

Lethal violence deep in the human lineage

Researchers estimate that the incidence of human lethal violence at the origin of our species was about six-times higher than the average mammal, but about as violent as expected given our Great Ape ancestry.

Mark Pagel

Are humans naturally violent as the 17th century philosopher Thomas Hobbes thought¹, with our condition in the state of nature being one of ‘continuall feare, and danger of violent death’, or, as Rousseau imagined a century later², neither good nor bad but moulded by their environments?

Social scientists have long confronted this question by examining large numbers of individuals from a variety of circumstances and then trying to average out extraneous factors to see what’s leftover. In a paper published in this issue, Gomez and colleagues³ adopt a different approach: they use phylogenetic comparative methods from evolutionary biology⁴ to reconstruct humans’ most probable ancestral rates of lethal violence at the origin of our species roughly 160,000 to 200,000 years ago. They conclude that we were about as violent as expected from our Great Ape and Primate past.

One of Darwin’s great insights was that all living things evolve by a process of descent with modification such that species give rise to daughter species that inherit many of their ancestors’ traits. Comparative biologists can use the family trees or phylogenies that arise from this process to infer the history of biological evolution, including dating past events, and reconstructing probable ancestral features of species that lived hundreds of thousands to hundreds of millions of years ago.

Gomez and colleagues applied comparative statistical techniques to a phylogeny of the Mammals (Figure), which includes the Primates, the order of mammals comprising the monkeys, the Great Apes, and the lineage that leads to modern humans. They compiled information on more than four million deaths in 1024 mammal species drawn from 137 or 80% of mammalian families including mice, horses, bats, rabbits and monkeys. Information for humans came from 600 studies including Palaeolithic samples, New and Old World Neo- and Mesolithic sites, Bronze and Iron age samples and anthropological sources from the past few centuries.

The authors then calculated for each species, the proportion of deaths, out of all counted, attributable to violence from a member of the same species. Including only acts of within-species violence is important. Lions and tigers routinely – we would say it is in their nature – kill members of other species, but are less often lethally violent towards each other. Within-species violence therefore gets at what Hobbes and Rousseau disagreed about, and is interesting because members of the same species typically have all of the same weapons, making violence among them risky.

Using the values from contemporary species, the authors reconstructed the rate of lethal violence at the origin of mammals at about 0.30% or approximately 1 in 300. Rates of lethal violence then rise steadily throughout the Mammalian phylogeny (Figure) as the reconstructed ancestors draw closer to Primates and the Apes: the rate is ~1.1% for the ancestor of primates, rodents and hares, 2.3% for the common ancestor of primates and tree shrews and roughly similar at 1.8% for the ancestor of the Great Apes. The increases in lethal violence coincide with species having increasing amounts of group living and territoriality: group living places individuals routinely in close contact, and territoriality means that groups might potentially compete over resources. Finally, Gomez et al. reconstruct the incidence of human lethal violence at the origin of our species at 2% or about six times higher than the Mammalian value.

The Gomez et al. study risks being misunderstood, and therefore misrepresented, so it is important to be clear about its interpretation. Humans emerged from an evolutionary lineage with a long history of higher than average levels of lethal violence towards members of the same species. Even so, Rousseauians, might step in to say that our species' figure of 2% tells us nothing about our innate tendencies, it might merely reflect a calculated or environmentally-induced response to the environments in which early humans lived.

Perhaps, but this objection falters when we appreciate that animals that live in particular kinds of environments over long periods of time tend to adapt to those environments genetically, and this makes some kinds of outcomes more likely than others: a wolf raised as a sheep will likely one day turn on its fellow sheep. So here, the authors' finding of a steady increase in violence throughout the many tens of thousands of years of the Mammalian tree is important – there was plenty of time for human ancestors to acquire and then bequeath to us genetic adaptations towards lethal violence. In this light, it is worth noting that our nearest living relatives, the chimpanzees (*Pan troglodytes*), with whom we share around 98% identity of our gene sequences, form packs to hunt down and kill stray males from other chimpanzee tribes⁵ and their hunting parties bear resemblances to human hunter-gatherer warfare⁶.

Others will object that it is difficult to derive reliable estimates of lethal violence. Anticipating this, the authors test for several biases including variation in sample sizes and sampling effort, and uncertainty about the phylogeny of mammals itself, showing that none of these qualitatively alters their results. The authors also find that species we expect to be violent, like the carnivores, are violent, and species we do not expect to be violent, like rabbits and whales, tend not to be. That, and they find that rates of violence are heritable in the Mammalian phylogeny.

Still, Rousseauians might have a corner to fight. The authors' estimates of lethal violence in humans vary widely over time, probably too quickly to be attributable to genetic changes. Their Palaeolithic samples (12 to 50 kya) have rates very close to the 2% predicted at the origin of our species, but then rates rise to as high as 15 to 30% (with high uncertainty) in samples from between 3000 and 500 years before the present, before declining in contemporary populations. The rise tends to correlate with moving from pre-societal (state of nature) to tribal and then organised political societies with a warrior class.

Where does this leave us? Social scientists take note: the Gomez et al. study, by opening up a new approach to uncovering the origins of human violence, gives good grounds for believing we are intrinsically more violent than the average mammal, and their findings fit well with anthropological accounts describing pre-state human societies as being engaged in 'constant battles'^{7,8}. But societies can also modify our innate tendencies. Rates of homicide in modern societies⁹ with police forces, legal systems, jails and strong cultural mores that reject violence are, at less than 10 in 100,000, or 0.01%, about two-hundred times lower than Gomez et al. predict for our state of nature. Hobbes has landed a serious blow on Rousseau but not quite knocked him out.
