Short title: Population PK of LMV, STV and ZDV in patients on HAART.

Objective: This work aimed at building a population pharmacokinetic (PK) model for lamivudine (LMV), stavudine (STV) and zidovudine (ZDV), estimating their inter and intra-individual PK variability and investigating the influence of different covariates.

Methods: Population PK of LMV, STV and ZDV was separately evaluated from plasma concentrations obtained in 54, 39 and 27 HIV1-infected patients, respectively, enrolled in the COPHAR1-ANRS102 trial. The primary objective of this trial was to study the pharmacokinetics of indinavir (IDV) and nelfinavir (NFV) in treated patients with a sustained virological response. Concentrations of nucleoside analogs (NA) were measured in plasma as a secondary objective. A one compartment model with first order elimination was used, with zero order absorption for LMV and first order absorption for STV and ZDV.

Results: Mean parameters (inter-patient variability in CV%) of LMV, STV and ZDV were: oral volume of distribution (V/F) 145L (52%), 24 L (81%) and 248 L (80%), oral clearance (Cl/F) 32 L/h, 16 L/h (74%) and 124 L/h (51%), respectively. For LMV, absorption duration (T_a) was 1.46 h (64%). For STV and ZDV, k_a was 0.46 h^{-1} and 2.9 h^{-1}, respectively. We found a systematic effect of combination with NFV vs IDV. We found that intra-patient variability was greater than inter-patient variability (except for STV) and greater than 55% for the three drugs.

Conclusion: This trial enabled the estimation of the population PK parameters of three NA in patients with a sustained virological response, and the median curves could be used as references for concentration-controlled strategies. We observed, as for the protease inhibitors, a great variability of PK parameters.

INTRODUCTION

Therapeutic drug monitoring (TDM) of protease inhibitors and non-nucleoside reverse transcriptase inhibitors has been largely investigated, and its importance has been demonstrated in special populations (pregnant women, hepatic failure, etc ...). Pharmacokinetic (PK) studies performed in patients having an optimal response to HAART, are the gold standard to define reference curves for TDM.

For nucleoside analogs (NA), TDM is generally not recommended because the concentration/effect relationship has not been clearly defined and because NA in plasma need to be phophorylated before becoming active in the cell. On the other hand, the potential interest of concentration-controlled regimens of NA has already been shown [1–4]. However, very few data are available on the PK of NA in patients succesfully treated with HAART. Such data are important to correlate plasma and intracellular concentrations and to establish a range of effective and non toxic plasma concentrations of all components of HAART.

The COPHAR1-ANRS102 trial was a prospective, open-label, multicenter trial which primary objective was to study the PK of indinavir (IDV) and nelfinavir (NFV) in patients on sustained virological success. Reference therapeutic windows for the TDM of IDV and NFV were defined according to the concentration data measured in this trial [5]. The population approach was also used to describe the PK of IDV and NFV, to estimate inter- and intra-patient variabilities of the PK parameters, and to test the effect of covariates. An increase of IDV and NFV clearance was found in patients receiving zidovudine (ZDV) as part of their treatment [6, 7]. In COPHAR1-ANRS102, patients received either lamivudine (LMV), stavudine (STV) or zidovudine (ZDV) as part of their treatment, in addition to one protease inhibitor. As a secondary objective, NA concentrations were measured in the same plasma samples collected to study the PK of NFV and IDV. The aim of the present study was to build a population PK model for LMV, STV and ZDV, to estimate their inter- and intra-individual PK variability and to investigate the influence of different covariates on the PK parameters of these three drugs.

