Paris (IPGP), Paris, FRANCE.*

(Dated:)

Secondary flow cells are commonly observed in straight laboratory channels, where they are often associated with duct corners. Here, we present velocity measurements acquired with an Acoustic Doppler Current Profiler in a straight reach of the Seine river (France). We show that a remarkably regular series of stationary flow cells spans across the entire channel. They are arranged in pairs of counter-rotating vortices aligned with the primary flow. Their existence away from the river banks contradicts the usual interpretation of these secondary flow structures, which invokes the influence of boundaries. Based on these measurements, we use a depth-averaged model to evaluate the momentum transfer by these structures, and find that it is comparable with the classical turbulent transfer.

I. INTRODUCTION

Turbulent shear flows often generate stationary vortices aligned with the primary flow. They appear in rapid granular flows¹, in Rayleigh-Bénard-Poiseuille flows², in the superficial layers of sea and lakes³, in straight tubes^{4,5}, as well as in straight channels and natural rivers⁶⁻⁸.

In laboratory channels, a broad spectrum of instruments provide detailed measurements of the velocity field. They reveal secondary flow structures in the plane normal to the primary flow^{6,7,9,10}, among which are the stationary helicoidal flows observed in straight channels (Prandtl refers to them as “*secondary flow of the second kind*”¹¹). They were originally associated with duct corners^{10,12,13}, where they were attributed to the turbulence anisotropy^{3,12,14-17}. Recent experiments reported their existence in wide channels (aspect ratio of about 10), where they arrange themselves as pairs of counter-rotating vortices aligned with the stream direction⁶⁻⁸.

To our knowledge, secondary flow cells have never been measured in very wide channels—the only configuration which separates unambiguously recirculation cells from corner vortices. Alluvial rivers are typically wide and shallow, with an aspect ratio of a few tens¹⁸. Therefore, a significant proportion of their flow should be free from the influence of the banks. Nonetheless, various indirect observations such as sediment streaks^{10,19,20} or fluctuations in the suspended particles concentration²¹ have been associated to secondary flows in alluvial streams. There is however no clear consensus on the physical origin of these patterns^{10,19,20}.

To identify directly secondary flow cells in rivers, we need accurate measurements of the velocity field. Unfortunately, because they require heavy infrastructures, laboratory measurement techniques are of delicate use in the field. Instead, many river studies involve Acoustic Doppler Current Profilers (ADCP). An ADCP emits a diverging bunch of ultrasonic beams from a single source. The three-dimensional velocity field is then reconstructed from the measured radial velocities, thus making it possible to record velocity profiles with a light measurement setup. Due to the divergence of the beams, the velocity reconstruction relies on the assumption that the flow is uniform in the horizontal plane. This configurational limitation generally precludes ADCPs from measuring flow structures smaller than the water depth²².

Recirculation cells, however, are still accessible to ADCP measurements, since they are streamwise invariant and stationary. Here we use these properties to identify recirculation cells in a straight reach of the Seine river (France). At this location, the river is wide and deprived of bed sediment, thus limiting the possible causes of recirculation. Based on these measurements, we then evaluate the momentum transfer by secondary flow cells, and compare it to the classical turbulent transfer.

II. MEASUREMENTS

A. Acoustic Doppler Current Profiler

Our ADCP (model RDI-Workhorse 1200 kHz) emits four divergent acoustic beams. Each beam measures the radial velocities u_r every 25 cm through the water column. The beam angle with respect to the vertical direction is $\alpha = 20^\circ$. Consequently, the distance $2l_{\text{cor}}$ between opposite beams is proportional to the measurement depth h :

$$2l_{\text{cor}} = 2h \tan(\alpha) \simeq 0.8h. \quad (1)$$

Used conventionally, an ADCP computes the Cartesian components of the velocity field (u_x , u_y and u_z) from the four radial velocities (figure 1b). For instance, to get the streamwise velocity u_x at a depth h , it uses the radial velocities from beam 3 and beam 4 (figure 1b).

