## A MULTIVARIABLE SCREENING PROCEDURE ADAPTABLE <br> TO ELECTRONIC COMPUTERS FOR THE EMPIRICAL EXPLORATION OF RESPONSE SURFACES

## ACKNOWLEDGMENTS

I am indebted to many individuals who contributed generously to this work. The guidance and continued encouragement to Dr. H. M. Wadsworth, my faculty advisor, is particularly appreciated. The suggestions of Dr. J. W. Walker, a member of the reading committee, contributed significantly to the content and style of this paper. The considerate advice of Professor F. F. Groseclose, Director of the School of Industrial Engineering, has benefited not only this work but also the writer personally.

Mr. W. W. Hines gave especially generously of his time to this
study. His recommendations and enthusiasm were extremely helpful. Mr. Max Allen of the Rich Electronic Computer Center offered helpful suggestions during the writing and testing of the computer program.

To Mr. Roger Milliken, Mr. J. J. Norton, Jro, and Mr. L. K. Fitzgerald, I am firmly indebted for their encouragement and assistance during a critical period of my graduate work.

Mrs. Jeanne Crawford provided many excellent comments and exercised exacting care during the tedious preparation of the final manuscript and drawings.

Finally, to my wife Nell, whose patient understanding, encouragement, and many hours of help made the completion possible, I humbly express my gratitude and dedicate this thesis.

## PREFACE

The subjective nature of the initial synthesis phase in industrial experimentation has drawn the attention of many writers. In particular the indeterminable most often mentioned in conection with this speculative stage of experimentation is the possible omission of an important variable。

A method of analysis applicable to observational data, not suitable for rigorous statistical analysis, is developed utilizing a Burroughs 220 electronic computer. The method used is essentially the classification of data poirts by setting class limits on each observed variable and thereby creating levels of a factor. These factors are treated in pairs as in factorial design and the error sum of squares is compared for each pair. The relative magnitudes of the error sum of squares for each pair provide indications of the relative goodness of fit for each pair and thereby assist the investigator in a preliminary screening of factors with which he reed not be concerned.

Through this after-the-fact stratification of observational data and through the use of an electronic computer to perform the myriad of calculations, the candidate variables are ranked according to the variation in the response which is removed when the effects of each factor are removed.

The ability to consider up to thirty cardidate factors reduces the risk of overlooking an important variable. Hence the latter stages
of the experiment are less susceptible to the irvitiating omission of an important variable.

In additior, the organization and display in tabular form of the estimates of the mean and variance for each factor-level combination of those factor combinations having a relatively small error sum of squares, provide the experimenter with an estimate of the general contour of the response surface over the observed range of paired factors.

As a results the experimenter obtains an appreciation for the nature of the response surface. The risk of failing to use appropriate transformations of the candidate variables in subsequent experiments is reduced.

Consideration of each possible three-factor classification of the data by this method is adjudged to be practical orly when the number of factors is small, say $n<10$, or otherwise only if a means is provided for eliminating certain of the less interesting factors prior to performing the calcuiations associated with all possible three-factor combirations.

The method deveioped permits the experimenter to lay the data open so as to be able, as Tukey expressed the need, "...to see what they look like irside, even though they do not give definite significance levelsa

It is concluded that for a given commitment of resources to an experimental program, the utilization, under the conditions for which designed, of the procedure herein developed will minimize the risk of failure of the experiment as a whole.

It is emphasized that this method is designed as a complement to, rather than a substitute for, existing methods of analysis.

## CHAPTER I

INT RODUCT ION

The objective of this work is to permit, under certain conditions to be defined, a reduction in the subjective nature of the initial synthesis phase in industrial experimentation. The hypothesis associated with this work is that an Industrial Engineer, through use of the procedure developed, will be able to design subsequent experiments that are less susceptible to the indeterminables which are associated with this phase of experimentation. These indeterminables are elaborated upon in Chapter II.

In essence, this hypothesis states that for a given commitment of resources to an experimental program, the utilization of the procedure herein developed will minimize the risk of failure of the "experiment as a whole," as defined by Box (1, p. 27).*

The method proposed is essentially to classify data points by setting class limits on each observed variable and thereby create levels of a factor, then to treat these factors in pairs as in factorial design and to compare the error sum of squares for each pair. The relative magnitudes of the error sum of squares for each pair provide indications of the relative goodness of fit for each pair and thereby assist the investigator in a preliminary screening of factors with which he need not be concerned.

