A finite dimensional approximation for pricing moving average options

Marie Bernhart* Peter Tankov† Xavier Warin‡

Abstract

We propose a method for pricing American options whose pay-off depends on the moving average of the underlying asset price. The method uses a finite dimensional approximation of the infinite-dimensional dynamics of the moving average process based on a truncated Laguerre series expansion. The resulting problem is a finite-dimensional optimal stopping problem, which we propose to solve with a least squares Monte Carlo approach. We analyze the theoretical convergence rate of our method and present numerical results in the Black-Scholes framework.

Key words: American options, indexed swing options, moving average, finite-dimensional approximation, Laguerre polynomial, least squares Monte Carlo

MSC 2010: 91G20, 33C45

1 Introduction

We introduce a new method to value American options whose payoff at exercise depends on the moving average of the underlying asset price. The simplest example (sometimes known as surge option) is a variable strike call or put, whose strike is adjusted daily to the moving average of the underlying asset over a certain fixed-length period preceding the current date. American-style options on moving average are widely used in energy markets. In gas markets, for example, these options are known as indexed Swing options and allow the holder to purchase an amount of gas at a strike price, which is indexed on moving averages of various oil-prices: typically gas oil and fuel oil prices are averaged over the last 6 months and delayed in time with a 1 month lag.

We shall denote by X the moving average of the underlying S over a time window with fixed length $\delta > 0$:

$$X_t = \frac{1}{\delta} \int_{t-\delta}^t S_u du, \quad \forall t \geq \delta. \quad (1)$$

The process X follows the dynamics

$$dX_t = \frac{1}{\delta} (S_t - S_{t-\delta}) dt, \quad \forall t \geq \delta.$$

This shows in particular that even if S is Markovian, the process (S, X) is not: it is, in general, impossible for any finite n to find n processes X^1, \dots, X^n such that (S, X, X^1, \dots, X^n) are jointly Markovian. This property makes the pricing of the moving window options with early exercise a challenging problem both from the theoretical and the numerical viewpoint. In a continuous time framework the problem is infinite dimensional, and in a discrete time framework (pricing of a Bermudan option instead of an American option) there is a computational challenge, due to high dimensionality: the dimension is equal to the number of time steps within the averaging window. This in particular makes it difficult to compute the conditional expectations involved in the optimal exercise rule.

The problem of pricing moving average American options should not be confused with a much simpler problem of pricing Asian American options with a fixed start averaging window, where the payoff depends on

$$A_t = \frac{1}{t} \int_0^t S_u du, \quad \forall t > 0.$$

It is well-known (see for example Wilmott and al. [25]) that in this case, adding a dimension to the problem allows to derive a finite dimensional Markovian formulation. On the other hand, partial average Asian options of European style can be easily valued (see for example Shreeve [22]). If the averaging period has a length $\delta > 0$, then on $[T - \delta, T]$ the option value is given by the price of the corresponding Asian option and on $[0, T - \delta]$ it solves a European style PDE with appropriate terminal and boundary conditions.

In this paper, we propose a method for pricing moving average American options based on a finite dimensional approximation of the infinite-dimensional dynamics of the moving average process. The approximation is based on a truncated expansion of the weighting measure used for averaging in a series involving Laguerre polynomials. This technique has long been used in signal processing (see for example [17]) but is less known in the context of approximation of stochastic systems. We compute the rate of convergence of our method as function of the number of terms in the series. The resulting problem is then a finite-dimensional optimal stopping problem, which we propose to solve with a Monte Carlo Longstaff and Schwartz-type approach. Numerical results are presented for moving average options in the Black-Scholes framework.

In the literature, very few articles discuss moving average options with early exercise feature [3, 4, 6, 11, 12]. A common approach (see e.g., Broadie and Cao [4]) is to use the least squares Monte Carlo, computing the conditional expectation estimators through regressions on polynomial functions of the current values of the underlying price and its moving average. Since the future evolution of the moving average depends on the entire history of the price process between $t - \delta$ and t , this approach introduces a bias. In our numerical examples we compare this approach to our results, and find that for standard moving average American options the error is not so large (less than 1% for the examples we took), which justifies the use of this approach for practical purposes in spite of its suboptimality. For moving average American options with time delay, whose payoff depends on the average of the price between dates $t - \delta_1$ and $t - \delta_2$, $0 < \delta_2 < \delta_1$, the suboptimal approximation leads to a bias of up to 11% of the option's price in our examples.

Bilger [3] uses a regression based approach in the discrete-time setting to compute the conditional expectations considering that the state vector is composed of the underlying price, its

moving average and additional partial averages of the price over the rolling period. Their number is computed heuristically and as it tends to the number of time steps within the rolling period, the computed price tends to the true price of the moving average option. The same kind of approach is used by Grau [11], but the author improves its numerical efficiency by a different choice of basis functions in the regressions used for the conditional expectations estimation.

Kao and Lyuu [12] introduce a tree method based on the CRR model to price moving average lookback and reset options. Their method can handle only short averaging windows: the numerical results that are shown deal at most with 5 discrete observations in the averaging period. Indeed, this tree-based approach leads to an algorithm complexity (number of tree nodes) which exponentially increases with the number of time steps in the averaging period. Finally, Dai et al. [6] introduce a lattice algorithm for pricing Bermudan moving average barrier options. The authors propose a finite dimensional PDE model for such options and solve it using a grid method.

The pricing of moving average options is closely related to high-dimensional optimal stopping problems. It is well-known that deterministic techniques such as finite differences or approximating trees are made inefficient by the so-called curse of dimensionality. Only Monte Carlo type techniques can handle American options in high dimensions. Bouchard and Warin [5] and references therein shall give to the interested reader a recent review of this research field.

More generally, a related problem is that of optimal stopping of stochastic differential equations with delay. With the exception of a few cases where explicit dimension reduction is possible [8, 10], there is no numerical method for solving such problems, and the Laguerre approximation approach of the present paper is a promising direction for further research.

The rest of the paper is structured as follows. In Section 2, we introduce the mathematical context and provide a general result which links the strong error of approximating one moving average process with another to a certain distance between their weighting measures. We then introduce an approximation of the weighting measure as a series of Laguerre functions truncated at n terms, which leads to $(n + 1)$ -dimensional Markovian approximation to the initial infinite dimensional problem. The properties of Laguerre functions combined with our strong approximation result then enable us to establish a bound on the pricing error introduced by our approach as n goes to infinity. In Section 3, our numerical method, based on least squares Monte Carlo algorithm, is presented. The final section of this paper reports the results of numerical experiments in the Black-Scholes framework which include pricing moving average options with time delay.

Throughout the paper we assume that the price of the underlying asset $S = (S_t)_{t \geq 0}$ is a non-negative continuous Markov process defined on the probability space $(\Omega, \mathcal{F}, \mathbb{F}, \mathbb{P})$, where \mathbb{P} is a martingale probability for the financial market and $\mathbb{F} = (\mathcal{F}_t)_{t \leq T}$ is the natural filtration of S .

For the sake of simplicity, we present our results in the framework of a 1-dimensional price model but they are directly generalizable to a multi-asset model or to a model with unobservable risk factors such as stochastic volatility.

