25 Abstract

26

27 Early successional birds have declined in the northeastern United States due to the 28 regeneration of forest on abandoned farm fields and the suppression of natural 29 disturbances that once provided appropriate habitat. These species have become 30 increasingly dependent on early successional habitats generated by such activities as 31 timber harvesting. Recent approaches of timber harvesting, which range from single tree 32 harvesting to clearcutting, create forest openings of different sizes and configurations 33 embedded in landscapes with different land use patterns. To assess the importance of 34 forest openings created by timber harvesting for shrubland birds, we surveyed birds on 35 50-m radius plots in 34 harvest sites (0.5 - 21 ha). We collected data on multi-scaled 36 habitat variables ranging from plot-level vegetation characteristics to land use patterns 37 within 1 km of each study site. We also monitored mating and nesting success of Blue-38 winged Warblers (Vermivora pinus) in 10 forest openings. 39 The abundance of most shrubland species was influenced by plot-level habitat

40 variables, such as tree density and vegetation height, rather than shrubland area or the 41 composition of land uses in the surrounding landscape. Only Eastern Towhees (*Pipilo* 42 *erythrophthalmus*) were more frequent in survey plots in larger forest openings. In 43 contrast, neither abundance nor reproductive activity of Blue-winged Warblers was 44 correlated with the size of the forest opening. Their abundance was negatively related to 45 vegetation height, however. Only 54% of the territorial male Blue-winged Warblers in 46 forest openings were mated. We documented relatively low nest success rates of 21.1% 47 during the egg laying and incubation nest stages, but increased success rates during the

48 later stages of nest development.

49	Our results indicate that even small forest openings with low vegetation provide
50	habitat for Blue-winged Warblers and other shrubland birds. The overall reproductive
51	rate of territorial male Blue-winged Warblers in forests openings was low during the two
52	years of the study, however. Further studies are needed to assess the long-term value of
53	this type of habitat for sustaining shrubland bird populations.

57	
58	1. Introduction
59	
60	Forestry in southern New England is increasingly dominated by uneven-aged
61	management characterized by selective cutting of individual trees or small groups of trees
62	(DeGraaf et al., 1992). Single-tree and group selection harvesting is also becoming more
63	common on both public and private land in many other regions in eastern North America
64	in response to public concerns about the visual and environmental impacts of clearcuts,
65	especially the problems of soil erosion, stream sedimentation, and degradation or loss of
66	habitat for forest species. Ironically, many declining species in eastern North America
67	depend on early successional woody habitats such as regenerating forest, and these
68	species generally benefit from even-aged management techniques that create large
69	expanses of open habitat (Hunter et al., 2001, Dettmers, 2003). An important question

for forest managers is whether these species can also use the smaller openings that are
created as a result of new methods and regulations for timber harvesting.

72 Numerous studies have documented that recent clearcuts support a diversity of 73 birds that are "shrubland specialists" (species that are restricted to low, woody 74 vegetation) (Conner and Adkisson, 1975; Webb et al., 1977; Crawford et al., 1981; 75 Hagan *et al.*, 1997; Yahner, 1997). These species are rare or absent in mature forests, so 76 they depend upon some sort of disturbance, such as fire, windstorms, severe flooding, or 77 logging, to generate low, woody habitat (Askins, 2002). Shrubland species are also 78 generally rare or absent in the small openings in forests created by single-tree and group 79 selection harvesting (Annand and Thompson, 1997; Rodewald and Smith, 1998: 80 Robinson and Robinson, 1999; Costello et al., 2000; Moorman and Guynn, 2001). These 81 small openings are colonized by only a few species of shrubland specialists and forest-82 edge species along with species such as the Hooded Warbler (Wilsonia citrina) that are 83 best characterized as canopy gap specialists (Annand and Thompson, 1997; Germaine et 84 al., 1997). Canopy gap specialists generally are associated with mature forests, not 85 extensive open habitats, because they are often concentrated in small, shrubby openings 86 created by tree falls. Thus, different harvesting methods favor different sets of bird 87 species.

Another approach to reducing the negative environmental effects of even-aged management is to shift from large clearcuts to small clearcuts (including patch cuts in the 0.5 - 2 ha range). This approach has been adopted in state forests in Connecticut, where clearcuts are generally no larger than 4 ha (10 acres). Compared to large clearcuts, small clearcuts reduce problems with soil erosion and stream sedimentation while still favoring

93 regeneration of commercially important oaks (which grow better in open, sunny 94 conditions (Meadows and Stanturf, 1997)). If these small clearcuts provide habitat for 95 shrubland birds, then they may be preferable to individual or group selection cuts in 96 regions where conservation of shrubland species is a high priority. The pressing question 97 is how large an opening is needed to provide appropriate and productive habitat for 98 shrubland birds. Rudnicky and Hunter (1993) addressed this question by surveying bird 99 populations in standardized plots in clearcuts with a wide range of areas (2 - 112 ha) in 100 Maine. When they included all of their sites in the analysis, they found that the 101 frequency of occurrence of particular species was not related to clearcut area. When the 102 analysis was limited to clearcuts  $\leq 20$  ha, however, many species showed positive trends 103 in frequency of occurrence as clearcut area increased, suggesting that these species may 104 be sensitive to clearcut area for small clearcuts. In a mist-net study of regenerating 105 clearcuts in longleaf pine forests in South Carolina, Krementz and Christie (2000) 106 carefully standardized sampling effort for all of their measures of bird abundance and 107 productivity. They found no relationship between area of clearcuts and either abundance 108 or productivity (as measured by juvenile: adult ratios) of scrub-successional birds for 109 clearcuts that ranged in area from 3 to 57 ha. In contrast, Rodewald and Vitz (2005) 110 found weak evidence that several species of shrubland birds were less frequent in mist net 111 samples from small clearcuts than in samples from large clearcuts. They found stronger 112 evidence that shrubland birds tended to avoid the area near the forest edge, which would 113 tend to reduce densities in small or irregularly shaped clearcuts. Thus, the limited 114 number of studies that address this question do not provide a clear answer about whether 115 the area of habitat patches should be an important management concern.