MATERIAL AND METHODS

Study design and patients

The COPHAR1-ANRS102 trial was a prospective, multicentre, open-label trial which included HIV-infected adults currently treated with an antiretroviral combination of at least two drugs, containing either IDV or NFV. Enrolment started in February 2001 and the last subject completed the study in October 2002. To be eligible, patients had to be treated with a stable

regimen for at least 4 months with a sustained virological response defined by a plasma HIV RNA level below 200 copies/mL for at least 4 months. The main exclusion criteria were the following: concomitant use of drugs interacting with IDV or NFV, renal failure (defined by a serum creatinine greater than 180 μmol/L), liver dysfunction (defined by a serum aminotransferase level greater than twice the upper limit of normal, a prothrombin test below 50% or a diagnosed liver cirrhosis), pregnancy, ongoing acute opportunistic infection or cancer.

All patients received the standard dose of 300 mg per day for LMV. The STV dose was prescribed according to subject's weight: 60 mg per day for subjects whose weight was less than 60 kg, and 80 mg per day for those whose weight was greater than 60 kg. The recommended standard daily dose for ZDV was 600mg.

The Ethical Review Committee of the Bicêtre Hospital, Paris, France reviewed and approved the study protocol. All participants provided written informed consent. At the screening visit (V0), inclusion criteria were checked. At visit 1 (V1), one month after inclusion, patients underwent a 6-hour blood sampling for concentration assay. At visit 2 (V2), four months after inclusion, two additional blood samples were collected. The trial ended 8 months after inclusion (V3), when clinical, immunological and virological data were collected. Only patients with a sustained virological response, i.e. 4 months before inclusion plus 8 months after inclusion, were analysed.

Adherence was evaluated using a validated auto-questionnaire and applying the algorithm proposed by Carrieri et al. [8]. Patients were classified as highly adherent if they reported taking 100% of their prescribed regimen in the last four days, moderately adherent if they reported missing no more than 20% of their treatment, and non-adherent if they reported taking less than 80% of their treatment.

PK samples and concentration measurement

PK sampling was designed according to the dosing regimen of the PIs. The interval between the last dose on the previous day and the morning dose was planned for 12 hours (+/-2 hours) for bid dosing and for 8 hours (+/- 2 hours) for tid dosing. At V1, plasma samples were collected before dosing (trough sample) and at 0.5 hour, 1, 3 and 6 hours after drug intake. At V2, a

sample was collected 8 hours (+/-2 hours) or 12 hours (+/-2 hours) for tid and bid dosing, respectively, after the last drug intake, and a second sample 1 hour after observed drug intake in patients treated with IDV alone, or 3 hours after observed drug intake in patients receiving NFV or IDV/ritonavir in order to reach the C_{max} of the corresponding PI. For each sample performed after the observed drug intake, the exact interval between last drug intake and blood sampling was recorded. For trough samples, the delay since last dose was evaluated from the time of last evening dose reported by the patient and the exact sampling time in the morning. All NA concentrations measured at V1 and NA concentrations measured one hour (C_{1h}) and three hours after dose (C_{3h}) measured at V2 are analysed in this paper.

NA concentrations were measured in each plasma sample in a central laboratory of pharmacology in Paris. NA were isolated from alkaline plasma samples by double-step solid-liquid extraction and their concentrations were determined by specific high-performance liquid chromatography assays with ultraviolet - photodiode array [9]. Interlaboratory quality control results at three concentrations (50, 400 and 1000 ng/mL for LMV and 25, 200 and 400 ng/mL for both STV and ZDV) were within 20% of the target values for the three NA. Lower limits of quantification (LOQ) were 20 ng/mL, 10 ng/mL and 10 ng/mL for LMV, STV and ZDV, respectively.

Population pharmacokinetic model

For each of the 3 NA, we tested a one-compartment model with first-order absorption or zero order absorption to analyse concentrations measured at V1. The parameters of these two models are the first-order absorption rate constant (k_a) or the zero order absorption duration (T_a), the apparent elimination clearance (Cl/F) and the apparent volume of distribution (V/F).

With respect to timing assumptions, exact sampling times were taken for samples scheduled at 0.5, 1, 3 and 6 hours after the morning dose. For modelling, we assumed that trough samples were obtained after the other measurements on the same PK profile.