The radial velocities $u_{r,1}$ and $u_{r,2}$ are decomposed as follows:

$$\begin{pmatrix} u_{r,3} \\ u_{r,4} \end{pmatrix} = \begin{pmatrix} u_{x,3}(-l_{\text{cor}}) & u_{z,3}(-l_{\text{cor}}) \\ -u_{x,4}(l_{\text{cor}}) & u_{z,4}(l_{\text{cor}}) \end{pmatrix} \cdot \begin{pmatrix} \sin(\alpha) \\ \cos(\alpha) \end{pmatrix}, \quad (2)$$

where $u_{z,n}$ and $u_{x,n}$ are respectively the vertical and the streamwise velocity in the n -th bins of each beam. This procedure relies on the assumption that the flow is uniform in the horizontal plane²³:

$$u_{i,3}(-l_{\text{cor}}) = u_{i,4}(l_{\text{cor}}). \quad (3)$$

The streamwise velocity at depth h thus reads $u_x = (u_{r,3} - u_{r,4})/2 \sin(\alpha)$. Similarly, beam 1 and beam 2 provide the transverse velocity u_y ²⁴.

The uniformity assumption proves reasonable to measure integrated quantities, such as the river discharge, or large flow structures. However, due to the large tilt angle α of a beam, the correlation length l_{cor} is of the order of the flow depth (equation 1, figure 1). Therefore,

FIG. 1. **(a)** Configuration of the ADCP beams, oriented with respect to the primary flow. **(b)** Configuration of beams 4 and 3, in the vertical streamwise plane. The tilt angle of the beam is $\alpha = 20^\circ$ and its opening angle is $\phi = 30^\circ$. The radial velocity is measured at depth h . The associated correlation length is l_{cor} .

it cannot detect flow patterns smaller than the flow depth²². This precludes ADCPs from measuring the complete velocity field associated to secondary flow cells in a river.

In a straight channel however, we expect the average flow to be uniform in the streamwise direction, even in the presence of stationary helicoidal cells. The uniformity assumption therefore holds along the primary flow and, in principle, we can calculate the vertical velocity of secondary flow cells from the two acoustic beams aligned with the flow (beam 3 and beam 4 in figure 1a)^{25,26}.

Secondary flow cells are weak stationary eddies in a highly turbulent flow. We thus need to average the velocity field over time to reveal them. In addition, since the uniformity assumption holds only on average, our experimental setup can only measure the average velocity field in the vertical streamwise plane (x, z) . We define the average velocity as

$$\bar{u}_i = \frac{1}{T} \int_0^T u_i dt, \quad (4)$$

where i denotes the coordinate x or z , and T is a time period long enough to average out the unsteady turbulent flow ($T \approx 10$ min). Fortunately, \bar{u}_x and \bar{u}_z suffice to identify secondary flow cells, and to estimate their influence on the flow.

B. Field site

We collected our measurements midway of a 3 km-long straight reach of the Seine river (France). The river flows above bedrock between two vertical banks (width: 148 m, depth: about 6.2 ± 0.3 m depending on the discharge, figure 2a). The ADCP was mounted on a raft moored to a suspension footbridge which does not perturb the flow (figure 2b). The horizontal velocity of the raft was recorded by an echo-sounder, and the measurements are corrected for it. The raft position was measured with an auto-tracking theodolite with a precision of about a centimeter. We also used the ADCP goniometer to correct the measurements for the angular motion of the raft.

FIG. 2. (a) Aerial picture of the field site (source: *Institut Géographique National*). Measurements are made from the footbridge. (b) Set-up of the measurement raft.

We acquired three data sets at the same location and at comparable discharges (January 2011: $900 \text{ m}^3 \text{ s}^{-1}$, February 2012: $950 \text{ m}^3 \text{ s}^{-1}$, February 2013: $780 \text{ m}^3 \text{ s}^{-1}$). For each set, we collected static measurements across the river, about 2 m apart from each other. Each static measurement lasted about 10 min, a duration sufficient for the turbulent component of the flow to average out. In addition, we collected measurements in a transect by slowly pulling the raft along the footbridge.

