) compared to 49/33718 (0.15%), OR 10.92, 95% CI: 3.79–25.72, $P = 3.54 \times 10^{-5}$; for South Asian, 5/88 (5.68%) compared to 3/2380 (0.13%), OR 44.75, 95% CI: 8.56–291.59, $P = 3.44 \times 10^{-6}$. In the validation cohort, one proband was black and the remainder were white.

The prevalence of voltage criteria for LVH (69%) in carriers of *ALPK3*tv was higher compared to sarcomere-positive patients and similar to sarcomere-negative patients. Short PR was more prevalent (10%) than for any of the other genotyped subgroups, as was the proportion of an apical/concentric hypertrophy pattern (60%) compared to asymmetric septal hypertrophy.

Six (12%) patients with *ALPK3*tv had resting left ventricular outflow tract obstruction and 3 of 49 (6%) had left ventricular systolic dysfunction (left ventricular ejection fraction <50%) at baseline evaluation; 3 patients developed left ventricular systolic dysfunction during follow-up. Eighteen (35%) HCM had >20 mm maximum left ventricular wall thickness and 16 (49%) had extensive myocardial fibrosis (assessed qualitatively as >15% of left ventricular segments affected) in 33 with cardiac magnetic resonance imaging. Figure 5 and Supplementary material online, Figure S1 show examples of a recurrent phenotype in this cohort.

Skeletal muscle involvement

Seven patients had raised serum creatine kinase out of 35 where it was determined (20%), one of whom was referred for skeletal muscle biopsy and had myopathic features and marked hypertrophic fibres with no evidence of inflammation (complete description in Supplementary material online, Table S4).

Outcomes

Follow-up time for patients with *ALPK3*tv and HCM was 5.3 ± 5.7 years. Fourteen patients (27.5%) were considered to be at high risk of SCD and were referred for an implantable cardioverter–

Means compared with one-way ANOVA. Frequencies compared by chi-square or Fisher's exact test, as appropriate.

defibrillator (ICD); two declined implant and no appropriate shocks have been registered during 4.0 ± 3.6 years of follow-up in the remainder. The patient with an ACM phenotype had an ICD implanted and had an appropriate shock. Four HCM patients (8%) were referred for cardiac transplantation, one of whom died of heart failure, one declined, one awaits and one was transplanted. One other patient died of heart failure.

A survival analysis for an outcome of heart failure death or transplant in patients with ALPK3tv showed a similar incidence compared to the sarcomere-positive population but significantly higher than in sarcomere-negative patients (Figure 6).

Family co-segregation and disease penetrance

ALPK3tv co-segregated with HCM in all seven available families. Combined LOD score was 2.99, indicative of significant segregation ($P < 0.05$).²² The family pedigrees are represented in Figure 1.

The information on the entire cohort suggests that ALPK3tv are associated with incomplete penetrance until the age of 75 years (Figure 2), when the cumulative percentage of diagnosed carriers increased to >95% among males and 80% among females. A positive correlation was observed for age and left ventricular wall thickness in females but not in males (Figure 3).

Histopathology

Histopathology analysis of the myocardial tissue in two probands (Figure 7 and Supplementary material online, Figures S2 and S3) showed cardiomyocyte hypertrophy with focal scarring and no significant cardiomyocyte disarray. There was endocardial fibrosis and the intramyocardial vessels were dysplastic. The cardiomyocytes were focally vacuolated in both patients around the areas of fibrosis, but vacuolation was also present in some non-fibrotic areas. Desmin and plakoglobin staining showed normal distribution patterns and intensities.

Discussion

In this study, we show that truncating variants in ALPK3 cause autosomal dominant HCM characterized by a severe cardiac phenotype with extensive myocardial fibrosis and progression to heart failure. Histopathological analysis of cardiac tissue confirmed extensive fibrosis and cardiomyocyte vacuolation with minimal myocyte disarray.