As usual, we denote by $L^2 \equiv L^2([0, +\infty))$ the Lebesgue space of real-valued square-integrable functions f on $[0, +\infty)$ endowed with its norm:

$$\|f\|_2 := \left[\int_0^\infty |f(x)|^2 dx \right]^{\frac{1}{2}}.$$

2 A finite dimensional approximation of moving average options price

Strong approximations of moving average processes Consider a general moving average process of the form¹

$$M_t = \int_0^\infty S_{t-u} \mu(du)$$

where μ is a finite possibly signed measure on $[0, \infty)$. Throughout the paper, we shall adopt the following convention for the values of S on the negative time-axis:

$$S_t = S_0, \quad \forall t \leq 0. \quad (2)$$

We shall use an integrability assumption on the modulus of continuity of the price process: there exists a constant $C < \infty$ such that

$$\mathbb{E} \left[\sup_{t,s \in [0,T]: |t-s| \leq h} |S_t - S_s| \right] \leq C\varepsilon(h), \quad \varepsilon(h) := \sqrt{h \ln \left(\frac{2T}{h} \right)}. \quad (3)$$

Fischer and Nappo [9] show that this holds in particular when S is a continuous Itô process of the form

$$S_t = S_0 + \int_0^t b_s ds + \int_0^t \sigma_s dW_s$$

with

$$\mathbb{E} \left[\sup_{0 \leq t \leq T} |b_s| \right] < \infty \quad \text{and} \quad \mathbb{E} \left[\sup_{0 \leq t \leq T} |\sigma_s|^{1+\gamma} \right] < \infty$$

for some $\gamma > 0$.

The following lemma provides a tool for comparing moving averages with different weighting measures.

Lemma 2.1. Let Assumption (3) be satisfied, and let μ and ν be finite signed measures on $[0, \infty)$ with Jordan decompositions $\mu = \mu^+ - \mu^-$ and $\nu = \nu^+ - \nu^-$, such that $\mu^+(\mathbb{R}_+) > 0$. Define

$$M_t = \int_0^\infty S_{t-u} \mu(du), \quad N_t = \int_0^\infty S_{t-u} \nu(du).$$

Then

$$\begin{aligned} \mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - N_t| \right] &\leq C |\mu(\mathbb{R}_+) - \nu(\mathbb{R}_+)| \\ &+ C \left(\mu^+([0, T]) + \nu^-([0, T]) + |\mu([0, T]) - \nu([0, T])| \right) \varepsilon \left(\frac{1}{\mu^+([0, T])} \int_0^T |F_\mu(t) - F_\nu(t)| dt \right) \end{aligned} \quad (4)$$

for some constant $C < \infty$ which does not depend on μ and ν , where

$$F_\nu(t) := \nu([0, t]) \quad \text{and} \quad F_\mu(t) := \mu([0, t]).$$

¹In the literature (see [2] and references therein), moving averages are usually defined via the stochastic integral of S . Our definition as an ordinary integral with respect to a weighting measure is closer to the financial specifications.

Proof. *Step 1.* We first assume that μ and ν are probability measures. Let F_μ^{-1} and F_ν^{-1} be generalized inverses of μ and ν respectively. Then,

$$\begin{aligned} \mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - N_t| \right] &= \mathbb{E} \left[\sup_{0 \leq t \leq T} \int_0^1 |S_{t-F_\mu^{-1}(u)} - S_{t-F_\nu^{-1}(u)}| du \right] \\ &\leq \int_0^1 \mathbb{E} \left[\sup_{0 \leq t \leq T} |S_{t-F_\mu^{-1}(u)} - S_{t-F_\nu^{-1}(u)}| \right] du \\ &\leq C \int_0^1 \varepsilon(|F_\mu^{-1}(u) \wedge T - F_\nu^{-1}(u) \wedge T|) du \\ &\leq C\varepsilon \left(\int_0^1 |F_\mu^{-1}(u) \wedge T - F_\nu^{-1}(u) \wedge T| du \right), \end{aligned}$$

where the last inequality follows from the concavity of $\varepsilon(h)$. The expression inside the brackets is the Wasserstein distance between the measures μ and ν truncated at T . Therefore, from the Kantorovich-Rubinstein theorem we deduce

$$\mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - N_t| \right] \leq C\varepsilon \left(\int_0^T |F_\mu(t) - F_\nu(t)| dt \right).$$

Step 2. Introduce $\tilde{\mu} = \mu 1_{[0, T]}$ and $\tilde{\nu} = \nu 1_{[0, T]} + (\mu([0, T]) - \nu([0, T]))\delta_{2T}$, where δ_{2T} is the point mass at the point $2T$. Then,

$$\begin{aligned} \mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - N_t| \right] &\leq C|\mu(\mathbb{R}_+) - \nu(\mathbb{R}_+)| + \mathbb{E} \left[\sup_{0 \leq t \leq T} \left| \int_0^\infty S_{t-u} \tilde{\mu}(du) - \int_0^\infty S_{t-u} \tilde{\nu}(du) \right| \right] \\ &\leq C|\mu(\mathbb{R}_+) - \nu(\mathbb{R}_+)| \\ &\quad + (\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+)) \mathbb{E} \left[\sup_{0 \leq t \leq T} \left| \int_0^\infty S_{t-u} \frac{\tilde{\mu}^+(du) + \tilde{\nu}^-(du)}{\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+)} - \int_0^\infty S_{t-u} \frac{\tilde{\mu}^-(du) + \tilde{\nu}^+(du)}{\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+)} \right| \right]. \end{aligned}$$

Since $\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+) = \tilde{\mu}^-(\mathbb{R}_+) + \tilde{\nu}^+(\mathbb{R}_+)$, both measures under the integral sign are probability measures, and we can apply Step 1, which gives

$$\begin{aligned} \mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - N_t| \right] &\leq C|\mu(\mathbb{R}_+) - \nu(\mathbb{R}_+)| \\ &\quad + C(\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+))\varepsilon \left(\frac{1}{\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+)} \int_0^T |F_{\tilde{\mu}^+ + \tilde{\nu}^-}(t) - F_{\tilde{\mu}^- + \tilde{\nu}^+}(t)| dt \right) \\ &= C|\mu(\mathbb{R}_+) - \nu(\mathbb{R}_+)| + C(\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+))\varepsilon \left(\frac{1}{\tilde{\mu}^+(\mathbb{R}_+) + \tilde{\nu}^-(\mathbb{R}_+)} \int_0^T |F_\mu(t) - F_\nu(t)| dt \right), \end{aligned}$$

because $\tilde{\mu}$ coincides with μ and $\tilde{\nu}$ coincides with ν on $[0, T]$. Using the properties of the function ε and the definition of $\tilde{\mu}$ and $\tilde{\nu}$, we then get (4) with a different constant C . \square

Introducing Laguerre approximation The aim of this paragraph is to provide heuristic arguments which lead to Laguerre approximation of the moving average. We would like to find a finite-dimensional approximation to M , that is, find n processes Y^1, \dots, Y^n such that (S, Y^1, \dots, Y^n)

are jointly Markov, and M_t is approximated in some sense to be made precise later by M_t^n which depends deterministically on S_t, Y_t^1, \dots, Y_t^n .

Since M is linear in S , it is natural to require that the approximation also be linear. Therefore, we assume that $Y = (Y^1, \dots, Y^n)$ satisfies the linear SDE

$$dY_t = -AY_t dt + \mathbf{1}(\alpha S_t dt + \beta dS_t), \quad (5)$$

where A is an $n \times n$ matrix, $\mathbf{1}$ is a n -dimensional vector with all components equal to 1 and α and β are constants. Similarly, the approximation is given by a linear combination of the components of Y : $M^n = B^\perp Y$, where B is a vector of size n and \perp denotes the matrix transposition.