[^0]THE QUALITAT IVE NATURE OF THE INITIAL

PHASE OF INDUSTRIAL EXPERIMENTATION

The nature of scientific investigation consists of two essential

```
processes:
```

(a) the devising of experiments suggested by the investigator's appreciation of the situation to date and designed to elucidate it further;
(b) the examination of results of experiments performed to date in the light of all knowledge available, with the object of postulating theories susceptible of test in future experimentation. (2, p. 318)

The qualitative nature of the initial synthesis phase in problem
solving has attracted the attention of Box and his co-workers.
Most investigations first pass through a "speculative" stage. Here statistical methods can rarely be of help but it is nevertheless vital that this early work should be done fully and with imagination, otherwise later efforts may be wasted in detailed investigation of the wrong basic system. (2, p. 319)

Box and Hunter are more specific.
It has been remarked that the only time an experiment can be properly designed is after it has been completed. The more one considers this paradoxical statement, the more one realizes that it is true. It is not uncommon to find after a set of experiments have been made
(i) one or more important variables have probably been overlooked;
(ii) more could have been learned if the factors could have been varied over different ranges;
(iii) some transformation of the variables would have been more appropriate and/or
(iv) some more elaborate pattern of experiments is needed to elucidate the situation. (3, p. 139)

Their next statement is or primary significance to this study. "Since the outcome of a group of experiments depends on all of the items mentioned above, and since no two experimenters studying the same problem are likely to have the same opinion about any one of them, it is quite clear that the type of experimentation we are discussing contains many indeterminacies:"

Box continues, "The ultimate success of an experiment as a whole (in contrast to the statistical exercise) must necessarily depend on the skill of the experimenter." (1, p. 27)

The attention of other writers (4, p. 506; 5, p. 5) has also been drawn to the problems associated with, and to the importance of, this "speculative" or qualitative stage of experimentation. The aspect most often mentioned is the possible omission of an important variable.

Budne notes the general failure to consider the risk of omitting one or more of the correct variables.
... risks have been associated with the failure to recognize an effect which exists or with the identification of an effect which does not exist - among the variables studied. The question as to whether the correct variables are being studied in a fact-finding situation raises the risk of real success or failure to large and unmeasurable magnitudes. However, this has generally not been considered as a "statistical risk." (6, p. 19)

Brownlee notes a reservoir of pertinent data, often available during the initial phase in industrial experimentation yet infrequently tapped. "In many production processes records are kept of conditions but often little use is made of these records; they are looked at cursorily and then put in files to gather dust till eventually they are thrown out." (7, p. 2068)

In view of the problem outlined above, the objective of this work, as stated in Chapter I, is to permit a reduction in the qualitative nature of the initial synthesis phase in industrial experimentation.

## SURVEY OF CURRENT LITERATURE

To achieve a reduction in the qualitative nature of the "speculative" stage of industrial experimentation, a review of the problems associated therewith, as outlined in the current literature, is necessary.

The class of problems here considered, and common to all industrial concerns, is the elucidation of functional relationships connecting a response $Y$ - such as yield, profit, or a measure of product quality - with the levels $x_{1}, x_{2}, \ldots, x_{k}$ of a group of $k$ variables or factors such as temperature, sales volume, or raw material. The relationship may be written

$$
Y=\varphi\left(x_{1}, x_{2}, \ldots, x_{k}\right) .
$$

As stated by Plackett and Burman, "A problem which often occurs in ... industrial research is that of determining ... or ascertaining the effect of quantitative or qualitative alterations in the various components upon some measured characteristic of the complete assembly." (8, p. 305)

To understand clearly certain of the difficulties inherent in industrial research on problems of this type, G. E. P. Box suggests a careful delineation between "... the problems in experimentation
which are statistical and those which are essentially nonstatistical

## ... ." (I, p. 26)

As suggested by Dr. Box, the experimenter (by which is meant the biologist, chemist, or engineer who is conducting the experiments) and the statistician will be spoken of as two individuals. If the experimenter is also the statistician in a particular investigation, the terms will differentiate between the work requiring statistical skill and the work requiring the application of other knowledge。

This study is limited to the situations wherein the experimenter has at his disposal pertinent observational data, as defined by Bryant to be "... the class of data represented by observations on a population or a segment thereof, where there has been no attempt to modify or 'control' any of the possible influencing factors." (9, p. 136) Examples in the industrial community are plant logs, quality test results, data processing records, and cost records which provide a series of determinations on a response variable and similar information concerning previous quantitative or qualitative alterations in one or more possible influencing factors.

Unfortunately, these data are not orthogonal, as defined by Chew (10, p. 16) and therefore there is no assurance of independence of the contrasts when the experimenter tries to disentangle the effects of the variables one from another.

Box reports discouragingly upon the analysis of plant records using multiple regression techniques in an attempt to determine the "effects" of the variables.

In my experience the results of such investigations are nearly always disappointing. The reasons are not far to seek:

1. Many of the factors that may vitally affect the efficiency of the process are not in the normal course of events altered at all.
2. Those factors which vary naturally do so, not over the ranges we should like, but over ranges dictated by the degree of control which happens to exist ... .
3. The fluctuations that occur naturally in the variables are often heavily correlated .... .
4. Accidental modifications often tend to happen in phases and so become spuriously correlated with causal unrelated time trends in resporise ... . (ii, po 98)

The inapplicability of existing methods of analysis in the preliminary stages of experimentation has drawn the attention of various writers. Box and Youle elaborate as follows on the statement, quoted in Chapter II, to the effect that statistical methods can rarely be of help during the speculative stage of an investigation.