116 The distribution and abundance of early successional birds is potentially 117 determined not only by vegetation characteristics and the area of forest openings, but also 118 by the amount and pattern of early successional habitats in the surrounding landscape 119 (Lichstein *et al.*, 2002). Habitat selection by birds often occurs at multiple spatial scales, 120 and may be influenced by habitat variables both within and surrounding habitat patches 121 (Cody, 1985). Although a substantial amount of research has focused on the landscape-122 scale effects of habitat selection in birds of mature forests, not much is known about the 123 importance of surrounding landscape features in explaining shrubland bird distributions. 124 The objectives of this study were to 1) determine the minimum area of early 125 successional habitat required by different species of shrubland specialists, 2) test whether 126 the size of openings is related to reproductive success by monitoring the mating and nest 127 success of the Blue-winged Warbler (Vermivora pinus), a shrubland specialist, and 3) 128 analyze the relative importance of habitat characteristics in explaining bird distributions 129 at three spatial scales (i.e., plot, patch, and landscape scales). Our broader goal was to 130 determine whether small clearcuts provide suitable habitat for a diversity of early 131 successional birds, and, if so, whether their value for these species diminishes if the 132 clearcuts are too small or if they are too isolated from other early successional habitat. 133

134 **2. Methods** 

135

136 2.1 Study Areas

137

138	Study sites consisted of 34 forest openings located in the Nehantic, Pachaug,
139	Cockaponset, Salmon River, and Meshomasic state forests in southeastern Connecticut.
140	These clearcuts, deferment cuts, shelterwood cuts, and wildlife openings were created
141	and managed by the Connecticut Department of Environmental Protection. All study
142	sites were openings dominated by low, woody vegetation surrounded by mature forest.
143	They ranged in size from $0.6 - 21$ ha and had been created by harvests during the
144	preceding three to 11 years. We avoided group selection cuts (which are <0.6 ha)
145	because previous studies showed that these primarily support mature-forest and canopy-
146	gap specialists rather than shrubland species, and thus are different from larger openings
147	(Costello et al., 2000). Adjacent study sites were separated from one another by at least
148	10 m of forest. The greatest distance between study sites was 61 km. The average
149	distance from other forest openings (including other study sites) was 235 m, and all study
150	sites were at least 100 m from powerline rights-of-way or other shrubby openings.
151	

....

#### 152 2.2 Abundance and reproductive success of birds

153

In 1997, we determined densities of breeding shrubland songbirds on 50-m, fixedradius circular plots (Bibby *et al.*, 2000) near the center of each forest opening. Each survey plot was visited once during the early breeding season (28 May to 13 June) and once during the late breeding season (16 June to 7 July), with a separation of at least three weeks between visits. We conducted surveys between 0530 and 0930 Eastern Daylight Time (EDT). Surveys began two minutes after arriving at the site and lasted for 10 min. We did not survey birds during inclement weather, such as rain or high wind (>15 km/hr)

161 (Vickery *et al.*, 1994). Locations and movements of all individual birds were noted for
162 the first and second halves of the observation period. We used the maximum number of
163 individuals of a particular species recorded during the 10-min observation periods during
164 the two visits as a measure of relative abundance for each study area.

165 We conducted spot-mapping and nest searches to assess the reproductive success 166 of Blue-winged Warblers in a total of 10 openings with comparatively low, woody 167 vegetation. In 1998, we surveyed five clearcuts ranging in size from 0.7 - 16.7 ha. In 168 1999, we surveyed five different openings ranging in size from 0.6 - 7.2 ha. Each site 169 was visited at least once per week between 20 May and 17 July. We used the following 170 methods to assess reproductive activity of Blue-winged Warblers within each study area: 171 (1) spot mapping of individual breeding territories (Robbins, 1970), (2) recording male 172 mating success (i.e., whether a male was associated with a female at least once during the 173 breeding season), (3) recording direct evidence of nesting activity (i.e., carrying nest 174 material, fecal sacs, or food), and (4) locating and monitoring nests to determine nesting 175 success. These measures were used to determine rates of mating success, nesting 176 activity, and nest success for each Blue-winged Warbler territory. 177

178 2.3 Vegetation Surveys

179

In conjunction with the bird surveys conducted in 1998, we performed vegetation surveys in each bird survey plot. We used the line-intercept method to determine plant species composition and percent cover of different plant species (Brower and Zar, 1977). A 25-m transect was set up in a random compass direction from the center of each bird

184 survey plot. We recorded the linear distance of the transect covered by each plant 185 species, including all foliage that physically touched or overlay the transect (Brower and 186 Zar, 1977). Total intercept lengths were used to estimate percent cover for each plant 187 species. At 1-m intervals we recorded the ground cover as leaf litter, dead wood, herb, 188 bare ground, grass, or other. To determine the average canopy height, we recorded the 189 maximum vegetation height at 5 m intervals along the transect using a meter stick or a 190 rangefinder and clinometer. In addition, we recorded the numbers of live trees and snags 191 with > 25 cm diameter at breast height (dbh) within the 50-m-radius survey plot. 192 We implemented an alternative vegetation sampling method that emphasizes 193 vertical vegetation structure for use in the study of reproductive success in Blue-winged 194 Warblers. A vertical profile of foliage density was determined at 20 random points 195 within each Blue-winged Warbler territory. At each point, the number of contacts 196 between living vegetation and a pole was recorded for the following height intervals: 0 – 197 0.25 m, 0.25 - 0.5 m, 0.5 - 1.5 m, 1.5 - 3.0 m, 3.0 - 6.0 m, 6.0 - 8.0 m, and > 8.0 m198 (Morimoto and Wasserman, 1991). This permitted a comparison of the vegetation 199 profiles in different Blue-winged Warbler territories.