The solution to (5) can be written as

$$Y_t = e^{-At} Y_0 + \int_0^t e^{-A(t-s)} \mathbf{1}(\alpha S_s ds + \beta dS_s)$$

or, assuming stationarity, as

$$Y_t = \int_{-\infty}^t e^{-A(t-s)} \mathbf{1}(\alpha S_s ds + \beta dS_s) \quad \text{and} \quad M_t^n = \int_{-\infty}^t B^\perp e^{-A(t-s)} \mathbf{1}(\alpha S_s ds + \beta dS_s).$$

Integration by parts then yields:

$$M_t^n = \beta B^\perp \mathbf{1} S_t + \int_{-\infty}^t B^\perp (\alpha - A\beta) e^{-A(t-s)} \mathbf{1} S_s ds := K_n S_t + \int_{-\infty}^t h_n(t-u) S_u du,$$

Recalling the structure of the matrix exponential, it follows that the function h_n is of the form

$$h_n(t) = \sum_{k=1}^K e^{-p_k t} \sum_{i=0}^{n_k} c_i^k t^i, \quad (6)$$

where $n_1 + \dots + n_K + K = n$ (K is the number of Jordan blocks of A). Therefore, the problem of finding a finite-dimensional approximation for M boils down to finding an approximation of the form $K_n \delta_0(dt) + h_n(t) dt$ for the measure ν . This problem is well known in signal processing, where the density h of ν is called impulse response function of a system, and h_n is called Hankel approximation of h . For arbitrary μ and n , Hankel approximations may be very hard to find, and in this paper we shall focus on a subclass for which $K = 1$, that is, the function h_n is of the form

$$h_n(t) = e^{-pt} \sum_{i=0}^{n-1} c_i t^i. \quad (7)$$

This is known as Laguerre approximation, because for a fixed p , the first n scaled Laguerre functions (defined below) form an orthonormal basis of the space of all functions of the form (7) endowed with the scalar product of $L^2([0, \infty))$ which will be denoted by $\langle \cdot, \cdot \rangle$. See [18] for a discussion of optimality of Laguerre approximations among all approximations of type (6).

Definition 2.1. Fix a scale parameter $p > 0$. The scaled Laguerre functions $(L_k^p)_{k \geq 0}$ are defined on $[0, +\infty)$ by

$$L_k^p(t) = \sqrt{2p} P_k(2pt) e^{-pt}, \quad \forall k \geq 0 \quad (8)$$

in which $(P_k)_{k \geq 0}$ is the family of Laguerre polynomials explicitly defined on $[0, +\infty)$ by

$$P_k(t) = \sum_{i=0}^k \binom{k}{k-i} \frac{(-t)^i}{i!}, \quad \forall k \geq 0 \quad (9)$$

or recursively by

$$\begin{cases} P_0(t) = 1 \\ P_1(t) = 1 - t \\ P_{k+1}(t) = \frac{1}{k+1} ((2k+1-t)P_k(t) - kP_{k-1}(t)), \forall k \geq 1. \end{cases} \quad (10)$$

The scaled Laguerre functions $(L_k^p)_{k \geq 0}$ form an orthonormal basis of the Hilbert space $L^2([0, \infty))$, i.e.

$$\forall (j, k), \quad \langle L_j^p, L_k^p \rangle = \delta_{j,k}.$$

Fix now an order $n \geq 1$ of truncation of the series. In view of Lemma 2.1, we propose the following Laguerre approximation of the moving average process M :

- Let $H(x) = \mu([x, +\infty))$.
- Compute the Laguerre coefficients of the function H :

$$A_k^p = \langle H, L_k^p \rangle.$$

Set $H_n^p(t) = \sum_{k=0}^{n-1} A_k^p L_k^p(t)$ and $h_n^p(t) = -\frac{d}{dt} H_n^p(t)$. In view of Lemma A.2, the function h_n^p can be written as

$$h_n^p = \sum_{k=0}^{n-1} a_k^p L_k^p, \quad a_k^p = pA_k^p + 2p \sum_{i=k+1}^{n-1} A_i^p. \quad (11)$$

- Approximate the moving average M with

$$M_t^{n,p} = (H(0) - H_n^p(0))S_t + \int_0^{+\infty} h_n^p(u)S_{t-u}du, \quad \forall t \geq 0. \quad (12)$$

Remark 2.1. The approximation proposed in (12) (and in particular the correction coefficient in front of S_t) is chosen so that the total mass of the weighting measure of the approximate moving average $M_t^{n,p}$ is equal to the total mass of the weighting measure μ of the exact moving average. In particular, such an approximation becomes exact for a constant asset price S .

From definitions (11) and (12), it seems natural to introduce n random processes $X^{p,0}, \dots, X^{p,n-1}$ defined by

$$X_t^{p,k} = \int_0^{+\infty} L_k^p(v)S_{t-v}dv, \quad \forall t \geq 0, \forall k = 0, \dots, n-1. \quad (13)$$

They will be called *Laguerre processes* associated to the process S throughout this paper and are related to the moving average approximation by

$$M_t^{n,p} = (H(0) - H_n^p(0))S_t + \sum_{k=0}^{n-1} a_k^p X_t^{p,k}, \quad \forall t \geq 0. \quad (14)$$

Proposition 2.1. *Let $n \geq 1$ and $p > 0$. The $(n+1)$ -dimensional process $(S, X^{p,0}, X^{p,1}, \dots, X^{p,n-1})$ is Markovian. The n Laguerre processes follow the dynamics:*

$$\begin{cases} dX_t^{p,0} = \left(\sqrt{2p}S_t - pX_t^{p,0} \right) dt \\ dX_t^{p,1} = \left(\sqrt{2p}S_t - 2pX_t^{p,0} - pX_t^{p,1} \right) dt \\ \vdots \\ dX_t^{p,n-1} = \left(\sqrt{2p}S_t - 2p \sum_{k=0}^{n-2} X_t^{p,k} - pX_t^{p,n-1} \right) dt \end{cases}$$

with initial values

$$X_0^{p,k} = S_0(-1)^k \frac{\sqrt{2p}}{p}, \forall k \geq 0. \quad (15)$$

Proof. Immediate, from Equations (13) and (8) and properties A.1-(i) and A.1-(ii). \square

Convergence of the Laguerre approximation

Proposition 2.2. *Let Assumption (3) be satisfied, and suppose that the moving average process M is of the form*

$$M_t = K_0 S_t + \int_0^\infty S_{t-u} h(u) du \quad (16)$$

where K_0 is a constant and the function h has compact support, finite variation on \mathbb{R} , is constant in the neighborhood of zero and is not a.e. negative on $[0, T]$. Then the error of approximation (14) admits the bound

$$\mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - M_t^{n,p}| \right] \leq C\varepsilon(n^{-\frac{3}{4}}).$$

Proof. We shall use Lemma 2.1. The measures μ and ν are defined by $\mu(dx) = K_0 \delta_0(dx) + h(x)dx$ and $\nu(dx) = (H(0) - H_n^p(0))\delta_0(dx) + h_n^p(x)dx$. Therefore, these measures have the same mass, and the first term in estimate (4) disappears. In addition,

$$|\mu([0, T]) - \nu([0, T])| = |H(T) - H_n^p(T)|,$$

which remains bounded by Lemma A.4. Let us show that $\nu^-([0, T])$ is bounded as well. For this it is enough to prove that $\|(H_n^p)'\|_2$ is bounded on n . A straightforward computation using Lemma A.2 shows that

$$c_k^p = \sqrt{2p}H(0) - 2p \sum_{i=0}^{k-1} A_i^p - pA_k^p, \quad (17)$$

where $c_k^p := \langle h, L_k^p \rangle$ are Laguerre coefficients of h . By definition of H_n^p and a_k^p in (11), this leads to

$$a_k^p = c_k^p - \sqrt{2p} [H(0) - H_n^p(0)].$$

We have thus:

$$\|(H_n^p)'\|_2^2 = \sum_{k \leq n-1} |a_k^p|^2 \leq 2 \sum_{k \leq n-1} |c_k^p|^2 + 2 \sum_{k \leq n-1} \left| \sqrt{2p} [H(0) - H_n^p(0)] \right|^2 = \mathcal{O}(n^{-\frac{1}{2}})$$

by Lemma A.4 and using $\sqrt{2p} [H(0) - H_n^p(0)] = c_n^p + pA_n^p$ issued from (17). Therefore, there exists a constant $C < \infty$, which does not depend on n , such that

$$\mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - M_t^{n,p}| \right] \leq C\varepsilon \left(\frac{1}{\int_0^T h^+(t) dt} \int_0^T |H(t) - H_n^p(t)| dt \right).$$