For each NA, the statistical model for the observed concentration C_{ij} of patient i at the sampling time t_{ij} is:

$$C_{ij} = f(t_{ij}, \theta_i) + \varepsilon_{ij}$$

where θ_i is the vector of the logarithm of all the PK parameters of patient i and ε_{ij} is the measurement error.

For each NA, we assumed that the errors ε_{ij} given θ_i are independent and normally distributed with a null mean and an heteroscedastic variance σ_{ij}^2, which was modelled using a combined proportional and additive error model:

$$\sigma_{ij}^2 = \sigma^2(a + f(t_{ij}, \theta_i))^2$$

This combined error model (additive and proportional) is commonly used in population pharmacokinetics. For high concentrations, variance becomes proportional to the squared concentration whereas for low concentrations, the variance becomes proportional to a^2. When LMV, STV or ZDV concentrations were below the LOQ, we set them at LOQ/2 [10]. If several consecutive concentrations were below the LOQ, the first was set to the corresponding value of LOQ/2 and the others were removed from the analysis.

We assumed that the logarithm of the individual parameters θ_i are random vectors and that θ_i can be decomposed as:

$$\theta_i = \theta + b_i$$

where θ is the population mean vector of size p, and b_i is the random effect of subject i, which is assumed to be normally distributed with zero mean and diagonal variance Ω. The standard deviations of the additive random effects on the log transformed PK parameters are then a first order approximation of the coefficient of variation (CV) of the original PK parameters. These standard deviations are the square roots of the diagonal elements of Ω.

The parameters were estimated using Lindström and Bates' algorithm implemented in the nlme function of R 2.0 software (R Foundation for Statistical Computing, Vienna, Austria) [11–13]. The estimates for the standard errors (SE) of the parameters were used to derive the corresponding asymptotic 95% confidence intervals.

Modelling strategy

For each drug, we first selected the pharmacokinetic model (one compartment model with zero order or first order absorption and first order elimination) based on the Akaike criterion (AIC) [14] using a combined error model. We then selected the error model, starting with the previous combined error model where a and σ are estimated. We also tried a model where a is fixed, a model where a is fixed to zero, and an additive error model. Using the best error model, selected according to the AIC, we built a model with random effects on all PK parameters. We used a backward elimination procedure to test whether each random effect should stay in the model. Goodness-of-fit plots (weighted residuals versus predicted concentrations and versus time) were examined for each model. Models were also compared using the AIC.

For each NA and for each PK parameter whose random effect remained in the model, we evaluated the effects of the following covariates: age, sex, body weight, co-administrated protease inhibitor (NFV or IDV), co-administration of other antiretroviral drugs (as a binary variable for each drug) and treatment adherence (as a categorical variable). We tested the covariates on the Empirical Bayes estimates of each individual parameter using Spearman non-parametric correlation tests for continuous covariates and Wilcoxon or Kruskal-Wallis tests for categorical covariates with two or more than two categories, respectively. The population covariate model was then built with the covariates which were found to have an effect on the Empirical Bayes estimates with a p-value smaller than 0.20. Continuous covariates were centered on their median. All population models with all the combinations of these selected covariates were then evaluated. The combination with the smallest AIC was chosen as the best population covariate model. The p-values of the covariates were then derived using the Likelihood Ratio Test (LRT).

Model evaluation

We produced the goodness-of-fit plots (population predicted concentrations vs observed concentrations, individual predicted concentrations versus observed concentrations and population weighted residuals versus observed concentrations) for each of the three NA. We also simulated steady-state concentration profiles for the three studied NA and compared them to the

6

observed data in order to evaluate the predictive performance of the model. More precisely, a vector of PK parameters was simulated for 5000 patients using the final model of each NA. Each parameter vector was drawn in a normal distribution with a variance equal to the inter-variability estimated before. We simulated the covariates included in the final model, using the estimated distribution in the sample of patients. A simulated measurement error was added to each simulated concentration. We simulated 5000 concentration profiles by increments of 0.01 hour. The 10th, 50th and 90th percentiles of the simulated concentrations at each time were compared with the observed concentration data for the patients with the corresponding regimen. The 50th percentile of the simulated concentrations was compared with the observed median of concentration data estimated at 0.5, 1, 3 and 6 hours after drug intake and for the trough concentration. For trough concentrations, we calculated the median from concentrations measured between 10 h and 14 h after drug intake, since there was an important variability of sampling time for that measurement. The simulations were performed using R 2.0 (R Foundation for Statistical Computing, Vienna, Austria) [13].