200

201 2.4 Patch and landscape characteristics

202

We used aerial photographs (1995-1996; American Reprograpaphics, Denver, CO) to determine the area of the forest opening and land use patterns in the region around the study area. We calculated the total area of residential developments, farmland, and clearcuts within 1 km of the periphery of each study site. In addition, we measured a

number of proximate landscape features including distances to the closest house, farm,clearcut, road, and powerline corridor within 1 km of the study site.

209

210 2.5 Statistical Analyses

211 To summarize information on habitat variables, we used separate principal 212 component analyses (PCA) at three different spatial scales. Five variables (percent cover 213 of trees, shrubs and herbs; tree density; and average canopy height) were used for the 214 plot-level scale, 3 variables (area of opening, time since final harvest, and distance 215 around perimeter/area of opening) were used for the patch-level scale, and six variables 216 (total area [ha] of residential developments and clearcuts within 1 km of the site; 217 distances [m] to nearest residence, road, powerline, and clearcut) were used for the 218 landscape-level scale. We analyzed landscape variables within a radius of 1 km 219 assuming that this distance would reflect (within an order of magnitude) dispersal 220 distances from natal to breeding areas for young songbirds and as a measure of the 221 immediate landscape context surrounding each study site. Natal dispersal distances are 222 not known for Blue-winged Warbler, but averaged 1.13 km for Prairie Warbler (Nolan, 223 1978: 463), which is another shrubland specialist.

By performing separate PCAs for the three different spatial scales, we maintained a sample to variable ratio of at least 3:1 (McGarigal *et al.*, 2000). Data for each variable were checked for normality using Q-Q plots in SPSS (Version 10), and transformed if necessary to approximate normality. Transformed variables were used in PCA for tree, shrub and herb cover (arcsine); canopy height and tree density (ln); and clearcut and residential area (square root).

230 Factor scores from the three principal component analyses were used as 231 independent variables for multiple regression analyses of the abundance of particular bird 232 species and for the overall abundance of groups of ecologically similar species. We 233 completed separate regression analyses for shrubland specialists (species largely 234 restricted to low, woody vegetation), shrubland generalists (species found both in low, 235 woody vegetation and other habitats), and mature-forest species (Table 1). We also 236 analyzed the relationship between Brown-headed Cowbird abundance and the abundance 237 of snags that had been retained in forest openings during timber harvests to enhance 238 habitat for cavity-nesting birds and other wildlife. Female cowbirds use high perches to 239 search for host nests (Norman and Robertson, 1975), so openings with numerous snags 240 may provide better breeding habitat for cowbirds than openings with few or no snags. 241 Differences in mating success and nesting activity were compared at two spatial 242 scales, among individual bird territories (n = 28) and forest openings (n = 10). Our null 243 hypotheses were that mating success, nesting activity and nest success rates are the same 244 in forest openings regardless of their area and do not differ between territories regardless 245 of vegetation structure. Spot mapping of individual bird territories allowed us to 246 document male mating status and nesting activity on individual territories. 247 We used a general linear model (GLM) function in R to perform a logistic 248 regression to determine whether foliage density influenced mating success and nesting 249 activity in individual territories (Hosmer and Lemeshow, 1989; R Development Core 250 Team, 2004). In the GLM model, mating success (e.g., a territory without mate = 0, a 251 territory with a mate = 1) and nesting activity (e.g., a territory with no evidence of nesting 252 = 0, a territory with evidence of nesting = 1) is provided as a binary dependent variable

253 and the foliage density categories were used as explanatory variables. We used Pearson 254 product-moment correlation analysis to determine if any of the foliage density variables 255 were highly correlated; only uncorrelated variables were entered into the GLM model. 256 Multiple regression analyses and Fisher's Exact Tests were used to test the 257 effects of forest opening area and age of the opening (time since final harvest) on mating 258 success and nesting activity (R Development Core Team, 2004). Study sites were also 259 re-classified into sites  $\leq 4$  ha and sites > 4 ha to allow for the use of the Fisher's Exact 260 Test to test for differences in the number of territories with evidence of mating or nesting 261 in small and large forest openings. This classification separates very small openings (0.6 262 -2.2 ha) that potentially could accommodate only one or two Blue-winged Warbler 263 territories from larger openings (4.1 - 16.7 ha) that potentially could accommodate more 264 territories. (According to Canterbury et al. [1995, as cited in Gill *et al.*, 2001], the 265 average territory size for Blue-winged Warblers was 1.1 ha in a study area in Ohio.) We set an a priori significance level of  $\alpha = 0.05$  and a marginal significance level of 0.10 > P266 267 > 0.05 for these analyses.