By Cauchy-Schwartz inequality and Lemma A.4,

$$\int_0^T |H(t) - H_n^p(t)| dt \leq \sqrt{T} \|H - H_n^p\|_2 = \sqrt{T} \left(\sum_{k \geq n} |A_k^p|^2 \right)^{\frac{1}{2}} = \mathcal{O}(n^{-\frac{3}{4}}),$$

from which the result follows using the properties of ε and the fact that h is not a.e. negative on $[0, T]$ (which means that $\int_0^T h^+(t) dt > 0$). □

Approximating option prices The price of the American option whose pay-off depends on the moving average M and the price of the underlying is given by

$$\sup_{\tau \in \mathcal{T}} \mathbb{E} [\phi(S_\tau, M_\tau)]$$

where \mathcal{T} is the set of \mathbb{F} -stopping times and ϕ is the payoff function. It can then be approximated by the solution to

$$\sup_{\tau \in \mathcal{T}} \mathbb{E} [\phi(S_\tau, M_\tau^{n,p})]. \tag{18}$$

Proposition 2.3. *Let Assumption (3) be satisfied, and suppose that the payoff function ϕ is Lipschitz in the second variable and that the moving average process M satisfies the assumptions of Proposition 2.2. Then the pricing error admits the bound*

$$\mathcal{E}_{\text{pricing}}(n, p) := \left| \sup_{\tau \in \mathcal{T}} \mathbb{E} [\phi(S_\tau, M_\tau)] - \sup_{\tau \in \mathcal{T}} \mathbb{E} [\phi(S_\tau, M_\tau^{n,p})] \right| \leq C\varepsilon(n^{-\frac{3}{4}}).$$

where $C > 0$ is a constant independent of n .

Proof. We have first:

$$\begin{aligned} \forall \tau, \mathbb{E} [\phi(S_\tau, M_\tau)] &= \mathbb{E} [\phi(S_\tau, M_\tau^{n,p})] + \mathbb{E} [\phi(S_\tau, M_\tau) - \phi(S_\tau, M_\tau^{n,p})] \\ \implies \sup_{\tau} \mathbb{E} [\phi(S_\tau, M_\tau)] &= \sup_{\tau} \left(\mathbb{E} [\phi(S_\tau, M_\tau^{n,p})] + \mathbb{E} [\phi(S_\tau, M_\tau) - \phi(S_\tau, M_\tau^{n,p})] \right) \\ &\leq \sup_{\tau} \mathbb{E} [\phi(S_\tau, M_\tau^{n,p})] + \sup_{\tau} \mathbb{E} [\phi(S_\tau, M_\tau) - \phi(S_\tau, M_\tau^{n,p})] \end{aligned}$$

In consequence,

$$\sup_{\tau} \mathbb{E} [\phi(S_{\tau}, M_{\tau})] - \sup_{\tau} \mathbb{E} [\phi(S_{\tau}, M_{\tau}^{n,p})] \leq \sup_{\tau} \mathbb{E} |\phi(S_{\tau}, M_{\tau}) - \phi(S_{\tau}, M_{\tau}^{n,p})|.$$

By symmetry and (A2), we get

$$\begin{aligned} \left| \sup_{\tau} \mathbb{E} [\phi(S_{\tau}, M_{\tau})] - \sup_{\tau} \mathbb{E} [\phi(S_{\tau}, M_{\tau}^{n,p})] \right| &\leq \sup_{\tau} \mathbb{E} |M_{\tau} - M_{\tau}^{n,p}| \\ &\leq \mathbb{E} \left[\sup_{0 \leq t \leq T} |M_t - M_t^{n,p}| \right] \end{aligned}$$

and the result follows from Proposition 2.2. \square

Uniformly-weighted moving average The uniform weighting measure

$$\mu(dx) = h(x)dx = \frac{1}{\delta} \mathbb{1}_{[0,\delta]} dx \quad (19)$$

satisfies the assumptions of Proposition 2.2. In particular, $H(x) = \frac{1}{\delta} (\delta - x)^+$. From Lemma A.2, the Laguerre coefficients $A_k^{\delta,p} = \langle H, L_k^p \rangle$ are related to the Laguerre coefficients of h , $c_k^{\delta,p} = \langle h, L_k^p \rangle_2$, via

$$A_k^{\delta,p} = (-1)^k \frac{\sqrt{2p}}{p} - \frac{1}{p} c_k^{\delta,p} - \frac{2}{p} \sum_{i=0}^{k-1} (-1)^{k-i} c_i^{\delta,p}, \quad (20)$$

and the coefficients of h can be computed from the values of Laguerre polynomials:

$$c_n^{\delta,p} = \frac{\sqrt{2p}}{\delta p} \left[(1 - e^{-p\delta} P_n(2p\delta)) + 2 \sum_{k=1}^n (-1)^k (1 - e^{-p\delta} P_{n-k}(2p\delta)) \right]. \quad (21)$$

Given the length of the averaging window $\delta > 0$ and an order $n \geq 1$ of approximation (number of Laguerre functions), we determine the optimal scale parameter $p_{\text{opt}}(\delta, n)$ as

$$p_{\text{opt}}(\delta, n) = \arg \min_{p>0} \|H - H_n^p\|_2 = \arg \min_{p>0} \left\{ \frac{\delta}{3} - \sum_{k=0}^{n-1} |A_k^{\delta,p}|^2 \right\}. \quad (22)$$

Finding an explicit formula to $p_{\text{opt}}(\delta, n)$ does not seem to be possible, but finding a numerical solution is easy using the explicit expressions (20), (21) and (22). In addition, once p_{opt} is computed for a couple $(1, n)$, the scaling property of Laguerre functions (8) gives the value of $p_{\text{opt}}(\delta, n)$, for any $\delta > 0$:

$$p_{\text{opt}}(\delta, n) = \frac{p_{\text{opt}}(1, n)}{\delta}.$$

Table 1 gives the values for $p_{\text{opt}}(1, n)$ for the first 10 values of n computed with an accuracy of 10^{-3} . Figure 1 (left graph) illustrates the approximation of H by the truncated Laguerre expansion $H_n^{p_{\text{opt}}(n)}$ for $n = 1, 3, 7$ Laguerre basis functions (with $\delta = 1$). The corresponding error $\|H - H_n^{p_{\text{opt}}(n)}\|_2$ as a function of n is shown in the right graph. The error is less than 5% already with $n = 3$. A simple least squares estimation by a power function gives a behavior in $\mathcal{O}(n^{-1.06})$.

n	1	2	3	4	5	6	7	8	9	10
$p_{\text{opt}}(1, n)$	2.149	4.072	6.002	4.234	5.828	7.473	9.155	10.866	9.153	10.726

Table 1: Optimal scaling parameters for approximating $H(x) = \frac{1}{\delta} (\delta - x)^+$.