III. OBSERVATIONS

A. Streamwise velocity

To visualize the primary flow, we define the depth-averaged streamwise velocity as

$$U_x(y) = \frac{1}{H} \int_0^H \overline{u_x} dz, \quad (5)$$

where H is the water depth. The primary velocity appears roughly constant around the center of the channel, and slows down near the banks (figure 3a). As a result, the velocity profile is curved over about two thirds of the river width. Since the water depth is virtually constant across the river, this profile suggests that the flow transfers streamwise momentum to the banks.

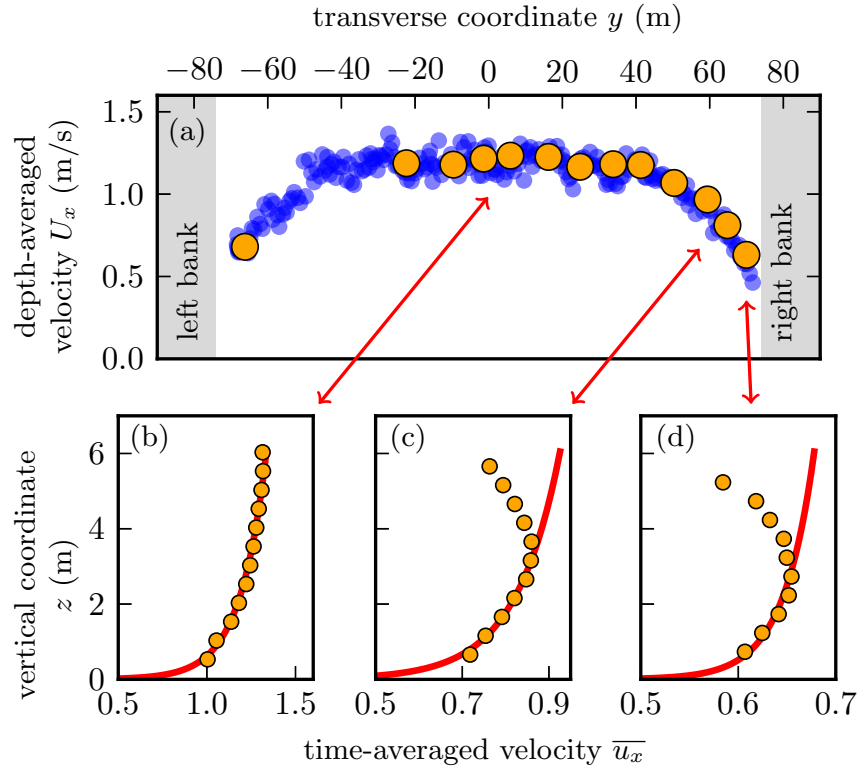

FIG. 3. Streamwise velocity measurements ($\text{m}\cdot\text{s}^{-1}$) in the Seine river during winter high flow. The discharge is $900 \text{ m}^3/\text{s}$. **(a)** Depth-averaged velocity U_x from moving measurements (blue) and from static measurements (yellow). **(b)**, **(c)**, **(d)** Time-averaged ($\simeq 10$ minutes) depth profiles ($\overline{u_x}$) with fitted logarithmic profiles (red curve).

The vertical velocity profile is also affected by the banks. At the center of the channel,

the velocity profile resemble the classical logarithmic law of the wall (figure 3b). However, as we approach the banks, the vertical profile deforms: the point of maximum velocity detaches from the water surface and migrates downwards, until it reaches approximately half the flow depth (figure 3c-d).

This observation is reminiscent of laboratory experiments showing a velocity maximum at about $z = 0.6H$ near the banks^{10,27}. This departure from the logarithmic profile is usually interpreted as a signature of secondary flow cells near duct corners^{7,10,11}: these cells create an upward velocity along the side wall, thus bringing slow fluid up to the surface. The center of the cell, hardly impacted by the cell velocity, flows faster than the surrounding fluid. The same flow cell would have a much weaker effect far away from the banks, since the slow water must be transported from the bottom to the surface, thus explaining why the profiles near the center and near the bank differ.

Similarly, the weak spatial oscillation of the streamwise velocity across the river suggests that periodic upwelling brings slow water from the bottom to the surface (figure 3a).

B. Vertical velocity

The streamwise velocity profiles suggests that secondary flow cells exist across the entire channel. We now turn our attention to the vertical velocity, which provides direct insight on such flow structures (figure 4).