268 Nests were considered successful if at least one fledged young was observed or if 269 the nest was found empty between visits and the nestlings were sufficiently well 270 developed to assume successful fledging. We assumed predation or nest failure when 271 eggs or nestlings too young to have fledged disappeared. We developed three candidate 272 models to estimate stage-specific daily survival probabilities for three different nest 273 stages (Stanley, 2000; 2004). The nest stages included egg laying (begins with the laying 274 of first egg and ends with incubation), incubation (begins with the onset of incubation) 275 and ends with hatching), and nestling (begins with hatching and ends when the nestlings

276	fledge) (Stanley, 2004). All models allowed for the joint estimation of stage-specific
277	survival probabilities for all three nest stages including egg laying ( $\rho_0$ ), incubation ( $\rho_1$ ),
278	and nestling ( $\rho_2$ ) stages, even when the exact time of nest failure is unknown (Stanley,
279	2004). The first model was the global model and estimated separate survival
280	probabilities for all nest stages ( $\rho_0, \rho_1, \rho_2$ ), the second model assumed equal
281	survivorship in the egg laying and incubation stages ( $\rho_0 = \rho_1$ , $\rho_2$ ), and the third model
282	assumed constant survivorship throughout the entire nesting period ( $\rho_0 = \rho_1 = \rho_2$ ).
283	The third model is equivalent to calculating nest success using the traditional Mayfield
284	method (Mayfield, 1961; Mayfield, 1975) and Johnson's (1979) formula to calculate
285	standard deviations. For all models, we specified an egg laying stage of 4 days,
286	incubation period of 11 days, and a nestling period of 9 days (Will, 1986). Maximum-
287	likelihood parameter estimates and standard errors were obtained using SAS PROC
288	NLIN (SAS Institute, 1989) (see Stanley [2004] for program details). We evaluated
289	model performance by calculating the $AIC_c$ value for each model (Hurvich and Tsai,
290	1989; Burnham and Anderson, 2002).
291	
292	3. Results
293	
294	3.1 Relative abundance of Different Species in Openings

The most abundant species of birds on survey plots in 34 forest openings were
three shrubland generalists (Gray Catbird [*Dumetella carolinensis*], Eastern Towhee

298 [*Pipilo erythrophthalmus*], and Common Yellowthroat [*Geothlypis trichas*]) and two

299 shrubland specialists (Chestnut-sided Warbler [Dendroica pensylvanica] and Blue-

300 winged Warbler) (Table 1). Another shrubland specialist, the Prairie Warbler (Dendroica

301 *discolor*), was infrequent at these sites. Brown-headed Cowbird was the most abundant

302 bird at these sites if both males and females are counted (Table 1), but these counts

303 included large numbers of males in highly conspicuous flocks. Female cowbirds are a

304 better measure of cowbird abundance and impact on host populations because they have

305 discrete (albeit overlapping) home ranges (Lowther, 1993) during the breeding season,

306 and they lay eggs in the nests of other species. The abundance of female cowbirds was

307 relatively low (Table 1). [INSERT TABLE 1]

308 Several species of birds typically associated with closed-canopy forests or forest

309 with canopy gaps (Black-and-white Warbler [Mniotilta varia], Wood Thrush [Hylocichla

310 mustelina], Veery [Catharus fuscescens], Great Crested Flycatcher [Myiarchus crinitus],

311 American Redstart [Setophaga ruticilla], and Red-eyed Vireo [Vireo olivaceus]) were

312 recorded in forest openings (Table 1). Most of these species were infrequent in openings,

313 but Black-and-white Warblers were fairly common.

314

315 3.2 Relationship between Habitat Variables and Bird Distributions

316

Using principal component analysis, we were able to reduce the number of habitat variables for use in multiple regression analysis from 14 to 5. The first two principal components for plot-level variables accounted for 70% of the variance in the original variables, the first principal component for patch-level variables accounted for 68% (the second component was excluded because there were only 3 original patch-level 322 variables and the first component accounted for most of the variance), and the first two 323 principal components for landscape-level variables accounted for 59% (Table 2). When 324 used as independent variables in multiple regression analysis, some of these principal 325 components were significantly related to the abundance of particular species of birds. 326 We completed regression analyses for all species that were detected in  $\geq 15$  sites (Table 327 3). Blue-winged Warbler, Chestnut-sided Warbler, Common Yellowthroat, and Eastern 328 Towhee were all significantly more abundant at sites with lower tree density and lower 329 vegetation height. Eastern Towhees were also significantly more common in larger 330 openings. The only species that was significantly related to principal components for 331 landscape variables was Gray Catbird, which was more abundant in openings closer to 332 residential areas and farther away from other clearcuts (Table 3). [INSERT TABLE 2] 333 We included counts for both males and females in regression analyses of Brown-334 headed Cowbirds because of low sample sizes when females were considered separately. 335 Although including conspicuous groups of male cowbirds probably exaggerates the 336 relative abundance of cowbirds compared to that of territorial songbirds, male and female 337 cowbirds probably occur in similar habitats along powerlines because males visit these 338 sites primarily to mate with females. Cowbirds were most abundant at sites with lower 339 vegetation height, higher shrub cover, and lower tree cover (Table 3). A separate linear 340 regression also showed that cowbirds were detected significantly more frequently in 341 forest openings with higher densities of snags (F=18.5, DF=32, P<0.001).