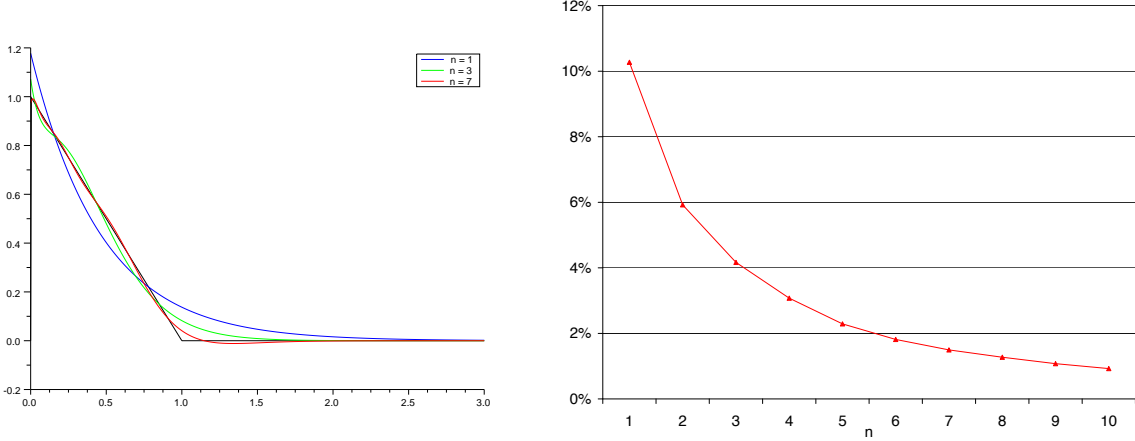

Figure 1: Left: Laguerre approximation of the function $H(x) = \frac{1}{\delta} (\delta - x)^+$. Right: L^2 error of the approximation.

Proposition 2.2 also applies when the moving average is delayed by a fixed time lag $l \geq 0$:

$$X_t = \frac{1}{\delta} \int_{t-l-\delta}^{t-l} S_u du, \quad \forall t \geq \delta + l. \quad (23)$$

In this case, the weighting measure is $\mu(dx) = \frac{1}{\delta} \mathbf{1}_{[l, l+\delta]} dx$ and $H(x) = \frac{1}{\delta} \{(\delta + l - x)^+ - (l - x)^+\}$. Figure 2 shows the approximation of H by $H_n^{p_{\text{opt}}(n)}$ for $n = 1, 3, 5, 7$ Laguerre basis functions with $\delta = 1$ and $l = 0.5$ as well as the L^2 -error made as a function of n (in the same way as above, we numerically compute $p_{\text{opt}}(n)$ for minimizing the L^2 -error made by Laguerre approximation). In comparison to the previous case, it appears that the number of Laguerre basis functions necessary to approximate H is greater for an equivalent accuracy of the approximation: the error is less than 5% from $n = 5$. This is due to the fact that the density of the weighting measure has two points of discontinuity.

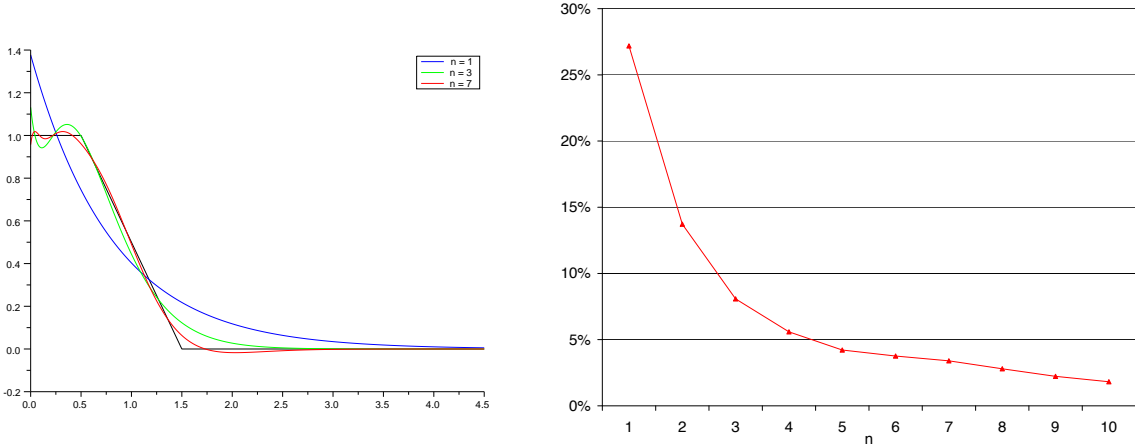

Figure 2: Left: Laguerre approximation of the function $H(x) = \frac{1}{\delta} \{(\delta + l - x)^+ - (l - x)^+\}$. Right: L^2 error of the approximation.

3 A Monte Carlo-based numerical method

In this section we present a numerical method for computing the solution to the approximate problem (18), which is a $(n + 1)$ -dimensional optimal stopping time problem. For the sake of simplicity, we restrict ourselves to uniformly weighted moving averages. Since the dimension of the problem may be high, we use a Monte Carlo technique. Our numerical approach corresponds to the one from Longstaff and Schwartz [16] and the computation of conditional expectations is done with a regression based approach. In particular, we shall use the technique of adaptive local basis proposed by Bouchard and Warin [5].

Forward simulation in discrete time We compute the price of the *discrete time version* of the American option (18) in which the moving average X has been replaced by its approximation $M^{n, \text{opt}}$ defined in (14) and the exercise is possible on an equidistant discrete time grid with $N \geq 1$ time steps $\Delta t = \frac{T}{N}$: $\pi = \{t_0 = 0, t_1, \dots, t_N = T\}$. We assume that there are exactly $N_\delta \geq 1$ time steps within the averaging window of length δ : $N_\delta = \frac{\delta}{\Delta t} = \frac{\delta}{T} N$, and that the spot price S can be simulated on π either exactly or using the Euler scheme. We denote this simulated discrete time price by

$$\{S_{t_0}^\pi = S_0, S_{t_1}^\pi, \dots, S_{t_N}^\pi\},$$

extend this definition to $[0, T]$ by

$$S_t^\pi = S_{t_{i+1}}^\pi, \quad \forall t \in (t_i, t_{i+1}] \quad (24)$$

and shall also apply convention (2) to S^π . We define the discrete time version X^π of the moving average process X by

$$X_{t_i}^\pi = \frac{1}{\delta} \int_{t_i - \delta}^{t_i} S_t^\pi dt = \frac{1}{N_\delta} \sum_{j=i-N_\delta+1}^i S_{t_j}^\pi, \quad \forall t_i \in \pi. \quad (25)$$

Similarly, the discrete time versions of the Laguerre processes are defined by

$$X_{t_i}^{p,k,\pi} = \int_{-\infty}^{t_i} L_k^p(t_i - v) S_t^\pi dt = \sum_{j=1}^i \left(S_{t_j}^\pi - S_{t_{j-1}}^\pi \right) (i - j + 1) \Delta t c_k^{(i-j+1)\Delta t, p} + S_0 (-1)^k \frac{\sqrt{2p}}{p}, \quad \forall t_i \in \pi.$$

Backward resolution of the optimal stopping time problem The resolution is based on the well-known backward American dynamic programming principle. We adopt a Longstaff and Schwartz-style approach which consists in estimating the optimal exercise time (or equivalently the optimal cashflows generated by the optimal exercise rule) instead of focusing on the computation of the option value processes (as for example in Tsitsiklis and Van Roy [24]). Throughout the paper, the approach presented below will be called (Lag-LS). The optimal payoffs are evaluated using the *approximate value* of moving average X^π derived from (14):

$$M_{t_i}^{n,p_{\text{opt}},\pi} = (H(0) - H_n^{p_{\text{opt}}}(0)) S_{t_i}^\pi + \sum_{k=0}^{n-1} a_k^{p_{\text{opt}}} X_{t_i}^{p_{\text{opt}},k,\pi}, \quad \forall t_i \in \pi. \quad (26)$$