ALPK3 is a poorly studied protein, but from the limited data available, it seems to be involved in the phosphorylation of cardiac relevant transcription factors including HEY2²³ and in cardiomyocyte differentiation. Recent evidence has shown that ALPK3 participates in intercalated disc and sarcomere structural organization and murine

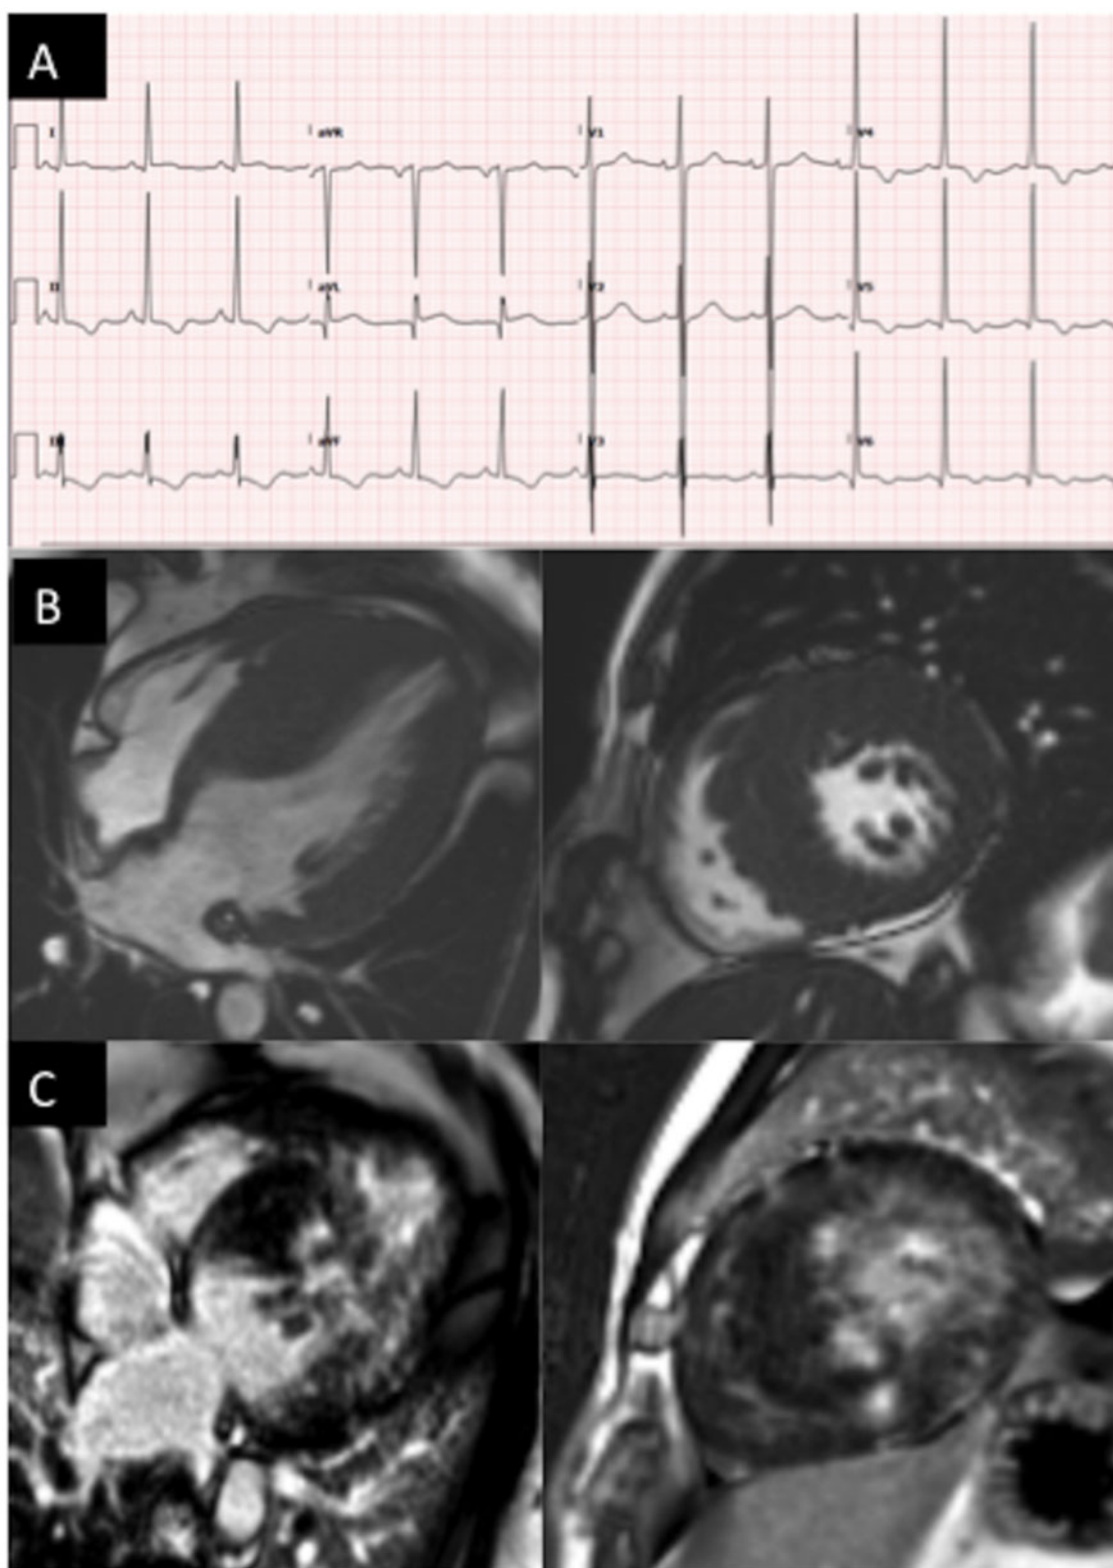

Figure 5 ECG (A), cine CMR image (B), and late gadolinium enhancement (C) images (four-chamber view on the left and mid short axis view on the right) of proband # 6 from the discovery cohort (*ALPK3* p.Gln1258*) illustrating some of the common phenotype traits of this cohort, including very high voltages on the ECG and extensive fibrosis. CMR, cardiovascular magnetic resonance; ANOVA, analysis of variance.

Figure 6 Kaplan–Meier analysis comparing incidence of an outcome of heart failure death and cardiac transplant between ALP3tv patients, sarcomere positive and sarcomere negative. Patients with ALPK3tv (probands and affected relatives from discovery and validation cohorts) with available follow-up data (45 out of 51) were compared to adult patients with HCM with available genotype and follow-up data.

knock-out models show ventricular hypertrophy and impaired contractility.^{3,24} Abnormal calcium handling has been observed in cardiomyocytes differentiated from stem cells carrying homozygous ALPK3 variants.⁴