When shrubland specialists were considered as a group, the total abundance was greatest at sites with higher shrub density, lower tree cover, lower tree density, and lower canopy height (Table 3). There were no significant relationships for patch-level or

345	landscape-level principal components. Shrubland generalists were most frequent at plots
346	in larger openings, with lower tree density, greater distance to the nearest clearcut, and a
347	greater area of residential development within 1 km (Table 3). The frequency of forest
348	birds showed no significant relationship with the any of the principal component
349	variables (Table 3).
350	[INSERT TABLE 3]
351	3.3 Territory-level Differences in Mating Success and Nesting Activity
352	
353	In the summers of 1998 and 1999, we documented 28 Blue-winged Warbler
354	territories in 10 study sites. A territory was considered potentially productive if we
355	recorded a female at least once during the breeding season (mating success) or we
356	recorded direct evidence of nesting (nesting activity). Over both years, 15 territories
357	(54%) showed evidence of female occupancy and 10 territories (28%) showed evidence
358	of nesting. We used foliage density data to determine whether vegetation density at
359	particular heights influenced mating success and nesting activity. The pole vegetation
360	method produced a relative density of foliage within 8 separate height classes: $0 - 0.25$
361	m, $0.25 - 0.5$ m, $0.5 - 1.5$ m, $1.5 - 3.0$ m, $3.0 - 6.0$ m, $6.0 - 8.0$ m, and $> 8.0$ m
362	(Morimoto and Wasserman, 1991). Pearson product-moment correlation analysis found
363	no significant correlations between any of these foliage density categories so all eight
364	categories were used as explanatory variables in the GLM. Territories were characterized
365	by relatively low, dense foliage, with 88% of the foliage heights $< 3$ m.
366	Our GLM analyses suggested that foliage density had a limited influence on the
367	probability of mating success and nesting activity on different territories. None of the

368	densities for particular foliage heights were significant predictors of mating success at the							
369	0.05 significance level. The density of vegetation between two height categories, $0 - $							
370	$0.25 \text{ m} (1.26 \pm 0.74 \text{ S.E.}, P = 0.088) \text{ and } 6.0 - 8.0 \text{ m} (4.68 \pm 2.82 \text{ S.E.}, P = 0.096), \text{ were}$							
371	marginally significant and positively correlated with mating success. Foliage density also							
372	was not a significant predictor of nesting activity. None of the foliage height categories							
373	were significant predictors of nesting activity at the 0.05 significance level. The density							
374	of vegetation between 0 – 0.25 m (0.94 $\pm$ 0.55 S.E., $P = 0.087$ ) was marginally							
375	significant and positively correlated with the probability of nesting activity. Our findings							
376	indicate that foliage density and height were not important factors in mating success or							
377	nesting activity in Blue-winged Warblers in forest openings.							
378								
379	3.4 Patch-level Differences in Mating Success and Nesting Activity							
380

At the patch-level our effective sample size was limited to 10 study sites. Patch area had no effect on the proportion of territories with mates (-0.07 $\pm$ 0.087 S.E., <i>P</i> = 0.415) or on the proportion of territories with evidence of nesting (-0.16 $\pm$ 0.096 S.E., <i>P</i> = 0.140).							
<ul> <li>381</li> <li>382</li> <li>383</li> <li>384</li> <li>385</li> <li>386</li> </ul>	level to represent the proportion of territories with evidence of mating or nesting. At the patch-level our effective sample size was limited to 10 study sites. Patch area had no effect on the proportion of territories with mates (-0.07 $\pm$ 0.087 S.E., <i>P</i> = 0.415) or on the proportion of territories with evidence of nesting (-0.16 $\pm$ 0.096 S.E., <i>P</i> = 0.140). Similarly, patch age (time since harvest) had no effect on the proportion of territories							
<ul> <li>381</li> <li>382</li> <li>383</li> <li>384</li> <li>385</li> <li>386</li> <li>387</li> </ul>	level to represent the proportion of territories with evidence of mating or nesting. At the patch-level our effective sample size was limited to 10 study sites. Patch area had no effect on the proportion of territories with mates (-0.07 $\pm$ 0.087 S.E., <i>P</i> = 0.415) or on the proportion of territories with evidence of nesting (-0.16 $\pm$ 0.096 S.E., <i>P</i> = 0.140). Similarly, patch age (time since harvest) had no effect on the proportion of territories with mates (-0.05 $\pm$ 0.058 S.E., <i>P</i> = 0.369) or on the proportion of territories with							

391 = 0.0147). Patch area was not significantly correlated with mating success (P = 0.710), 392 however, but was a significant predictor of nesting activity (P = 0.026), with the 393 proportion of territories with evidence of nesting higher in small patches ( $0.67 \pm 0.19$ 394 S.E.) than in large patches ( $0.18 \pm 0.11$  S.E.) (Figure 1). Our results suggest that mating 395 success and nesting activity of Blue-winged Warblers were not strongly influenced by the 396 age of the forest opening, but that nesting activity was significantly higher in smaller 397 openings within the range of variability in our sample (Figure 1).

398

#### [INSERT FIGURE 1]

399 3.5 Nest Survival Rates

400

401 Despite extensive nest searches in ten openings, we were able to document and follow 402 only eight Blue-winged Warbler nests. This limited sample size was primarily a result of 403 the relatively low number of pairs that attempted to nest within the study sites. Given 404 such a limited sample size, we were unable to test effects between sites, and all nest data 405 were pooled for analysis. We documented a mean clutch size of  $3.56 (\pm 0.18 \text{ S.E.})$  eggs. 406 None of the nests were parasitized by cowbirds. The second model, in which the daily 407 survival probabilities for the egg laying and incubation stages were assumed to be equal 408  $(\rho_0 = \rho_1, \rho_2)$ , had the lowest AIC<sub>c</sub> value (AIC<sub>c</sub> = 12.52) when compared to the global 409 (AIC<sub>c</sub> = 13.62) and the constant survivorship model (AIC<sub>c</sub> = 16.27). We chose the second 410 model as the best model because it minimizes information loss. This model assumes a 411 constant survival probability in the egg laying and incubation stages, which may be 412 appropriate for our data because of the limited sample size and small number of nests 413 observed in the egg-laying stage. The second model produced stage-specific survival