Denote by $(\tau_i^\pi)_{i=N_\delta, \dots, N}$ the sequence of discretized optimal exercise times: τ_i^π is the optimal exercise time after $t_i \in \pi$. The backward algorithm works as follows:

1. Initialization: $\tau_N^\pi = T$
2. Backward induction for $i = N - 1, \dots, N_\delta$:

$$\tau_i^\pi = t_i \mathbb{1}_{A_i} + \tau_{i+1}^\pi \mathbb{1}_{\mathcal{C}_{A_i}} \quad \text{with } A_i = \left\{ \phi \left(S_{t_i}^\pi, M_{t_i}^{n,p_{\text{opt}},\pi} \right) \geq \mathbb{E}_{t_i} \left[\phi \left(S_{\tau_{i+1}^\pi}^\pi, M_{\tau_{i+1}^\pi}^{n,p_{\text{opt}},\pi} \right) \right] \right\}$$

3. Estimation of the option price at time 0:

$$V_0^\pi = \mathbb{E} \left[\phi \left(S_{\tau_{N_\delta}^\pi}^\pi, M_{\tau_{N_\delta}^\pi}^{n,p_{\text{opt}},\pi} \right) \right]$$

in which:

$$\mathbb{E}_{t_i} [\cdot] = \mathbb{E} \left[\cdot \mid \left(S_{t_i}^\pi, X_{t_i}^{p_{\text{opt}},0,\pi}, \dots, X_{t_i}^{p_{\text{opt}},n-1,\pi} \right) \right].$$

Estimators of the conditional expectations are constructed with a Monte-Carlo based technique. It consists in using $M \geq 1$ simulated paths on π of the $(n + 1)$ -dimensional state process:

$$\left(S^{\pi,(m)}, X^{p_{\text{opt}},0,\pi,(m)}, \dots, X^{p_{\text{opt}},n-1,\pi,(m)} \right), \quad m = 1, \dots, M.$$

The corresponding paths of the approximate moving average are denoted by:

$$M^{n,p_{\text{opt}},\pi,(m)}, \quad m = 1, \dots, M.$$

Conditional expectations estimators $\mathbb{E}_{t_i}^M$ are then computed by regression on local basis functions (see the precise description of the procedure in Bouchard and Warin [5]). We shall denote by $(b^S, b_0^X, \dots, b_{n-1}^X)$ the numbers of basis functions used in each direction of the state variable: b^S for S^π , b_0^X for $X^{p_{\text{opt}},0,\pi}$, b_1^X for $X^{p_{\text{opt}},1,\pi}$, etc. The Monte-Carlo based backward procedure becomes thus:

1. Initialization: $\tau_N^{\pi,(m)} = T, m = 1, \dots, M$
2. Backward induction for $i = N - 1, \dots, N_\delta, m = 1, \dots, M$:

$$\begin{cases} \tau_i^{\pi,(m)} = t_i \mathbb{1}_{A_i^{(m)}} + \tau_{i+1}^{\pi,(m)} \mathbb{1}_{\mathcal{C}A_i^{(m)}} \\ A_i^{(m)} = \left\{ \phi \left(S_{t_i}^{\pi,(m)}, M_{t_i}^{n,p_{\text{opt}},\pi,(m)} \right) \geq \mathbb{E}_{t_i}^M \left[\phi \left(S_{\tau_{i+1}^{\pi,(m)}}^{\pi,(m)}, M_{\tau_{i+1}^{\pi,(m)}}^{n,p_{\text{opt}},\pi,(m)} \right) \right] \right\} \end{cases}$$

3. Estimation of the option price at time 0:

$$V_0^\pi = \frac{1}{M} \sum_{m=1}^M \phi \left(S_{\tau_{N_\delta}^{\pi,(m)}}^{\pi,(m)}, M_{\tau_{N_\delta}^{\pi,(m)}}^{n,p_{\text{opt}},\pi,(m)} \right)$$

Remark 3.1. We will use a numerical improvement to this standard backward induction algorithm, which might seem rather natural for practitioners. It consists in evaluating the optimal payoffs using the *exact value* (25) of the moving average. In particular, the optimal stopping frontier becomes:

$$A_i^* = \left\{ \phi \left(S_{t_i}^\pi, X_{t_i}^\pi \right) \geq \mathbb{E}_{t_i} \left[\phi \left(S_{\tau_{i+1}^\pi}^\pi, X_{\tau_{i+1}^\pi}^\pi \right) \right] \right\}.$$

This improved method will be called (Lag-LS*) and unlike (Lag-LS) will exhibit a monotone convergence as n goes to infinity.

”Non Markovian” approximation for moving average options Motivated by a reduction of dimensionality, the numerical method that is most often used in practice to value moving average options consists in computing the conditional expectations in the Longstaff-Schwartz algorithm using only the explanatory variables (S, X) : namely, the price and the moving average appearing in the option payoff. The resulting exercise time is thus suboptimal, but the approximate option price is often close to the true price. To assess the improvement offered by our method, we systematically compare our approximation to this suboptimal approximate price, also computed using a Longstaff and Schwartz approach and referred to as (NM-LS).

Let $(\theta_i^\pi)_{i=N_\delta, \dots, N}$ denote the discrete time sequence of the estimated optimal exercise times (θ_i^π being the optimal exercise time after $t_i \in \pi$). (NM-LS) algorithm works as follows:

1. Initialization: $\theta_N^\pi = T$
2. Backward induction for $i = N - 1, \dots, N_\delta$:

$$\theta_i^\pi = t_i \mathbb{1}_{A_i} + \theta_{i+1}^\pi \mathbb{1}_{\mathcal{C}A_i} \text{ with } A_i = \left\{ \phi \left(S_{t_i}^\pi, X_{t_i}^\pi \right) \geq \mathbb{E} \left[\phi \left(S_{\theta_{i+1}^\pi}^\pi, X_{\theta_{i+1}^\pi}^\pi \right) \mid (S_{t_i}^\pi, X_{t_i}^\pi) \right] \right\}$$

3. Estimation of the option price at time 0:

$$U_0^\pi = \mathbb{E} \left[\phi \left(S_{\theta_{N_\delta}^\pi}^\pi, X_{\theta_{N_\delta}^\pi}^\pi \right) \right]$$

Similarly to other methods, the conditional expectations are computed with the adaptative local basis regression-based technique from [5]. The numbers of basis functions used in each direction will be denoted by b^S for S^π and b^X for X^π .

4 Numerical examples

For our examples, we use the single-asset Black and Scholes framework. We study standard moving average options for different values of the averaging window δ as well as moving average options with delay (23).

With the same notations as in Section 3, recall that the dimension of the discrete time version of moving average option pricing problem is equal to N_δ with a Markovian state:

$$\left(S_{t_i}^\pi, S_{t_{i-1}}^\pi, \dots, S_{t_{i-N_\delta+1}}^\pi \right), \forall t_i \in \pi, t_i \geq t_{N_\delta}.$$

We use the standard Longstaff and Schwartz algorithm for such a Bermudan option in dimension N_δ as the benchmark method. This method will be called (M-LS) and our Monte Carlo regression based approach (see more details in [5]) allows to deal with cases up to dimension 8. For applications in which N_δ is larger, this method becomes computationally unfeasible.

We provide at the end of this section a numerical comparison between the convergence rate of our Laguerre-based approximation and (M-LS) with respect to the state dimension.