Statistical methods provide efficient tools for investigating a system whose general nature has been broadly decided. They provide no substitute for basic scientific thinking about what the system to be investigated should be. (2, p. 319)

The statistician's function is to advise the experimenter on the best positioning of experimental points in a space which the experimenter must of necessity construct for him and construct purely on the basis of the experimenter's expert background knowledge of the subject in which he is experimenting. (l, p. 26)

The experimenter must decide during this phase:

1. which factors should be varied,
2. in what way the factors should be varied,
3. by how much the factors should be varied, and
4. the probable nature of the response surface.

The aspect of the experimenter"s decision, at this stage, most often mentioned in the literature is the possible omission of
an important variable. Because the amount of effort which can be exerted on any given problem is in practice limited, the experimenter must often select a few factors which he believes will be important out of a large number which might be important. "In some investigations, particularly in preliminary work, the number of factors of potential importance may be much larger than the number than can be dealt with." (12, p. 134)

Youden places considerable importance upon this problem and recognizes its nonstatistical nature. "The discriminatory powers of trained investigators to dichotomize factors into those worth investigating and those of distinctly secondary interest constitutes our strongest weapon of research." (13, p. 158)

Satterthwaite emphasizes the lack of quantitative guidance in this decision period.
... there are often compelling engineering reasons to include a large number of independent variables (i.e 0,10 to 100) in a single experimental program with many of these variables at five to ten levels. Historical statistical principles give almost no guidance for such experimental programs. (14, p. 55)

The basic unifying concept of the experimental designs developed by Dr. Box and his co-workers is that of research as an iterative process. (15, p. 63)

During a complete investigation these processes of synthesis and analysis used in alternation will normally be employed many times and, by what we may call "experimental iteration," the investigator should be led closer and closer to the truth. (2, p. 319)

Davies uses the term "sequential approach" to describe "The idea of using information from the early parts of a series of observations to design the later work ...." (4, p. 5)

Davies and Hay point out that the circumstances surrounding industrial experimentation lend themselves to the sequential approach in problem solving, more so than the circumstances encountered in agricultural experimentation.

Once a field experiment in agriculture has been started it is not usually possible to change or modify the design but in most industrial work a high degree of flexibility exists because the situation may be reviewed after every observation or set of observations come to hand. It is not necessary to adhere strictly to the design drawn up at the outset of an experiment but the design may be modified as the result of information gained from the earlier observations. (16, p. 245)

Typical of the interest during the past decade in the sequential nature of experimentation is the observation of Read, "The key to the whole problem ... [estimation of optimum conditions] ... lies in making full use of the sequential nature of the test procedure, by carrying out experiments in a sequence of small groups ... ." (5, p. 5)

Davies accords a permanent role in overall experimental strategy to the sequential approach.

In addition to its use in sequential experiments for simple comparative trials, the sequential approach can also be employed in a less formal way in the general strategy of experimental design. An investigation may proceed as a series of small experiments instead of as a single comprehensive experiment so that the information obtained in the earlier experiments may be used in the later ones. Industrial research offers a particularly favourable field for the application of methods of this sort. (4, p. 10)

Interest in the sequential approach to experimentation, as far as this study is concerned, arises because the state of knowledge concerning a response variable under investigation is likely to change during the course of the investigation. In different stages of the experimental
iteration, the experimenter's knowledge concerning the response is at different levels. Hence a single method of analysis is not necessarily the most applicable in all stages of an investigation.

For example, the method of steepest ascent recommended by Box and Wilson (17, p. 18) for exploring a response surface consists first of performing a pattern of experiments designed to detect, in the initial region explored, any general sloping teadency of the surface. If such a tendency is found, further experiments are performed in the indicated direction of increasing response. After several cycles of this search enable the experimenter to attain a region in which no sloping tendency can be detected, the region so attained is examined by performing a more elaborate pattern of experiments which permits the curvature in the surface and the dependence between variables to be taken into account.

Brooks (18, p. 454) suggests a further sequentialization due to the fact that the method of steepest ascent can find only local maxima. He suggests that the procedure be augmented with a preliminary exploration in experimental regions suspected of having more than one maximum.

From the realization that a single method of analysis is not necessarily the most applicable throughout all stages of an investigation, it follows that a method of analysis appropriate for the requirements of the preliminary stage of experimentation, need not necessarily be applicable in the latter stages wherein the requirements are changed.