Biallelic ALPK3tv were first identified in five children (four diagnosed *in utero*) presenting with severe, early-onset cardiomyopathy. Three died from heart failure between 35 weeks of gestation and 5 days after birth, and two survived up to the age of 11 years with severe concentric HCM.³ Similar phenotypes were reported in other small case series of biallelic ALPK3tv carriers.^{5–7} A recently expanded cohort of 19 patients with biallelic ALPK3 variants, including 9 of the previously published paediatric patients (10 new probands including two compound heterozygous adults), displayed similar phenotypes, with most presenting initially as DCM without LVH and then evolving to HCM with impaired systolic function associated with extracardiac manifestations including scoliosis, facial dysmorphism and cleft palate.⁸ This series included compound heterozygotes with missense variants, for which pathogenicity is more challenging to ascertain. In our study, we did not analyse patients with only rare missense ALPK3 variants.

We have identified ALPK3tv in 1.56% of HCM probands and confirmed significant enrichment compared to controls and gnomAD. This is in line with data reported in a recent publication, where an increased burden against gnomAD was reported for a Dutch population of 1548 index patients with various types of cardiomyopathy and a US proband cohort of 149 cardiomyopathy patients, including 129 with HCM (8 carrying ALPK3tv)⁸; however, the phenotypes of the heterozygous patients were not described in this report. Importantly, we have demonstrated co-segregation for ALPK3tv in heterozygosity.