Moving average options: benchmark prices Consider a standard moving average American option with value at time 0:

$$\sup_{\tau \in \mathcal{T}_{[\delta, T]}} \mathbb{E} \left[e^{-r\tau} \phi(S_\tau, X_\tau) \right], \quad X_\tau = \frac{1}{\delta} \int_{\tau-\delta}^{\tau} S_u du$$

where the asset price S is assumed to follow the risk-neutral Black and Scholes dynamics:

$$dS_t = S_t (rdt + \sigma dW_t), \quad S_0 = s$$

and W is a standard Brownian motion. We shall consider call options with pay-off $\phi(s, x) = (s-x)^+$. Unless specified otherwise, the following parameters are used below:

Maturity	$T = 0.2$
Risk free interest	$r = 5\%$
Volatility	$\sigma = 30\%$
Initial spot value	$s = 100$

and we consider a Bermudan option with exercise possible every day (when $T = 0.2$, the time interval $[0, T]$ is divided into $N = 50$ time steps).

Table 2 shows the prices of moving average call options computed by (NM-LS) and (M-LS) for various averaging periods δ , with $M = 10$ million of Monte Carlo paths and $b^S = b^X = 2$. The prices are averages over 5 valuations and the relative standard deviation is given in brackets. For reasonable volatility coefficients of the underlying price process and relatively small averaging window δ , (NM-LS) seems to provide a very good approximation (from below) to moving average options prices. This justifies the approximation made by practitioners and (among others) by Broadie and Cao [4].

N_δ	(NM-LS)	(M-LS)
2	1.890 (0.011 %)	1.890 (0.011 %)
3	2.684 (0.011 %)	2.685 (0.010 %)
4	3.183 (0.018 %)	3.186 (0.012 %)
5	3.526 (0.016 %)	3.531 (0.007 %)
6	3.773 (0.016 %)	3.780 (0.013 %)
7	3.955 (0.011 %)	3.964 (0.215 %)
8	4.092 (0.015 %)	4.103 (0.316 %)
9	4.193 (0.016 %)	
10	4.268 (0.019 %)	

Table 2: Moving average options pricing with (NM-LS) and (M-LS).

Figure 3: Simulated trajectory of the moving average process and its Laguerre approximations.

Moving average American options: Laguerre approximation Figure 3 shows a simulated trajectory of the underlying price S^π , its moving average X^π with $\delta = 0.04$ and the corresponding Laguerre-based moving average approximation $M^{n,p_{\text{opt}},\pi}$ with $n = 1, 3$ and 7 Laguerre basis functions. Already for $n \geq 3$ Laguerre basis functions, $M^{n,p_{\text{opt}},\pi}$ accurately mimics the exact moving average dynamics of X^π and this approximation seems to be almost exact when $n = 7$.

Table 3 reports the prices of moving average call options computed using the Laguerre-based method presented in Section 3 (Lag-LS) and its improved version (Lag-LS*) (with the same parameters as above, in particular $\delta = 0.04$). The price values are means over 5 valuations, the relative standard deviation is given in brackets and we used $M = 5$ million Monte Carlo paths for $n = 1, \dots, 3$ Laguerre functions and $M = 10$ million Monte Carlo paths for $n = 4, \dots, 7$ Laguerre functions, with $b^S = 4$ and $b_k^X = 1, \forall k \geq 0$. With $M = 10$ million Monte Carlo paths, $b^S = 4$ and

$b^X = 1$, (NM-LS) gives an option value equal to 4.268.

n	(Lag-LS*)	(Lag-LS)
1	4.266 (0.020 %)	4.092 (0.017 %)
2	4.273 (0.022 %)	4.302 (0.019 %)
3	4.276 (0.023 %)	4.182 (0.018 %)
4	4.276 (0.022 %)	4.227 (0.020 %)
5	4.277 (0.023 %)	4.275 (0.020 %)
6	4.277 (0.024 %)	4.287 (0.022 %)
7	4.277 (0.024 %)	4.258 (0.022 %)

Table 3: Moving average options pricing with (Lag-LS) and (Lag-LS*).

Remark 4.1. When the averaging window is large, the variance of the Laguerre states $(X_k^{p,k})_{k \geq 0}$ is small, and at least much smaller than the variance of the price S . In consequence, increasing the numbers b_k^X of basis functions in the directions of these states does not have a strong impact on the conditional expectation estimators and the resulting option price. On the contrary, the number b^S of basis functions in the direction of the spot price S should be sufficiently large.

Whereas (Lag-LS) oscillates as n increases (this is due to the non monotone approximation of the moving average X by $M^{n, \text{opt}}$), (Lag-LS*) shows a monotone convergence when increasing n , as shown in Figure 4. The limiting value (almost 4.277) is around 0.2% above the value computed by the practitioner's approximation (NM-LS).

Figure 4: Convergence of the improved Laguerre-based approximation.

Figure 5 presents the prices of moving average call options computed by (Lag-LS*) and (NM-LS) when varying δ from 0 to T with the same parameters as above. 7 Laguerre basis functions were used with method (Lag-LS) as soon as $N_\delta \geq 8$. For smaller N_δ , we take $n = N_\delta - 1$: n must satisfy the condition $n \leq N_\delta - 1$ because otherwise the estimation of the conditional expectation at time

t_{N_δ} leads to a degenerate linear system. In the limit case when $\delta = T$, we retrieve the price of the Asian option with payoff $\left(S_T - \frac{1}{T} \int_0^T S_t dt\right)^+$. For large averaging periods, the price that we obtain with 7 Laguerre functions is about 0.30% above the benchmark value given by the (suboptimal) non Markovian approximation.

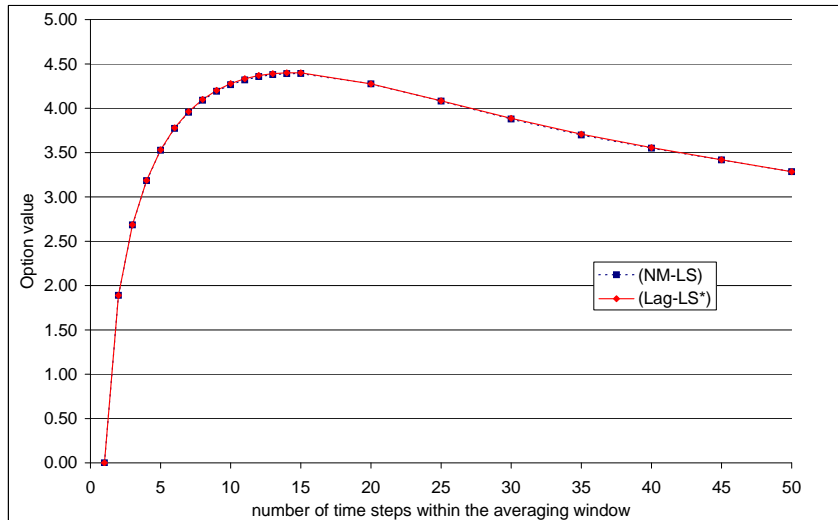

Figure 5: Moving average option price as function of the averaging window δ .

Moving average American options with time delay Consider now a moving average American option with time delay $l \geq 0$ whose value at time 0 is:

$$\sup_{\tau \in \mathcal{T}_{[\delta+l, T]}} \mathbb{E}[\phi(S_\tau, X_\tau)], \quad X_\tau = \frac{1}{\delta} \int_{\tau-l-\delta}^{\tau-l} S_u du.$$

With the same option characteristics and parameters as above and an averaging period equal to $\delta = 0.02$ (number of time steps $N_\delta = 5$), Figure 6 presents the prices of delayed moving average call options computed by (Lag-LS*) and (NM-LS) when varying l from 0 to $T - \delta$. In the limit case when $l = T - \delta$ we retrieve the price of the Asian option with payoff $\left(S_T - \frac{1}{T-l} \int_0^{T-l} S_t dt\right)^+$.