To reduce the scatter, the data set is divided into 2 m-wide bins. The vertical velocity is then averaged over each bin, and the standard deviation within a single bin provides an estimate of the error on the mean. The mean vertical velocity shows periodic oscillations across the river, with an amplitude significantly larger than the measurement error. As expected, the average vertical velocity across the channel vanishes, indicating that the vertical motion of the raft does not perturb significantly the measurements.

Despite considerable scatter, both the amplitude and the wavelength of this oscillation are roughly constant over the right-hand half of the river (the duration of the high-flow conditions did not allow measurements across the entire channel). They also show a reasonable consistency between data sets collected one year apart.

Fitting a cosine to the data leads to a wavelength of about 12 ± 0.5 m, and an amplitude of about 0.4 ± 0.1 cm s⁻¹. The Fourier spectrum of the same data set shows a maximum at

FIG. 4. **(a)** Time-averaged vertical velocity \bar{u}_z in a transect, at half the flow depth. The shaded envelopes represent the standard error on the mean. The red curve is a cosine fitted to the data. **(b)** Topography of the river cross-section at the measurement location (scales are preserved). The distance y is measured from the middle of the channel.

a wavelength of about 12 ± 0.5 m (figure 5). Based on this observation, and in accordance with previous experiments^{7,8}, we suggest that the flow generates recirculation cells across the entire channel. The wavelength of the velocity oscillation corresponds to a series of counter-rotating vortices with a diameter of about the flow depth (figure 4b and figure 6). The amplitude of the vertical oscillation is about 0.3% of the streamwise velocity, in accordance with previous findings in laboratory flumes⁷.

IV. MOMENTUM TRANSFER BY RECIRCULATION CELLS

In this section, our intention is to quantify the contribution of secondary flow cells in transporting momentum across the flow. To do so, we use a heuristic model to include the advection by secondary flow cells in the streamwise momentum balance.

FIG. 5. Energy spectrum of the vertical velocity field, calculated from the data set of figure 4.

A. Momentum balance

In steady state, the Reynolds-averaged Navier-Stokes equation for streamwise momentum reads

$$\rho \frac{\partial \langle u_j \rangle \langle u_x \rangle}{\partial x_j} = \frac{\partial \tau_{x,j}}{\partial x_j} + \rho g S, \quad (6)$$

where g , S and ρ are the acceleration of gravity, the river slope and the density of water respectively. The repeated j index implies summation over the transverse y and vertical z coordinates. The brackets denote ensemble average and $\tau_{x,j}$ is the stress tensor, including the Reynolds components.

In a rectangular channel with a steady free surface, the integration of equation (6) over depth leads to

$$\frac{\partial}{\partial y} \int_0^H (\rho \langle u_x \rangle \langle u_y \rangle - \tau_{y,x}) dz = -\tau_{\text{bottom}} + \rho g H S. \quad (7)$$

In the above equation, the left-hand term represents the cross-stream momentum transfer by the conjugate action of the secondary flow and turbulence⁹. Even though the two integrands $\rho \langle u_x \rangle \langle u_y \rangle$ and $\tau_{y,x}$ can be isolated formally, they are physically interdependent.

The bottom shear stress τ_{bottom} is often empirically approximated by a friction law:

$$\tau_{\text{bottom}} \approx \rho C_f U^2, \quad (8)$$

where U is the mean velocity and C_f is a friction coefficient.

B. Turbulent transfer of momentum

We first consider the contribution of turbulence to the cross-stream transfer of momentum. Discarding temporarily the influence of the secondary flow, we use an empirical eddy viscosity ν_t to get a rough estimate of the turbulent transfer:

$$\tau_{x,y} \approx \rho \nu_t \frac{\partial \langle u_x \rangle}{\partial y}. \quad (9)$$

Based on laboratory and field measurements, the vertical profile of eddy viscosity in an open channel is often approximated by a parabola^{10,28–30}:

$$\nu_t \equiv \kappa u_* z \left(1 - \frac{z}{H}\right), \quad (10)$$

where κ is the von Kármán constant and u_* is the friction velocity defined as $\rho u_*^2 = \tau_{\text{bottom}}$.