All variants in our study were absent or very rare in gnomAD.¹⁷ p.Arg1059*, a stop-codon variant, was previously reported^{3,8} as a cause of autosomal recessive cardiomyopathy (p.Arg1261*, in the previous isoform version). Previously published variants also include the very recently reported p.Trp1563* (previously published in homozygosity, p.Trp1765* in the previous isoform), p.Pro804Alafs*4

(p.Pro1006fs*4 in the previous isoform), and p.Lys184* (p.Lys386*) in a US HCM cohort and p.Pro1385Leufs*23 (p.Pro1587Leufs*23) in a Dutch patient with ACM.⁸

Four variants showed a relatively high prevalence. One was the aforementioned p.Arg1059*, present in five of the patients in our cohort and another two truncating variants were present in 3 patients each.

Truncating variants were mainly stop codon and frameshift, with only 1 splice-site variant identified. ALPK3tv were mainly present in the largest exons 5 and 6, but were also additionally scattered throughout the gene, including distinct functional domains. No truncating variants were found in the last exon. These data suggest haploinsufficiency due to RNA nonsense mediated decay as the main mechanism of pathology.

To date, clinical descriptions of heterozygous carriers of ALPK3tv have shown variable findings with only 5 of 37 previously published heterozygous carriers fulfilling HCM criteria⁸ and a very recent case report describing co-segregation of a heterozygous ALPK3tv in one family.¹⁴ Evidence from our study points to possible incomplete (age-related) penetrance, which is quite usual in most autosomal dominant HCM genes, and might explain the variable penetrance in smaller studies.

This study suggests that the HCM phenotype associated with ALPK3tv is characterized by a high prevalence of apical and concentric patterns of LVH and a low prevalence of left ventricular outflow tract obstruction. Almost half of patients had extensive fibrosis on cardiac magnetic resonance. Although not directly comparable as we did not perform a quantitative assessment, this still seems to be a much higher proportion than is reported in large cohort studies, including the recently published HCM Registry study, where 9.1% had extensive scar.²⁵ The extensive fibrosis was also confirmed in the histopathology analysis.

One-fourth of ALPK3tv carriers was judged to be at high risk of SCD and were referred for ICD implantation; however, no appropriate shocks were reported during a relatively short follow-up period. Thus, the arrhythmic risk profile associated with this phenotype remains to be ascertained, particularly in comparison with other genetic causes of autosomal dominant HCM.

Twelve percent of ALPK3tv carriers had left ventricular systolic dysfunction at baseline or during follow-up and almost 10% were referred for cardiac transplantation. The incidence of end-stage heart failure during follow-up was similar to a cohort of patients without a detectable pathogenic genetic variant, but survival analysis demonstrated a similar rate of heart failure endpoints when compared to carriers of pathogenic sarcomere gene mutations. While these data should be interpreted with caution as the ALPK3tv cohort was much smaller and the follow-up duration shorter than in the comparator populations, the higher prevalence of myocardial scar and frequent referral for transplantation suggests that the risk of progressive myocardial dysfunction is high in ALPK3tv carriers.

When stratifying the enrichment analysis for ethnicity in the discovery cohort, the OR for South Asians was 44.75 compared to 10.92 in whites. This observation must be confirmed in other cohorts, but it is of potential relevance as some non-white cohorts including South Asians tendentially show a larger prevalence of genotype elusive (VUS and genotype negative) patients,²⁶ where the discovery of novel causal genes would have a significant clinical impact.

Figure 7 Histopathology images for index patient # 23. (A) A section of myocardium stained with Masson trichrome. There are four dysplastic vessels in the field. The muscle of the tunica media is irregularly distributed around the circumference of the vessels and in places is almost absent. There is accompanying mural fibrosis. The surrounding myocardium shows patchy interstitial fibrosis and focal myocyte vacuolation. (B) Low power view of myocardium showing a collagenous scar. The scar tissue contains thin-walled ectatic vessels and interdigitates with the surrounding myocardium that is vacuolated and shows foci of fine interstitial fibrosis (Masson-trichrome stain). (C) Low-power view of myocardium stained with Masson trichrome. The field shows an area of central pallor caused by a localized focus of vacuolated myocytes. There is fine interstitial fibrosis. There is no myocyte disarray. A dysplastic vessel is visible at the left edge of the field. (D) High-power view of a section of myocardium stained with Masson trichrome. It contains myocytes with irregular central areas of clearing of the cytoplasm to give vacuoles. Some of the vacuoles are traversed by fine strands of cytoplasm and other contain abundant normal mitochondria (seen as small red dots). Many of the vacuoles, however, are empty. Periodic acid-Schiff staining was negative. Desmin and plakoglobin staining was normal ([Supplementary material online](#)).