414	probabilities of 21.1% ( $\pm$ 0.18 S.E.) for the egg laying and incubation stage and 100% ( $\pm$
415	0.00 S.E.) for the nestling stage. Although the third model was the least supported of all
416	three models, we calculated a nest success rate of 42.7% to allow for comparison with
417	past studies that used the Mayfield method.
418	
419	4. Discussion
420	
421	4.1 Importance of habitat area and vegetation structure to shrubland birds
422	
423	The abundance of shrubland specialists in forest openings was related to
424	vegetation structure rather than to the extent of continuous early successional habitat at a
425	study site or to surrounding land use patterns. Two common shrubland specialists, Blue-
426	winged Warbler and Chestnut-sided Warbler, were most abundant on study plots
427	dominated by relatively low vegetation with few trees. When considered as a group,
428	shrubland specialists were most abundant at sites with low vegetation, few trees, and a
429	high density of shrubs. Within the range of forest openings we studied $(0.6 - 21 \text{ ha})$ ,
430	none of the common shrubland specialists displayed a significant relationship between
431	abundance (average number per survey plot) and forest opening size, indicating that they
432	occupy even very small clearcuts. Openings created by timber harvesting that are smaller
433	than our smallest site (0.6 ha) are classified as individual or group selection cuts rather
434	than clearcuts. These generally support relatively few shrubland specialists (Robinson
435	and Robinson, 1999; Costello et al., 2000, Moorman and Guynn, 2001). The minimum
436	recorded territory areas are 0.3 ha for Blue-winged Warbler (Gill et al., 2001) and 0.4 ha

for Chestnut-sided Warbler (Richardson and Brauning, 1995), so it is not surprising thatthese species were infrequent or absent in individual and group selection cuts.

439 In contrast to shrubland specialists, the occurrence of some shrubland generalists 440 appears to be influenced by the size and landscape context of the forest opening. 441 Shrubland generalists as a group were most frequent in plots in larger forest openings, 442 with lower tree density, greater distance to the nearest clearcut, and more residential area 443 within 1 km. The abundance of the two most frequent shrubland generalists was related 444 to patch or landscape level variables. Eastern Towhee is the only species we analyzed 445 that was more abundant in larger openings, and Gray Catbird was more abundant at sites 446 closer to residential areas and farther from other clearcuts, so these two species may drive 447 the pattern for the entire group of shrubland generalist species. Abundance of another 448 common shrubland generalist, Common Yellowthroat, was significantly related only to 449 vegetation characteristics.

450 Among species that are usually classified as mature-forest birds, only Black-and-451 white Warblers were observed frequently enough in forest openings to permit multiple 452 regression analysis. The abundance of this species was not significantly related to the 453 habitat variables we measured. The frequent detection of this species in shrubby 454 openings was surprising because previous studies in various parts of its breeding range 455 showed that this species was strongly associated with mature, closed canopy forests 456 rather than early successional forest (Kricher, 1995). However, Hagan et al. (1997) and 457 Costello et al. (2000) reported that Black-and-white Warblers were more abundant in 458 clearcut regeneration plots than in mature-forest plots, indicating that this species may be 459 associated with early successional habitat as well as mature forest. We found no

evidence of nesting by Black-and-white Warblers in forest openings, however. The
Black-and-white Warbler, like the Wood Thrush (Anders *et al.*, 1998), might nest in
mature forests and feed in shrubby openings during certain periods of the breeding
season, but this requires further study.

464 We could not find clearcuts >21 ha in southeastern Connecticut (an example of 465 the current shift to smaller-scaled silvicultural practices), so we were unable to test the 466 hypothesis that very large clearcuts support a higher density of shrubland specialists. 467 When Rudnicky and Hunter (1993) surveyed birds in clearcuts in eastern Maine that 468 ranged in size from 2 to 112 ha, they found no relationship between the frequency of 469 occurrence of particular species on survey plots and the area of the opening, indicating 470 that larger clearcuts do not provide more favorable habitat. Interestingly, they found that 471 there was a relationship between frequency of occurrence and clearcut area for many 472 species if only sites <20 ha (which happens to be the size range for our study) are 473 considered. They provide few details, however, and the bird species composition of 474 openings in their northern coniferous forest sites differs from that of the deciduous forest 475 openings we studied. Two species that were frequently detected in both studies, the 476 Chestnut-sided Warbler and Common Yellowthroat, do not show a consistent negative 477 relationship between frequency and clearcut area in clearcuts <20 ha in Maine (Figure 3 in Rudnicky and Hunter, 1993), which is consistent with our results. 478

The lack of a relationship between the abundance of shrubland specialists on survey plots and the area of habitat patches or the composition and configuration of surrounding landscapes contrasts with the pattern for mature-forest birds in the same region of eastern North America. The abundance of many mature-forest bird species on

483 survey plots tends to be highly correlated with forest area and with the amount and 484 configuration of forest cover in the surrounding landscape (Askins et al., 1987; Robinson 485 et al., 1995; Villard et al., 1999). This difference in sensitivity to the composition and 486 configuration of preferred habitats may reflect adaptations to different patterns of habitat 487 availability for early successional and late successional species during most of their 488 evolutionary history. In eastern North America, mature deciduous and boreal forests 489 frequently occurred in large, unbroken stretches, while shrubby early successional patches occurred in small, isolated patches created by windstorms, fires, beaver activity 490 491 and severe flooding along rivers and streams (Askins, 2001). Consequently, early 492 successional species may be adapted to colonize and reproduce successfully in small, 493 isolated habitat patches that are a product of more stochastic and spatially restricted 494 disturbance regimes. This general pattern of landscape insensitivity for shrubland species 495 may be less frequent in those shrubland birds that can exploit a greater breadth of 496 resources (i.e., shrubland generalists). Also, many species among both open grassland 497 and mature forest breeding birds tend to be area-sensitive and are similar in that they 498 have evolved to depend on extensive habitats that are influenced by a number of 499 landscape-scale abiotic and biotic factors. In contrast, shrubland specialists that depend 500 on more stochastic, small-scale disturbances to generate appropriate habitat may not be 501 influenced as much by patterns of habitat availability and disturbance at landscape scales, 502 as our results indicate. Once bird assemblages in enough habitats in different parts of the 503 world have been studied, this hypothesis can be tested by determining whether there is a 504 consistent relationship between sensitivity to habitat fragmentation and historical patterns 505 of habitat continuity.