Estimation of intra-patient variability

From the two concentration measurements of the same time at visit 1 and visit 2, we estimated the inter- and intra-patient variability for C_{1h} in patients receiving IDV alone and for C_{3h} in patients receiving IDV/ritonavir or NFV. We did not estimated the intra-patient variability of trough concentrations since the time of drug intake on the previous day suffered from too much uncertainty. Moreover, since the sampling protocole had been designed for the two PIs, an important proportion of the NA trough concentrations were below the LOQ : 7.3% for LMV; 35.7% for STV and 46.3% for ZDV; therefore, the estimation of intra-patient variability would have been difficult.

We used a linear mixed effects model and assumed that the logarithm of the individual concentrations y_{ik} of patient i on visit k ($k = 1, 2$) can be decomposed as:

$$\log(y_{ijk}) = \mu + \beta.T_i + \eta_i + \kappa'_{ik} \tag{1}$$

7

where T_i is equal to 0 if C_{1h} was analysed for subject i and 1 if C_{3h} was analysed; β is the effect quantifying the difference between concentrations measured 1 hour and 3 hours after drug intake, η_i is the random effect of subject i with null mean and variance γ^2 and κ_{ik} is the intra-individual random effect, with null mean and variance ψ^2. Using a first order approximation, γ and ψ are estimates of the inter- and intra-patient coefficient of variation of the untransformed concentrations. The estimation was performed using the lme function of R 2.0 [12, 13].

RESULTS

Patients

Ninety-five patients were included in the COPHAR1-ANRS102 trial. Eighty-eight of them had a sustained virological response for the 8 months of follow-up and were analysed. The characteristics of these patients are shown on table I. The pharmacokinetics of 54, 39 and 27 patients also receiving LMV, STV and ZDV respectively could be analysed. Some patients had to be excluded since their NA intake was not compatible with the PK samples. The number of patients is therefore different between table I and table II. For LMV, the only regimen was 150 mg twice daily. For STV, 31 patients received 40 mg bid and 8 patients received 30 mg twice daily. For ZDV, 24 patients received 300 mg twice daily and 3 patients received 250 mg twice daily. The repartition of these patients between the two PI groups is shown on table II.

Lamivudine

Two hundred and sixty-seven concentration data were obtained from the 54 patients receiving LMV (Fig. 1.A). Eight concentrations were below the quantifition limit (LOQ); six were set to LOQ/2, and the other two were exluded, since they were consecutive to a first concentration found below the quantification limit. The one-compartment model with zero-order absorption and first order elimination achieved the smallest AIC. Moreover, the model had to be parametrized in $log(k)$ rather than $log(Cl/F)$ to achieve convergence. A combined error model, where a was estimated, was selected. Random effects could be estimated on $log(T_a)$ and $log(V/F)$. The parameter estimates of this basic model are displayed in table III.

From the univariate selection performed on the individual parameters, several significant covariates were found on $log(T_a)$ only: the co-administered PI, combination with ZDV, combination with STV, age, BMI and creatinine clearance. Since a model with these 6 covariates did not achieve convergence, we performed a preselection using a multiple linear model with a backward selection on the individual parameters of $log(T_a)$. The final model included the co-administered PI, age and BMI, and was therefore:

$$T_a = 1.46 \times 0.605^{NFV} \times 0.896^{(BMI-23)} \times 1.03^{(Age-41)} \text{ h}$$