In an infinitely wide channel (that is, without any flux of momentum across the stream), the velocity profile resulting from equation (6) with a turbulent viscosity closure (10) is logarithmic:

$$\langle u_x \rangle = \frac{u_*}{\kappa} \ln \left(\frac{z}{z_0} \right). \quad (11)$$

where z_0 is the roughness length.

In a bounded channel, on the other hand, momentum is transferred from the flow bulk to the banks and, strictly speaking, equation (11) does not hold. However, if the channel aspect ratio is sufficiently large, we may assume that the vertical velocity profile remains logarithmic, in tune with the classical shallow-water approximation:

$$\langle u_x \rangle = U(y) \frac{\sqrt{C_f}}{\kappa} \ln \left(\frac{z}{z_0} \right), \quad (12)$$

where $U(y)$ is the depth-averaged velocity.

Based on equations (9) and (12), the cross-stream flux of momentum associated to the Reynolds stress tensor then reads

$$\int_0^H \tau_{x,y} dz \approx \mathcal{B} C_f H^2 U \frac{\partial U}{\partial y} \quad (13)$$

where \mathcal{B} depends on the ratio of the water depth to the roughness length only:

$$\mathcal{B} = \frac{1}{6} \ln \left(\frac{H}{z_0} \right) - \frac{5}{36}. \quad (14)$$

FIG. 6. Schematic representation of the recirculation cells.

Using the above expression to model the cross-stream momentum transfer, the momentum balance (7) reads

$$gHS = C_f U^2 - \frac{\mathcal{B} C_f H^2}{2} \frac{\partial^2 U^2}{\partial y^2}, \quad (15)$$

To evaluate \mathcal{B} from equation (14), we need an estimate of the roughness length z_0 . Fitting a logarithm on several vertical velocity profiles near the center of the Seine river (figure 3b), we find an average value of $z_0 \approx 2 \pm 1$ mm (this value is comparable with prior field measurements³¹), and therefore $\mathcal{B} \approx 1.2 \pm 0.1$.

C. Influence of the the secondary flow on the momentum transfer

We now consider the influence of the secondary flow on the cross-stream transfer of momentum. Based on both the fluctuation of the vertical velocity across the stream (figure 4), and mass balance, we expect the recirculation cells to be arranged in a series of counter-rotating eddies, with a diameter of about the water depth and a velocity $\langle U_t \rangle$ (figure 6). Such a flow configuration, by itself, cannot transfer momentum beyond one cell diameter, as it is compartmented by vertical planes of vanishing cross-stream velocity. However, turbulent diffusion can take over the momentum transfer across these vertical planes, where the momentum gradient is enhanced by the recirculation cells. The mixing due to counter-rotating eddies could thus increase the diffusion of momentum across the stream³².

Assuming that the momentum transfer is limited by convection within the cells, we expect it to scale like $\rho H \langle U_t \rangle (U^- - U^+)$ where U^- and U^+ stand for the streamwise velocity left and right of a cell, respectively (figure 6). If the streamwise velocity varies on scales much

larger than the water depth, we can approximate the velocity difference across a cell by a gradient, namely $U^- - U^+ \approx H\partial U/\partial y$. This approximation is valid only in channels much larger than their depth, which is usually true for alluvial rivers¹⁸.

Finally, based on prior experimental observations^{7,10} and on the measurements presented in section III, we assume that the velocity of the secondary flow scales like that of the primary flow:

$$\langle U_t \rangle \approx C_d U(y), \quad (16)$$

where $C_d \approx 0.003 \pm 0.001$. The momentum balance then reads

$$gHS = C_f U^2 - \frac{C_d H^2}{2} \frac{\partial^2 U^2}{\partial y^2}. \quad (17)$$

This expression is similar to equation (15), except the dimensionless coefficient C_d is substituted for $\mathcal{B}C_f$.