Tukey points out the requirements for data analysis during the preliminary stage of investigation and places emphasis upon insight
rather than proofs. He includes as a part of "... the current revolutions in statistical thinking ....,"
$\ldots$ a return to an interest in the wider aspects of the data, growth of interest in procedures that are incisive, that lay the data open so that we can see what they look like inside, even though they do not give definite significance of confidence levels. This means emphasis on insight and understanding rather than "proven" knowledge. (19: p. 172)

Box concurs.
The situation... [screening a large number of candidate factors]... is frequently such that groups of experiments should be performed in sequence and the data ought to be viewed from a number of different aspects and points of view .... . There is still a great deal of room for research on how screening experiments ought to be analyzed and standard models are not necessarily appropriate。 (20, p. 174)

Thus the conclusions drawn from this survey of current literature are:

1. For an understanding of the difficulties in industrial experimentation, it is necessary to delineate between the problems which are statistical and those which are essentially nonstatistical.
2. The lack of orthogonality of observational data renders it not amenable to the usual statistical methods of analysis.
3. Most industrial research is iterative in nature and employs the process of synthesis and analysis in alternation.
4. A method of analysis appropriate for the requirements of the preliminary stage of experimentation need not necessarily be applicable in the latter stages.
5. The primary requirement for a method of analysis applicable in the preliminary stage of experimentation is that it provide insight and understanding rather than proven knowledge.

CHAPTER IV

A METHOD FOR THE DISPLAY AND ANALYSIS

OF OBSERVATIONAL DATA

The methodology relating to the elucidation of the features of the relationship between a response and independent variables is called by Muller (21, p. 11) "response surface methodology." A response surface is a graphical representation of a relationship between a response and a number of factors or variables. Box uses the term "candidate" factors in referring to independent variables whose relationships to a response are being explored.

Brooks (18, p. 454), $\operatorname{Box}(1, \mathrm{p} .58)$, and others have noted that the results of a complete factorial experiment provide a desirable, systematic, overall picture of the response surface.

Brownlee (22, p. 17) notes that interactions between factors "can only be detected by one form or another of a factorial experiment." The factorial type method may be thought of as the conduction of trials at the points of a grid in the factor space. For each factor, several levels are selected; and for each combination of these factor-levels, the response is determined from a trial.

The factorial design increases the number of necessary observations rapidly with the number of dimensions or independent factors. Plackett and Burman demonstrate this difficulty:
> ... to carry out a complete factorial experiment (i.e., to make up assemblies of all possible combinations of the $n$ components) would require $L^{n}$ assemblies where $L$ is the number of values at which each component can appear. For $L$ equal to 2 this number is large for moderate $n$ and quite impractical for $n$ greater than, say, 10. For larger $L$ the situation is even worse. $(8$, p. 305)

Box and Hunter concur as to the general impracticability of the complete factorial experiment in situations encountered in industry. The carrying out of "a close grid of experiments sufficiently widespread to cover the whole region of possible operation conditions would usually be too prodigal a policy to contemplate." (3, p. 141)

However, in the event of availability of observational data, such as plant logs, the use of an after-the-fact factorial-type display is here considered. In this case simultaneous observations, say 50 or more, are often available on a relatively large number of candidate factors, say six or more.

By arbitrarily segmenting the observed range of each continuous variable into discrete levels, each observation may be classified as a particular factor-level combination and represented by an $n+1$ dimensional vector where $n$ is the number of candidate factors and the $(n+1)^{s t}$ dimension is the response. Each observation may be considered as falling within a particular cell formed by the intersection of parallel planes drawn through the class limits, or boundaries of each level, and perpendicular to each axis of the $n$-dimensional factor space, where each of the $n$ axes represents one candidate variable.

Thus each observation provides an indication of the response at a particular point in an $n$-dimensional space. The mean and variance
of each cell provide an indication of the magnitude and variability of the response at a particular point on a n-dimensional grid formed by the intersection of parallel lines drawn through the midpoint of each interval and drawn perpendicular to each axis. The mean value of the response at a point within the grid - that is, at the midpoint of a particular cell - is an estimate of the height of the response surface above that cell. Each cell includes an infinite number of points of which only a few are represented among the observations. In some cases there may be no observations falling into a particular factor level combination.

To illustrate, a hypothetical situation involving only two candidate factors is given. Suppose a plant log contained the following 29 observations on two candidate factors suspected of influencing the yield of a chemical reaction. The observations are recorded as in Table l.

By constructing an arbitrary $3 \times 3$ grid - that is, with each candidate factor segmented into three discrete levels - with equal class intervals for each factor, the experimenter may distribute the observations to the appropriate cell, as for example has been done in Table 2 . A discussion of the determination of class intervals will follow in the latter portion of Chapter $V$.

The sample means and variances for the observed yields within each cell are calculated and displayed in similar $3 \times 3$ grids, Tables 3 and 4. Consideration of a method for determining the relative goodness of fit for and meaningfulness of various two factor surfaces will be discussed in Chapter V.

!. 'By considering the grids such as in Tables 3 and 4 as surfaces viewed from above and by considering the values within the grid as representing the estimated heights of the surface above each grid point or cell mean, a mental image or picture of the estimates of the two surfaces emerges:

1. the response surface (Table 3 ),
2. the surface representing the variance of the observed responses within each cell. (Table 4) This is not to be confused with the variance of the estimate of the cell means which is a function of the number of observations that happened to be available for each cell as well as the cell response variance.

The geometrical interpretation of three-factor grids is more complicated due to the additional dimension involved. It is difficult to "picture" mentally a fourth dimension.