The relative difference between the option values given by (Lag-LS*) and (NM-LS) is significant (bigger than 5%) for time lags such that $l \in [0.04, 0.152]$ (corresponding to $10 \leq N_l \leq 38$). For example, when $l = 0.1$ (corresponding to $N_l = 25$ time steps), the relative difference is around 11%.

Figure 6: Price of the moving average option with time delay as function of the lag l .

Now fix $l = 0.08$ ($N_l = 20$). As shown in Figure 7, when the averaging window increases this relative difference decreases. But it is still around 5% when $N_\delta = 15$.

Figure 7: Price of the moving average option with time delay as function of the averaging window δ .

As expected, for pricing delayed moving average options, the non Markovian approximate method (NM-LS) seems to be a worse approximation than in the case without time lag: the error increases with the time lag but decreases with the length of the the averaging period. For large time lags and relatively small averaging period, our improved Laguerre-based method (Lag-LS*) gives option prices up to 11% above the benchmark value given by the suboptimal approximation (NM-LS) (cf. $N_l = 25$ on Figure 6). For a good accuracy of (Lag-LS*), the required number of Laguerre functions is however bigger than in the case without time lag as explained at the end of Section 2.

Pricing of moving average Bermudean options: a convergence rate improvement To compute the exact price of a moving average Bermudan option, one can either use the classical method (M-LS) taking a sufficient number of steps within the averaging window or use the Laguerre-based method with sufficient number of state processes. In this last example we illustrate the fact that our method (Lag-LS*) converges much faster than classical method (M-LS) with respect to the state dimension for pricing the same Bermudan option.

Let us consider a moving average call option with maturity $T = 0.5$ and moving window $\delta = 0.1$. Figure 8 provides a comparison between price values given by (Lag-LS*) for a time step $\Delta t = \frac{1}{80}$ when varying the number of Laguerre functions from 1 to 7 and by (M-LS) when varying the number of time steps within the averaging period from 2 to 8, that is $\Delta t = \frac{1}{20}, \frac{1}{30}, \dots, \frac{1}{80}$ (the state dimension varies in both cases from 2 to 8). $M = 20$ million of Monte Carlo paths were used in both cases and $b^S = 2$, $b^X = 1$.

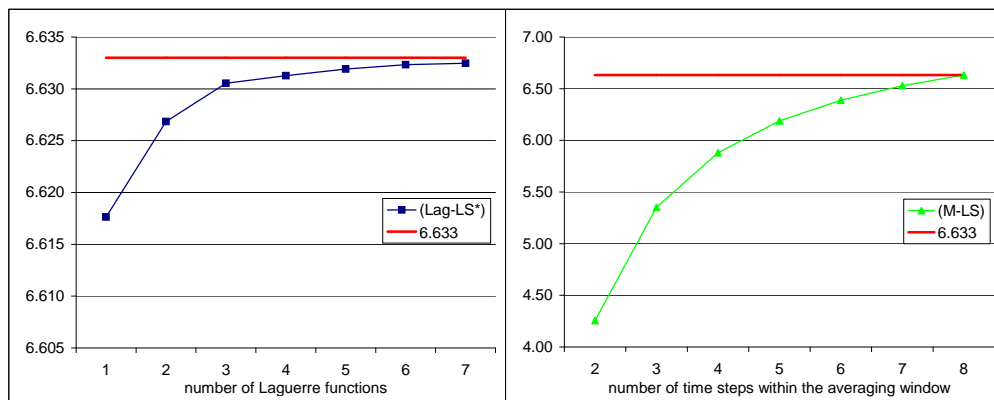

Figure 8: Convergence of the improved Laguerre-based approximation and the benchmark method for pricing a Bermudan option.

A Appendix

Lemma A.1. The Laguerre polynomials $(P_k)_{k \geq 0}$ belong to $\mathcal{C}^\infty([0, +\infty))$ and:

- (i) $\forall k \geq 1, tP'_k(t) - kP_k(t) + kP_{k-1}(t) = 0$
- (ii) $\forall k \geq 1, \frac{k}{t}(P_k(t) - P_{k-1}(t)) = -\sum_{i=0}^{k-1} P_i(t)$

Proof. (i) can be found for example in Szegö [21] and (ii) is a consequence of (10). □

Lemma A.2. The definite integrals and derivatives of Laguerre functions can be computed using the following formulas:

$$\int_t^\infty e^{-s/2} P_n(s) ds = 2e^{-t/2} P_n(t) + 4e^{-t/2} \sum_{k=1}^n (-1)^k P_{n-k}(t). \quad (27)$$

$$\left(e^{-t/2} P_n(t) \right)' = -\sum_{k=0}^{n-1} e^{-t/2} P_k(t) - \frac{1}{2} e^{-t/2} P_n(t). \quad (28)$$

Proof. This follows, after some computations, from the contour integral representation of Laguerre polynomials:

$$P_n(t) = \frac{1}{2\pi i} \oint \frac{e^{-\frac{ts}{1-s}}}{(1-s)s^{n+1}} ds.$$

□

Lemma A.3. The Laguerre functions and their integrals admit the following representation in terms of Bessel functions:

$$e^{-x/2}P_n(x) = \sum_{k=0}^{\infty} A_k \left(\frac{x}{\nu}\right)^{k/2} J_k(\sqrt{\nu x}), \quad \nu = 4n + 2 \quad (29)$$

$$I_n(x) := \int_0^x e^{-x'/2} P_n(x') dx' = 2 \sum_{k=0}^{\infty} A_k \left(\frac{x}{\nu}\right)^{(k+1)/2} J_{k+1}(\sqrt{\nu x}) \quad (30)$$

$$\int_0^x I_n(x') dx' = 4 \sum_{k=0}^{\infty} A_k \left(\frac{x}{\nu}\right)^{(k+2)/2} J_{k+2}(\sqrt{\nu x}), \quad (31)$$

where $A_0 = 1$, $A_1 = 0$, $A_2 = \frac{1}{2}$ and other A_i -s satisfy the equation $(m+2)A_{m+2} = (m+1)A_m - \frac{\nu}{2}A_{m-1}$. The series converge uniformly in x on any compact interval.

Proof. The first formula is from [7]. The other two follow readily using the integration formula for Bessel functions:

$$\int_0^1 x^{\nu+1} J_{\nu}(ax) dx = a^{-1} J_{\nu+1}(a).$$

□

Lemma A.4. Let μ be a finite signed measure on $[0, \infty)$, with bounded support which does not contain zero. Let $\{c_n\}$ denote the Laguerre coefficients of the function $h(x) := \mu([x, \infty))$ and $\{A_n\}$ denote the Laguerre coefficients of the function $H(x) := \int_x^{\infty} h(t) dt$. Then

$$c_n = \mathcal{O}(n^{-3/4}) \quad \text{and} \quad A_n = \mathcal{O}(n^{-5/4}).$$

In addition, for $x > 0$ fixed, $e^{-x/2}P_n(x) = \mathcal{O}(n^{-1/4})$.

Proof. This result follows from Lemma A.3, using the asymptotic expansion for Bessel functions

$$J_n(x) = \left(\frac{1}{2}\pi x\right)^{-1/2} \cos\left(x - \frac{\pi}{2}n - \frac{\pi}{4}\right) + \mathcal{O}(x^{-3/2}),$$

which holds uniformly [7] on bounded domains outside a neighborhood of zero. □