In our cohort, the phenotypes for the single homozygous patient and for the double heterozygotes with sarcomere variants did not seem substantially different from the heterozygous *ALPK3*tv patients. This is inconsistent with previous publications where homozygous patients were characterized by a severe form of cardiomyopathy with prominent extra-cardiac features and childhood onset.

It has been suggested that patients with HCM and no detectable pathogenic mutations in sarcomere genes are likely to have relatively benign disease caused by an oligogenic/polygenic predisposition under a higher influence of environmental modifiers¹²; the corollary is that the screening strategies in genotype-negative families can be less stringent. However, our demonstration that disease in patients without sarcomere mutations can be caused by penetrant monogenic variants with a prognosis that is at least similar to and possibly worse than that associated with sarcomere gene mutations, shows

that this is an oversimplification. Relatives that carry heterozygous *ALPK3*tv variants should be followed-up in accordance with current guidelines for pathogenic sarcomere variant carriers.

Histological findings in cardiac tissue reported in two previous studies from homozygous patients included features such as focal cardiomyocyte hypertrophy, and subendocardial fibroelastosis.^{4,8} Immunohistochemistry in one publication showed disrupted plakoglobin and desmoplakin in cardiac tissue, suggesting a downstream effect of abnormal *ALPK3* function on desmosome structure;³ it was also suggested that the effect on desmosome might partially contribute to the arrhythmogenic trait observed. We have re-analysed the cardiac tissue from two of our patients that had a septal myectomy and also observed myocyte hypertrophy and fibrosis without prominent cardiomyocyte disarray. Unexpectedly, we observed PAS negative vacuoles (indicating absence of glycogen), the significance of which remains to be

determined. Interestingly, we observed a high prevalence of short PR interval compared to other genotyped patients, which is considered a red-flag for some inborn errors of metabolism causing HCM.¹ We did not observe an abnormal pattern of plakoglobin or desmin staining.

Only one of our patients had clinically apparent skeletal muscle involvement, but one-fifth of the proband cohort had raised plasma creatine kinase indicating sub-clinical skeletal muscle disease. This has not been described in other cohorts, where extra-cardiac findings in biallelic variant patients consisted mainly of dysmorphic features.⁸ Histopathological assessment of peripheral (quadriceps) muscle from a homozygous patient in a previous report showed normal findings in contrast to that of the heterozygous patient in our cohort, where myopathic features were described. It is possible that the genetic location of the variants might generate different phenotypes but more studies are required to clarify the relation between ALPK3tv and skeletal muscle involvement.

Limitations

The cohort of patients with ALPK3tv had a relatively short follow-up, mostly reflecting the very recent application whole-exome sequencing strategies or the inclusion in large panels as a possible candidate gene. This resulted in a limited power to confirm the observed tendency for left ventricular systolic dysfunction and a higher number of heart failure-related events. The absence of arrhythmic events despite of the high proportion of ICD referrals, fibrosis and non-sustained ventricular tachycardia at baseline and follow-up did not allow modelling of SCD risk in patients with this particular genotype.

In common with other multicentre studies, the data collection is inevitably subject to a degree of heterogeneity. Particularly for a more accurate and quantitative comparison of fibrosis in the cardiac magnetic resonance imaging data between this cohort and other genotyped HCM patients, a central imaging laboratory analysis should be applied.

Previously, we have reported that ALPK3-deficient cardiomyocytes in homozygosity display altered contraction kinetics.⁴ Further studies on these models are essential to further refine the pathogenicity of rare ALPK3 variants in heterozygosity.

Conclusions

Heterozygous ALPK3tv are associated with an autosomal dominant form of HCM that is characterized by a distinctive clinical phenotype.