For example, a three-factor combination involving factors which each have four levels may be mentally pictured as a $4 \times 4 \times 4$ cube, each cell of which contains a number representing the mean or variance of that cell. The magnitude of the cell mean may be considered an estimate of the height of the response surface "above" that point of the grid, as measured in a fourth dimersion. An easier interpretation is to consider a three-factor combination as simply a separate two-factor combination for each level of the third factor. A separate grid may be presented for each of the third factor levels. Geometrical interpretations of higher factor combinations are of little assistance to the experimenter.

In the industrial situation considered in this study, there are more than two candidate factors to be examined. If two-factor grids or tables - and possibly three-factor combination grids are used to aid an experimenter in appreciating the salient features of the response surface, he faces the awesome task of considering each possible twofactor grid and surface. When the number of candidate factors is moderately large, say 15 , the total number of two-factor combinations is

$$
\mathrm{C}_{2}^{15}=\frac{15!}{2!13!}=105 .
$$

Assuming for the moment that it is possible to obtain the grids for each possible two-factor combination, the experimenter needs a method by which to eliminate the majority of these grids and surfaces from consideration. It is necessary to develop a means for determining which of the many possible surfaces, so displayed, most nearly describes the real or true response surface.

For this purpose, attention is focused upon the variance-surface grid mentioned above. Until one or more of the factor-combination-surface displays are selected for further consideration, the plots of the cell means - the points of the grid - are of little interest.

For a given set of data, the smaller the within cell variances for a particular factor combination, the larger the proportion of the overall variance in the response which may be attributed to that factor combination or to some factor combination correlated thereto.

The similarity between this concept and that of using randomized blocks in experimental design is noteworthy. The total variation among
the observed yields is decomposed into one assignable cause and one unassignable - blocks and error. The more the blocks are made to differ from one another in terms of the response, the bigger will be the sum of squares for blocks, and the smaller will be the error sum of squares and within cell variances due to the removal of the block effect from the error sum of squares. Thus the more successful the blocking - that is, the more variation in the response explained by the effects over which blocked - the less the remaining unexplained variance.

Ordinarily, blocking is used in self-defense due to lack of knowledge concerning variability between blocks and is an effort to remove the unknown and unpredictable sources of variation by elimination of effects (other than treatment effects) which only dilute the strength of the statistical conclusions. In this case however, the situation is somewhat reversed. The unexplained or residual variation is that which remains after blocking out the effects present in the particular factor combination under consideration or by blocking out effects correlated with the factor combination over which blocked.

The smaller the remaining unexplained variance after blocking, the larger the variance which may be attributed to or explained by those effects over which blocked. Since the data are not orthogonal, the presence of a correlation between the factors over which blocked and another factor having a real effect may produce a spurious reduction in the unexplained within cell variance.

If the reductions in the unexplained variance which occur when blocking over each two-factor combination are compared, the largest reduction would be expected when blocking over the real effect, as opposed to merely a correlated effect.

Because the blocking method herein used is a type of two-factor factorial, variation in the response caused by a two-factor interaction, as well as the main effects: is blocked out. Thus the variation removed by the two-factor blocking is the sum total of that caused by the main effects of the two factors and the two-factor interaction. In the case of three-factor combination blocking, the variation removed is made up of that caused by the three main effects, all two-factor interactions, and the three-factor interaction.

It is necessary to determine a method for measuring the overall unexplained variation remaining after blocking. This measure is the index herein used as an indication of the most important factor combination. In essence the problem is one of weighting the individual within cell variances to determine the overall unexplained variance. The problem is discussed in the following chapter.

## CHAPTER V

## AFTER-THE-FACT STRATIFICATION OF OBSERVATIONAL DATA

The analysis underlying factorial design assumes replications of the entire design and thereby the same number of observations in each cell. Observational data, however, are not orthogonal. The number of observations falling into the various cells constructed as outlined in Chapter IV will almost certainly be different. Thus the problem arises as to how to weight the data in each cell in order to arrive at an estimate of the overall surface variance for any given factor combination. This chapter is concerned with that problem.

In this study it is assumed for the calculation of expected values, that sampling is from a finite population of elements even though the size of the population may be large enough to permit the use of limiting distributions. The logic of Madow and Madow, as expressed below, provides the basis for this assumption.

The same results would be obtained by assuming a correctly defined multivariate normal distribution and using the notions of conditional probability. From a physical point of view, however, there are several factors that lead to the use of the finite population. We are most frequently sampling an existing population whose laws of transformation are either unknown or not mathematically expressed. Consequently, the notion of a normal or other specified distribution from which we sample and use conditional probability is not part of our thinking concerning the physical problem. On the other hand, if we consider the population to be a finite population, and use a table of random numbers to draw our sample from the finite population, we are using only mathematics implicit in our physical problem.