where NFV equals 1 if patient received NFV as a part of his treatment, and 0 otherwise. Absorption duration was 40% smaller in patients receiving NFV versus IDV as a PI ($p < 10^{-4}$). The effect found for age corresponds to an increase of 36% of T_a for an increase of 10 years of age (p=0.0143). The effect found for BMI corresponds to a decrease of 10% of T_a for an increase of one BMI unit ($p < 10^{-4}$). Parameters estimates are presented in table III. Inter-patient variability was found to be large: 63.7% for $log(T_a)$ and 52.1% for $log(V/F)$. The predicted curve for the mean PK parameters corresponding to each co-administered PI are overlayed on the observed concentration data of LMV in Fig. 1.A.

Stavudine

One hundred and eighty two concentration data were obtained from the 39 patients receiving STV. Seventeen concentrations were below the quantifition limit (LOQ) and were fixed to LOQ/2. The one-compartment model with first-order absorption and first order elimination achieved the smallest AIC. A combined error model with a fixed to 120 ng/mL was selected, and random effects could be estimated on $log(Cl/F)$ and $log(V/F)$. The parameter estimates of the basic model are displayed in table IV. The univariate covariate selection identified the co-admisitered PI, creatinine clearance and body weight as possibly significant factors explaining the variability observed on $log(Cl/F)$. No covariate was found to be associated with $log(V/F)$. The final model found for Cl/F included only NFV as a covariate and was:

$$Cl/F = 15.94 \times 1.56^{NFV} \text{ L.h}^{-1}$$

where NFV equals 1 if patient received NFV as a part of his treatment, and 0 otherwise. The oral clearance was found to be 56% higher in patients receiving NFV versus IDV as a PI (p=0.031). Inter-patient variability was found to be even larger than for LMV: 77.2% for $log(Cl/F)$ and 82.4% for $log(V/F)$. The predicted curve for the mean PK parameters corresponding to each co-administered PI are overlayed on the observed concentration data of STV in Fig. 1.B.

Zidovudine

One hundred and thirty three concentration data were obtained from the 27 patients receiving ZDV. Sixteen concentrations were below the quantifition limit (LOQ); fourteen were set to LOQ/2, and the other four were exluded, since they were consecutive to a first concentration found below the quantification limit. The one-compartment model with zero-order absorption and first order elimination achieved the smallest AIC. A combined error model with a fixed to 120 ng/mL was selected. Random effects could be estimated on $log(Cl/F)$ and $log(V/F)$. The parameter estimates of the model are displayed in table V. The co-administered PI was the only possibly significant covariate found on both $log(Cl/F)$ and $log(V/F)$ during the univariate analysis performed on the individual parameters. The model used for Cl/F and V/F was therefore:

$$Cl/F = 124 \times 2.24^{NFV} \text{ L.h}^{-1} \quad V/F = 248 \times 1.88^{NFV} \text{ L}$$

where NFV equals 1 if patient received NFV as a part of his treatment, and 0 otherwise. The oral clearance and the oral volume were found to be 124% (p=0.0003) and 88% (p=0.0263) higher, in patients receiving NFV versus IDV as a PI, respectively. Inter-patient variability was found to be 50.9% for $log(Cl/F)$ and 80.1% for $log(V/F)$. The predicted curve for the mean PK parameters corresponding to each co-administered PI are overlayed on the observed concentration data of ZDV in Fig. 1.C.

Model evaluation

The goodness-of-fit plots are displayed in Fig. 2. They were satisfactory for the three studied NA. The adequacy of the observed concentrations with the simulated 10th and 90th percentiles and the adequacy of the 50th percentile with the median of the observed concentrations are displayed in the log scale in Fig. 3. The model seems to underpredict residual concentrations for STV and ZDV. The percentage of concentrations outside the interval defined by 10th and 90th percentiles were 22.85%, 24.10% and 21.80% for LMV, STV and ZDV, respectively. We considered that these results were close enough to the expected value of 20% to keep the final model for the three NA.