D. Comparison with field data

We now proceed to compare the estimates of the cross-stream flux of momentum to our field measurements in the Seine river. Equations (15) and (17), with the requirement that the velocity vanishes at the banks, share the following analytical solution:

$$U_x = U_\infty \sqrt{1 - \frac{\cosh(y/L_t)}{\cosh(w/(2L_t))}}, \quad (18)$$

where

$$U_\infty = \sqrt{\frac{gHS}{C_f}}. \quad (19)$$

The diffusion length L_t determines the inflection of the velocity profile near the banks. Its mathematical expression depends on the cross-stream diffusion model:

$$L_t = H\sqrt{\frac{\mathcal{B}}{2}} \quad (\text{no secondary flow, equation (15)}) \quad (20)$$

$$L_t = H\sqrt{\frac{C_d}{2C_f}} \quad (\text{with secondary flow, equation (17)}). \quad (21)$$

We evaluate the parameters $U_\infty \approx 1.2 \text{ m s}^{-1}$ and $L_t \approx 14 \text{ m}$ by fitting equation (18) to the data (figure 7). The resulting shape of the velocity profile accords reasonably with the data.

FIG. 7. Comparison of the depth-averaged momentum balance (red curve) with the ADCP measurements (yellow dots). Equation (18) is represented with $U_\infty \approx 1.2 \text{ m s}^{-1}$ and $L_t \approx 14 \text{ m}$ fitted to the data.

Since the the slope of the Seine river in Paris is about 10^{-4} , we find $C_f \approx 0.0042 \pm 0.0001$, which is consistent with classical empirical formulas^{33,34}. The estimation of U_∞ , and therefore of C_f , is virtually independent from the value of the diffusion length L_t .

Based on our estimate of C_f and on relations (20) and (21), we can calculate the diffusion length for the two diffusion models:

$$L_t \approx 4.8 \pm 0.1 \text{ m} \quad (\text{no secondary flow}) \quad (22)$$

$$L_t \approx 3.7 \pm 0.6 \text{ m} \quad (\text{with secondary flow}). \quad (23)$$

The estimated diffusion length is similar for both models, and about three times smaller than the fitted value. Therefore, the two diffusion models not only share the same mathematical expression (equations (15) and (17)), but also involve similar constants. We thus expect the turbulent transfer of momentum to be comparable with the transfer induced by the secondary flow.

The similarity between the two transfer mechanisms implies (i) that recirculation cells cannot be neglected in the momentum balance, and (ii) that the momentum transfer by the recirculation cells cannot be distinguished from the turbulent transfer in the shallow-water framework presented here.

V. DISCUSSION AND CONCLUSION

Due to the diverging configuration of its acoustic beams, an ADCP generally cannot detect flow structures smaller than the flow depth. However, if the measurements are averaged over a sufficient period of time, this instrument can measure stationary and spatially extended flow structures.

We can unambiguously identify secondary flow cells in the vertical velocity field of the Seine River. These stationary vortices extend across the entire channel and rotate at about 0.3% of the streamwise velocity, in accord with prior laboratory observations^{6,7}.

An order-of-magnitude analysis suggests that the momentum transfer by these secondary flow cells could compare with the intensity of the turbulent stress. If confirmed, this would indicate that the secondary flow influences significantly the primary flow in open channels. This is a strong incentive for further investigations. For instance, detailed flow measurements in laboratory experiments could reveal the streamwise extension of the flow cells, their stability in time and how they depend on the Reynolds number. Experiments would also guide us towards the mechanism which generates these structures.

In rivers, the momentum distribution determines stress on the bed, and therefore controls sediment transport and bed erosion. In addition, secondary cells are likely to enhance the horizontal mixing of passive markers, such as suspended particles, temperature or solutes³⁵.

Finally, beyond open-channel flows, similar recirculation cells appear in a variety of turbulent sheared flows, such as longitudinal streaks in boundary layers^{36,37}, Langmuir circulations below the wind-blown surface of lakes and oceans³⁸, or even granular flows³⁹. To this day, we do not know how many of these phenomena share a common physical origin, if any.

ACKNOWLEDGMENTS

The authors would like to thank the Navigation Service of the Seine river, represented by X. Fromageau, who granted access to the field site. A. Vierra built the measurement set-up. We also thank M. Rossi, P.Y. Lagrée and F. Moisy for fruitful discussions.