Furthermore, we do obtain a repeatable experiment; that of selecting a random number, that we know is in a state of statistical control. (23, p. 2)

Using, in general, the symbol structure of Cochran (24, p. 65), consider a heterogeneous population of $N$ units divisible into $L$ subpopulations which are internally homogeneous relative to the entire population. Let the $L$ subpopulations be nonoverlapping strata of size $N_{1}, N_{2}, \ldots, N_{L}$ units and:
$y_{h i}=$ the $i^{\text {th }}$ unit in the $h^{\text {th }}$ stratum;
$N_{h}=$ number of items in the $h^{\text {th }}$ stratum g
$n_{h}=$ number of observations in the $h^{\text {th }}$ stratum;
$N=\sum_{h=1}^{L} N_{h}=$ total number of units.
Henceforth $\sum$ will be taken to mean $\sum_{h=1}^{L}$.
Also let:

$$
\begin{aligned}
& n=\sum n_{h}=\text { sample size; } \\
& \bar{Y}_{h}=\frac{1}{N_{h}} \sum_{i=1}^{N_{h}} y_{h i}=\text { population stratum mean; } \\
& \bar{y}=\frac{1}{N} \sum \sum_{i=1}^{N_{h}} y_{h i}=\text { population grand mean. }
\end{aligned}
$$

Assuming the finite population correction to be negligible,

$$
\sigma_{h}^{2}=\sum_{i=1}^{N_{h}} \frac{\left(y_{h i}-\bar{Y}_{h}\right)^{2}}{N_{h}}=\text { variance within the } h^{\text {th }} \text { cell }
$$

$$
\sigma^{2}=\frac{1}{N} \sum \sum_{i=1}^{N_{h}}\left(y_{h i}-\bar{Y}\right)^{2}=\text { population variance. }
$$

For a method of weighting the data in each cell, it might be argued that since the experimenter has more confidence in estimates based on larger sample sizes, each cell estimate should be weighted according to the number of observations. The assumption of subpopulation parameter equality: however, and the use of its associated method for weighting stratum estimates according to the number of observations or degrees of freedom may not always lead to tenable estimates for population parameters. Consider, for example, the hypothetical task of estimating the average fractional number of automobiles per person in the entire world. Suppose that stratification according to nationality is deemed advantageous. Suppose also that the availability of recent census data for the United States permits the calculation of what is, for practical purposes, the exact or true fractional number of automobiles per person in the United States.

Unfortunately for the purpose of this hypothetical study, data relating to population and automobile registration in various other nations, for example the Soviet Union, may be scarce, or unreliables or both scarce and unreliable.

From an extension of the method of weighting subpopulation estimates according to the confidence in the estimate, as for example under a null hypothesis of parameter equality, it follows that complete knowledge regarding the subpopulation parameter from any stratum is
equivalent to complete knowledge of the population parameter and the stratum parameters from all strata.

However, in the hypothetical case under consideration, the fact that in a particular stratum, namely that made up of the people living in the United States, the fact that the deviation of the estimate of the subpopulation mean from the true subpopulation mean is negligible does not justify the conclusion that the number of automobiles per person in the world is equal to that in the United States. However, if stratum estimates are weighted in a fashion inversely proportional to the estimated variance of the estimate--that is, weighted in relation to confidence in the estimates--the pooled estimate of the fractional number of automobiles per person would be equal to the estimate of the parameter for the United States stratum, since this estimate was considered to be without error. This result, of course, is illogical and incorrect.

Thus, where the assumption of subpopulation parameter equality is untenable, the weighting of estimates of stratum parameters according to confidence in the within stratum estimates will provide a poor estimate of the population parameter. In a situation where a functional relationship between subpopulation means cannot be stated, such as is the case during the initial stages of industrial experimentation, knowledge of data concerning one or more of the stratum means offers no assistance in the estimation of the remainder of the subpopulation means. No matter how well one mean is known, the other stratum estimates do not benefit.

An alternative estimate of the population mean is

$$
\overline{\mathrm{y}}^{*}=\frac{1}{\mathrm{~N}} \sum \mathrm{~N}_{\mathrm{h}} \overline{\mathrm{y}}_{\mathrm{h}},
$$

which is appropriate for estimates based on stratified sampling. In this case the individual stratum estimates are weighted according to the true proportion, $N_{h} / N$, of the total population units included in the individual stratum.

It will be helpful at this point to compare in more quantitative detail these two alternative methods for the estimation of population parameters and specifically the population mean.

The more frequently encountered estimate, $\bar{y}$, is merely the sample mean, which is a weighting of stratum means in proportion to the number of observations which happen, through the process of random sampling, to fall within each stratum. Thus,

$$
\begin{aligned}
\bar{y} & =\frac{1}{n} \sum_{i=1}^{n} y_{i} \\
& =\frac{1}{n} \sum \sum_{i=1}^{n_{h}} y_{h i} \\
& =\frac{1}{n} \sum n_{h} \bar{y}_{h} .
\end{aligned}
$$

Duncan shows (25, p. 824) that for a random sample from the population of all possible responses, the expected value of the estimate is

$$
\begin{aligned}
E(\bar{y}) & =E\left(\sum \frac{n_{h}}{n} \bar{y}_{h}\right) \\
& =\sum E\left(\frac{n_{h}}{n}\right) E\left(\bar{y}_{h}\right) \\
& =\sum \frac{N_{h}}{N} \bar{Y}_{h} \\
& =\bar{Y}
\end{aligned}
$$

The assumption of randomness of the sample insures independence between the random variables $n_{h} / n$ and $\bar{y}_{h}$. The applicability of this assumption when considering observational data will be discussed later in this chapter.