Inter- and intra-patient variability

The observed C_{1h} and C_{3h} at the two visits are displayed in Fig. 4. For each NA, the estimates of the inter- and intra-patient coefficient of variation of these concentrations are shown in table VI, together with the coefficient of variation for total variability. Both inter- and intra-patient variabilities were important. Moreover, intra-patient variability was greater than inter-patient variability, except for STV, and was greater than 55% for the three NA. These large variabilities were not expected in patients with sustained virological response, since the exact sampling times and the exact time of drug intake, which took place at the hospital, were known for C_{1h} and C_{3h}.

DISCUSSION

The COPHAR1-ANRS102 study, first designed to study the pharmacokinetics of protease inhibitors, allowed us to estimate the population PK parameters of three NA, LMV, STV and ZDV, together with their inter-patient variability. Concentration data obtained at a second visit allowed us to estimate the intra-patient variability of concentrations.

Population PK approach for NA has essentially been applied to analyze data obtained in patients treated with mono or bitherapies [15–21]. A first population analysis of all the components of an antiretroviral treatment was performed in patients receiving a triple combination

of nevirapine plus zidovudine plus didanosine [22], and found a large intra-patient variability (greater than 50%) for ZDV. A population analysis of tenofovir in patients on HAART was also recently performed [23], but did not estimate intra-patient variability. None of these papers proposed reference concentration curves for the studied NA.

We observed a systematic interaction effect of combination with NFV vs IDV for the three drugs. It resulted in lower ZDV concentrations in patients receiving NFV, that may be related to the induction of glucuronidation by NFV via an increase of the activity of glucuronosyltransferase. It also resulted in lower STV concentrations in the NFV group, that may be due to the interaction of NFV on the hepatic enzymes involved in the metabolism of the drug. These results should be taken into account for the choice of ZDV or STV regimens when prescribed in combination with NFV. A decreased exposition to NFV in patients co-medicated with ZDV had also been found in COPHAR1-ANRS102 [7], indicating that precautions should be taken when co-prescribing these two drugs.

For LMV, the increased absorption duration in patients receiving NFV may be partly explained by a food effect. Indeed, patients of the NFV group received a light meal before drug intake. In the IDV group, the 7 patients also receiving ritonavir were fed, whereas the other 17 receiving IDV alone took their medication in fasted conditions. Absorption of LMV has been shown to be slower in fed compared to fasted patients [24, 25], which is in agreement with the increased T_a observed in the NFV group. However, the clinical relevance of this effect and those of BMI and age seem small, since these covariates influence the absorption duration, which has a smaller influence on the AUC. It should be noticed that adherence measured at V1 by the auto-questionnaire was not found to influence significantly the PK parameters of the three NA.

We performed the population analysis from concentration data of the first visit only since the model including data from both V1 and V2 could not be fitted using nlme for LMV and STV. We therefore estimated both inter- and intra-patient variability from the observed C_{1h} or C_{3h} measured at two occasions for the three NA. Both variabilities were important for the three drugs, and intra-patient variability is always greater than 55%, resulting in an overall variability of 85% to 155%, even greater than the variability found by Zhou et al. for ZDV [22]. As drug accumulation is very small for the three studied NA, as illustrated by the important

proportion of trough concentrations below the LOQ, and as the exact time of drug intake is know for these measurements, this high intra-patient variability may be essentially due to an important variability of bioavailability, both absorption and presystemic metabolism.

The simulated concentrations used for the graphs of Fig 3 could be used to build reference intervals for NA concentrations. For the three NA, the logarithm of the 5000 concentrations simulated one hour after drug intake was distributed according to a normal distribution, with a variability of 82%, 67% and 61% for LMV, STV and ZDV, respectively. The corresponding whithin-patient variabilities were 67.7%, 56.8% and 122.9% (cf table IV). A reasonable hypothesis is to perform TDM only for drug with a within-patient variability of concentrations inferior to the inter-patient variability used to define target concentration intervals. The within-patient variability observed for ZDV would therefore question the interest of TDM for this specific drug. However, results obtained for a single sampling time are not sufficient, and it would be necessary to analyse more complete PK profiles taken at several occasions to be able to better estimate within-patient variability for these three drugs and connect it to safe and effective concentration intervals.