## *4.2 Breeding Success of a Shrubland Specialist*

509	Blue-winged Warblers are considered shrubland specialists because they typically
510	breed in early-to mid-succession habitat (Confer and Knapp, 1981; Will, 1986; Buckelew
511	and Hall, 1994; Gill et al., 2001). Although their territories are characterized by a mosaic
512	of dense herbs, shrubs, and trees, their breeding habitats are typically dominated by low-
513	growing herbs and shrubs (Confer and Knapp, 1981; Gill et al., 2001). Consequently,
514	forest management techniques that promote early-successional habitat, such as clearcuts
515	and shelterwood cuts, may produce optimal breeding areas. In our study, although 28
516	territories were characterized by short dense vegetation rarely exceeding 3 m in height,
517	we did not find a significant relationship between reproductive success and vegetation
518	height or foliage density. This was surprising considering that only 28% of Blue-winged
519	Warbler territories showed evidence of nesting. The nest success rate of 21.1% during
520	the egg laying and incubation stages (41.2% assuming $\rho_0 = \rho_1 = \rho_2$ ) is also relatively
521	low compared to other studies of this species (Gill et al., 2001), including a study in
522	clearcuts and shelterwood cuts where the nest success rate was 51% (Annand and
523	Thompson, 1997). These findings suggest that, although Blue-winged Warblers become
524	established in artificial forest openings, their reproductive success may not be optimal
525	and is not affected by the structural characteristics of these openings as long as the
526	vegetation remains low. The reproductive success rates of other species nesting in
527	clearcuts in Missouri and Illinois (Annand and Thompson, 1997; Morse and Robinson,
528	1999) are even lower than the rate we documented for Blue-winged Warblers in

529 Connecticut. In contrast, nest success was much higher (60 - 99% of nests fledged  $\ge 1$ 530 young) in clearcuts in New Hampshire (King *et al.*, 2001). Comparison of the results of 531 these studies suggests that nest success in clearcuts may be higher in heavily forested 532 regions with relatively little agricultural or suburban habitat (King *et al.*, 2001), but this 533 requires more study.

534 Brown-headed Cowbirds were frequent in the forest openings we studied. 535 Although they did not parasitize any of the Blue-winged Warbler nests we monitored, 536 they could potentially reduce the reproductive success of this species and other shrubland 537 specialists. Like many of the shrubland specialists that they parasitize, they were most 538 frequent at sites with low, dense vegetation and live trees. Their abundance increased 539 with the density of snags on survey plots, so snags left in clearcuts to enhance wildlife 540 habitat may have a negative effect on nesting success of songbirds. This relationship 541 should be studied more thoroughly.

542 The size and age (time since harvest) of the forest opening may affect the 543 reproductive success of Blue-winged Warblers. Robinson and Robinson (1999) found 544 that Blue-winged Warblers were more likely to be found in larger clearcuts than in 545 smaller group cuts in southern Illinois. However, we found that the abundance of Blue-546 winged Warblers was similar on survey plots in clearcuts of different sizes, and we found 547 no significant effect of forest opening size on Blue-winged Warbler reproductive activity 548 within the range of sizes we were studying (0.6 to 16.9 ha). We did, however, find a 549 general trend of higher mating success and nesting activity within smaller forest openings 550 (< 4 ha) (Figure 1). This general trend could be an artifact of a relatively low number of 551 study sites, however, especially with respect to larger sites (n = 4).

#### 553 4.3 Conclusions

554

555 We found high densities of shrubland birds in small clearcuts and shelterwood 556 cuts, including species such as Blue-winged Warbler, Chestnut-sided Warbler, and 557 Eastern Towhee that have shown long-term population declines in southern New England 558 (Dettmers and Rosenberg, 2000). All of the species detected frequently enough to 559 analyze with regression analysis were found in both small and large clearcuts and 560 shelterwood cuts, and only the Eastern Towhee showed a significant tendency to occur 561 more frequently in larger openings. This supports the conclusions of previous studies 562 that indicate that the density of shrubland birds generally does not increase with clearcut 563 area (Rudnicky and Hunter, 1993; Krementz and Christie, 2000). The evidence from 564 distribution of shrubland birds in clearcuts of different sizes suggests that small clearcuts 565 provide appropriate habitat, and there is no need to create larger areas of continuous early 566 successional habitats for these species. One caveat, however, is that two shrubland 567 species that tend to be missing in small shrubland openings, the Yellow-breasted Chat 568 (Icteria virens) and Golden-winged Warbler (Vermivora chrysoptera) (Thompson and 569 Nolan, 1973; Confer, 1992), were not detected in our study areas. Both of these species 570 were once common in southern New England but are now almost extirpated (Dettmers 571 and Rosenberg, 2000).