For the estimate weighted according to the population proportionality, again assuming a random sample, the expected value of the estimate is

$$
\begin{aligned}
E\left(\bar{Y}^{*}\right) & =E\left(\sum \frac{N_{h}}{N} \bar{Y}_{h}\right) \\
& =\sum \frac{N_{h}}{N} \bar{Y}_{h} \\
& =\bar{Y}
\end{aligned}
$$

As might be expected, both estimates are unbiased. However, the two estimates are not the same. In the first case above, the population estimate involves two random variables. The first of these is the sample proportion $n_{h} / n$, which does not appear in the second weighting method since the random variable is there replaced by the true stratum proportions $N_{h} / N$. The random nature of the sampling process
insures that in a long series of such samples, the average of $n_{h} / n$ will approximate very closely the true ratio $N_{h} / N$ and that deviations for any given sample are strictly random. That is, by the law of large numbers,

$$
\operatorname{limP}\left\{\left|\frac{\sum_{j=1}^{k}\left(n_{h}\right)_{j}}{n k}-\frac{N_{h}}{N}\right|>\varepsilon\right\}=0
$$

where $K=$ number of trials.
It does not insure that the two will be equal. In fact the random nature of the sampling makes it unlikely that the two proportionalities would be equal.

The difference in the two estimates for a given sample is:

$$
\begin{aligned}
\bar{y}-\bar{y}^{*} & =\frac{1}{n} \sum_{i=1}^{n_{h}} \sum_{i=1}^{y_{h i}}-\frac{1}{N} \sum_{i=1}^{n_{h}} \sum_{n_{h}}^{n_{h}} y_{h i} \\
& =\sum_{i=1}^{n_{h}}\left(\frac{y_{h i}}{n}-\frac{N_{h} y_{h i}}{n_{h} N}\right) \\
& =\sum \sum_{i=1}^{n_{h}}\left(\frac{1}{n}-\frac{N_{h}}{n_{h} N}\right) y_{h i} \\
& =\sum\left(\frac{1}{n}-\frac{N_{h}}{n_{h} N}\right) \sum_{i=1}^{n_{h}} y_{h i} \\
& =\sum\left(\frac{1}{n}-\frac{N_{h}}{n_{h} N}\right) \bar{y}_{h} n_{h} \\
& =\sum\left(\frac{n_{h}}{n}-\frac{N_{h}}{N}\right) \bar{y}_{h} \cdot
\end{aligned}
$$

The two estimates are identical under the following two conditions.

$$
\text { 1. } \bar{y}_{\mathrm{h}}=\bar{y} \quad \text { for all } \mathrm{h}
$$

In this case $\bar{y}_{h}$ is a constant and

$$
\sum\left(\frac{n_{h}}{n}-\frac{N_{h}}{N}\right) \bar{y}_{h}
$$

becomes

$$
\begin{array}{r}
\bar{y} \sum\left(\frac{n_{h}}{n}-\frac{N_{h}}{N}\right)=0 \\
\text { since } \sum \frac{n_{h}}{n}=1 \quad \text { and } \quad \sum \frac{N_{h}}{N}=1 . \\
\text { 2. }\left(\frac{n_{h}}{n}-\frac{N_{h}}{N}\right)=0 \quad \text { for all } h .
\end{array}
$$

In this case the sampling fraction is the same as the population fraction in all strata and the sample is, in effect, a proportionally allocated stratified random sample.

Neither of these conditions is assumed to hold in the proposed analysis of observational data. Thus, the two estimates $\bar{y}$ and $\bar{y}^{*}$ are not, in general, identical.

The term"proportional stratification" is used to describe a method of sampling in which the observations or sample units are allocated among the strata in proportion to the total number of units in each stratum; that is, $n_{h}=n N_{h} / N$. The use of the word "random" with this method of sampling will be taken to mean that each unit within a particular stratum is equally likely to be included in the sample from that stratum. The variance of the estimate of the population mean for a stratified sample is show by Cochran (24, p. 67) to be

$$
\sigma_{\bar{y}^{*}}^{2}=\sum \frac{N_{h}^{2}}{N^{2}} E\left(\bar{y}_{h}-\bar{Y}_{h}\right)^{2}
$$

with the restrictions that:

1. $\bar{y}_{h}$ is an unbiased estimate of $\bar{Y}_{h}$, and
2. The samples are drawn independently in different strata.

As noted by Cachran, (24, p. 68), "The important point about this result is that the variance of $\ldots\left[\bar{y}^{*}\right] \ldots$ depends only on the variances of the estimates of the individual stratum means $\bar{Y}_{h}$."