The concentration-effect relationships, that are a prerequisite for TDM [26], have only been demonstrated for some NA, and only when given in monotherapies [27,28]. We could not study these relationships in this trial since all patients had a sustained undetectable viral load. We believe that if all the elements justifying TDM of NA are not available yet, concentration-controlled therapy of the NA composing HAART could be performed. Indeed, Kakuda et al. have already demonstrated the usefulness of this approach for a treatment composed of ZDV, LMV and IDV [4]. Since patients of COPHAR1-ANRS102 achieved sustained virological response, the 50th percentile curves simulated to evaluate the final model for the three drugs (Fig. 2.) could be used as reference curves for LMV, STV and ZDV in patients. In Western countries, new combinations of nucleoside analogues have appeared since this trial, but the combination of lamivudine plus zidovudine remains largely prescribed, as well as new QD regimens including LMV with either abacavir or tenofovir. LMV, STV and ZDV are still commonly used used all over the world. It is therefore important to have an adequate reference PK profile obtained in patients with sustained virological response for the TDM of these three NA.

Legends for figures

Fig 1: Observed concentrations of LMV (A), STV (B) and ZDV (C) and curve predicted for the fixed effects for patients comedicated with IDV (dashed line) and NFV (solid line). Two concentrations greater than 2000 ng/mL are not displayed for STV.

Fig 2: Goodness of fit plots for the final model for LMV (A), STV (B) and ZDV (C): population predicted concentrations versus observed concentrations, individual predicted concentrations versus observed concentrations and population weighted residuals versus population predicted concentrations.

Fig 3: Evaluation of the final model: comparison between the 10th, 50th (solid line) and 90th percentiles for the 1000 simulations for patients receiving LMV (A), STV (B) and ZDV (C) with the observed data and the median of the observed concentrations measured at 0.5, 1, 3 and 6 hours, and between 10 and 14h for the trough sample (dark grey rectangles and dark grey line). Two concentrations greater than 2000 ng/mL are not displayed for STV.

Fig 4: Variability of the concentrations observed 1 hour (C_{1h}, ∘ and dotted line) and 3 hours (C_{3h}, • and full line) after drug administration between the two visits (V1 and V2) in patients receiving LMV (A), STV (B) and ZDV (C).

Tables

Table I. Characteristics at baseline of the 88 studied patients with sustained virological response.

	Median	[range]
Sex (Male/Female)	73/15	
Age (years)	41	[21-66]
Weight (kg)*	70	[41-110]
BMI (kg.m^{-2})**	23	[16-40]
Time since first ARV treatment (years)	4.0	[0.8-11.7]
CD4 cell count (mm^{-3})	516	[150-1425]
PI prescribed		
Indinavir	42	
Nelfinavir	46	
NA combinations		
Lamivudine + Stavudine	31	
Lamivudine + Zidovudine	25	
Didanosine + Stavudine	16	
Lamivudine + Didanosine	3	
Lamivudine + Abacavir	1	
Didanosine + Abacavir	1	
Zidovudine + Didanosine	1	
0, 1 or 2 NA + Nevirapine	6	
1 NA + Efavirenz	3	
Adherence (High/Moderate/Low)*	49/31/3	

* Five missing values
** Eight missing values

Table II. Repartition of patients treated with LMV, STV or ZDV between the two PI groups.

NA	PI		Nelfinavir
	Indinavir		
	Alone	With ritonavir	
LMV	17	7	30
STV	9	5	25
ZDV	10	2	15

Table III. Population pharmacokinetic parameters of LMV and 95% confidence intervals.

	Basic model		Final Model	
Parameters	Estimate	95% CI	Estimate	95% CI
T_a (h)	1.09	[0.84-1.42]	1.46	[1.04-2.04]