572 Even if the abundance of shrubland birds is similar on survey plots in small and 573 large openings, we cannot be certain that the habitat quality is similar without assessing 574 reproductive success. Our results for mating success and evidence of nesting in Blue-

575 winged Warblers did not indicate that larger forest openings represent better breeding 576 habitat. In fact, males in smaller openings tended to have higher mating success and rates 577 of nesting. However, the low average rates of mating success and nesting activity of 578 Blue-winged Warblers in forest openings during the two years of our study suggest that 579 these forest openings (both small and large) are relatively poor breeding habitat. We 580 were unable to test whether nest success was influenced by the area of the forest opening 581 due to a limited sample of nests. Nest failures were due to predation and were more 582 likely to occur during the early stages of nesting (i.e., egg laying and incubation). A 583 longer-term study should reveal whether the rate of nest success is consistently low for 584 Blue-winged Warblers in clearcuts. Also, although none of the Blue-winged Warbler 585 nests we monitored were parasitized by cowbirds, the high density of cowbirds in 586 clearcuts is a cause of concern for this species and other declining shrubland birds. The 587 higher abundance of cowbirds in clearcuts with more snags, which are frequently left 588 after timber harvesting to provide wildlife habitat, indicates that the effect of isolated 589 snags on cowbird density and activity should be studied.

590 Clearcuts are an ephemeral habitat for Blue-winged Warblers, Chestnut-sided 591 Warblers, Common Yellowthroats, and Eastern Towhees. The abundance of each of 592 these species is greatest at sites with low vegetation and few trees, so they decline as low, 593 woody vegetation grows into closed-canopy forest. Consequently, stable regional 594 populations of these species depend on a continual production of new forest openings as 595 old openings undergo succession. These openings may also be important feeding areas 596 for some forest bird species, particularly Black-and-white Warbler.

597	In conclusion, small forest openings support populations of several species of
598	shrubland birds. Unlike other bird species and guilds, the abundance and occupancy of
599	shrubland specialists in forest openings does not appear to be heavily influenced by the
600	area of the habitat patch (as long as the patch accommodates a breeding territory) or the
601	landscape context. Habitat selection for many shrubland specialists appeared to be
602	determined by plot-scale characteristics including vegetation structure and tree density.
603	The low reproductive rate in Blue-winged Warblers in our study sites, however, indicates
604	that more information on reproductive rates of shrubland birds in small clearcuts will be
605	needed before we can conclude that they provide productive, long-term habitat for these
606	birds.

#### 608 Acknowledgements

609

610 This study would not have been possible without the financial support of the 611 Endangered Species/Wildlife Income Tax Checkoff Fund of the Connecticut Department 612 of Environmental Protection Wildlife Division, as well as the Keck Undergraduate 613 Science Program and the Andrew W. Mellon Environmental Research Fund at 614 Connecticut College. Matthew Heflin, April Muse, Christopher Schafer and Donald 615 Wardwell assisted with the field work. Jenny Dickson, Lise Hanners and Greg Chasko 616 provided invaluable advice about the field research, and Thomas R. Stanley helped us 617 with the analysis of nest data. Two anonymous reviewers gave us advice that greatly 618 improved the clarity and precision of the paper. Helene Flounders, Emery Gluck and 619 Huber Hurlock of the Connecticut DEP Forest Division gave us permission to work in

- 620 state forests and assisted us in finding appropriate sites. We would not have been able to
- 621 complete the project without their help.

Table 1. Abundance (mean number of individuals per survey plot) for species detected in 34 forest openings in Connecticut. Some species were grouped according to their association with a restricted range of habitats: open shrubland ("shrubland specialist"), the shrub layer in habitats with both open and closed tree canopies ("shrub generalist"), and closed-canopy forest ("forest specialist").

Table 2. Results of three separate principal component analyses at different spatial scales: plot scale (variables sampled within the 100-m diameter survey plot), patch scale (variables associated with the forest opening), and landscape scale (variables associated with the region within 1 km of the study site). Factor scores are shown for each independent variable for principal components that explain a high percentage of the variance.

Table 3. Relationships between principal components and abundance of particular species in forest plots. Components are shown for three separate principal components at different spatial scales: plot scale (first 2 components), patch scale (first component), and landscape scale\* (first 2 components).

	Model	_ 2					Abundance increases
Species	(P)	R <sup>2</sup>	Plot 1	Plot 2	Patch 1	Landscape 1	
							smaller distance to houses,
Curry Cathind	0.022	0.24				0.001 (1)	greater distance from other
Gray Catbird	0.032	0.34				0.001 (+)	clearcuts
Black-and-white Warbler	0.92						
							lower tree density, lower
Blue-winged Warbler	0.03	0.34		0.037 (-)			vegetation (veg.) height
							lower tree density, lower veg.
Chestnut-sided Warbler	0.047	0.32		0.034 (-)			height
							lower tree density, lower veg.
Common Yellowthroat	0.01	0.29		0.006 (-)			height
							higher shrub cover, lower
Brown-headed Cowbird	0.004	0.45	<0.001 (+)				tree cover and veg. height
							larger habitat patch, lower
Eastern Towhee	0.013	0.39		0.034 (-)	0.005 (-)		tree density and veg. height
Habitat groups							
<u> </u>							higher shrub density, lower
Shrubland specialists	0.001	0.42	0.019 (+)	0.001 (-)			tree cover, lower tree density
			× •				larger patch size, lower tree
							density, greater distance to
							clearcut, lower area of
							clearcuts and larger amount
Shrubland generalists	0.04	0.34		0.006 (-)	0.037 (-)	0.039 (+)	of housing nearby
Forest species	0.87						

\*Landscape Principal Component 2 is not shown because there were no significant relationships.

**Caption** 

Figure 1. Blue-winged Warblers were generally more successful in finding mates and establishing nests in smaller forest openings ( $\leq 4$  ha) than in larger forest openings ( $\geq 4$  ha). Although mating success was not significantly different in either small or larger forest openings ( $\alpha = 0.05$ ), the general trend was similar to that for nesting activity, which was significantly greater in small forest openings.