But $E\left(\bar{Y}_{h}-\bar{Y}_{h}\right)^{2}=\sigma_{h}^{2} / n_{h}$. Thus, for stratified random sampling,** by substituting in Cochran's equation, the estimate $\bar{y}^{*}$ is

$$
\sigma_{\bar{y}} *^{2}=\sum \frac{N_{h}^{2}}{N^{2}} \frac{\sigma_{h}^{2}}{n_{h}}
$$

where

$$
\sigma_{h}^{2}=\sum_{i=1}^{N_{h}} \frac{\left(y_{h i}-Y_{h}\right)^{2}}{N_{h}}
$$

as defined earlier.
In the case of stratified sampling, deviations of the true stra* tum means from the grand population mean do not reduce the precision of the estimate $\overrightarrow{\mathrm{Y}}^{*}$.
**With proportional allocation,

$$
\frac{n_{h}}{n}=\frac{N_{h}}{N} \quad \text { and } \quad n_{h}=\frac{N_{h}}{N}
$$

Substituting for $n_{h}$. in the above equation for $\sigma_{-}{ }^{2}$, the variance
reduces to

$$
\sigma \bar{y}^{*^{2}}=\sum \frac{N_{h}}{N} \frac{\sigma_{h}^{2}}{n}
$$

Note in contrast the development below of the variance of the estimate $\bar{y}$ obtained by weighting stratum results in relation to sample proportions.

The estimate $\frac{n_{h}}{n} \bar{y}_{h}$ is an indication of the contribution of the $h^{\text {th }}$ stratum to the population mean $\bar{Y}$. For large samples the variance of the product of two random variables is (26, p. 513):

$$
\sigma_{x y}^{2}=(\overline{X Y})^{2}\left(\frac{\sigma^{2}}{\frac{x}{\overline{2}}}+\frac{\sigma^{2}}{\bar{Y}_{Y}^{2}}+\frac{2 \operatorname{cov} x y}{\bar{X} \bar{Y}}\right)
$$

where $x$ and $y$ are random variables, $\bar{X}$ and $\bar{Y}$ are the parameters estimated. $\sigma_{x}^{2}$ and $\sigma_{y}^{2}$ are the respective variances of the random variables and cov $x y=P_{x y} \sigma_{x} \sigma_{y}$ is the covariance of $x$ and $y$, and rho is the correlation coefficient.

In the case of a sample which is random with respect to the various strata, the random variables $\frac{n_{h}}{n}$ and $\bar{y}_{h}$ are independent. Hence the variance of the product reduces to

$$
\begin{aligned}
\sigma_{n_{h}}^{2} \bar{Y}_{h} & =\left(\frac{N_{h}}{N} \bar{Y}_{h}\right)^{2}\left[\frac{\sigma_{n_{h}}^{2}}{\left(\frac{N_{h}}{N}\right)}+\frac{\sigma_{Y_{h}}^{2}}{\left(Y_{h}\right)^{2}}\right]+\frac{\sigma^{2}}{\frac{n_{h}}{n}} \sigma_{\bar{y}_{h}}^{2} \\
& =\bar{Y}_{h}^{2} \sigma_{\frac{n_{h}}{n}}^{2}+\left(\frac{N_{h}}{N}\right)^{2} \alpha_{\nabla_{h}}^{2}+\frac{\sigma_{n_{h}}^{2}}{\sigma_{n}} \sigma_{h}^{2}
\end{aligned}
$$

Note that the estimate $\frac{N_{h}}{N} \bar{y}_{h}$ of the $h^{\text {th }}$ stratum's contribution to the grand mean is not a product of two random variables. Hence the variance of that estimate is

$$
\sigma_{\frac{N_{h}}{N} \nabla_{h}}^{2}=\left(\frac{N_{h}}{N}\right)^{2} \sigma_{\bar{y}_{h}}^{2}
$$

By substitution,

$$
\frac{\sigma_{n_{h}}^{2} \bar{y}_{h}}{2}=\frac{\sigma_{N_{h}}^{2}}{N} \bar{y}_{h}+\bar{Y}_{h}^{2} \frac{\sigma_{n_{h}}^{2}}{2}+\sigma_{\frac{n_{h}}{n}}^{2} \sigma_{\bar{y}_{h}}^{2}
$$

and

$$
\sigma_{\frac{n_{h}}{n} \bar{y}_{h}^{2}}^{\frac{\sigma_{h}}{N} \nabla_{h}^{2}}
$$

Therefore the estimate utilizing the true stratum proportions in determining the individual stratum contribution to the grand mean has a variance equal to or less than the individual cell estimate using the sample proportions.

The variance of the sum of $k$ random variables, $u_{h}$, where $h=1,2, \ldots . k$, is (26, p. 513):

$$
\sum_{\sum_{h=1}^{2} u_{h}}^{2}=\sigma_{u_{1}}^{2}+\sigma_{u_{2}}^{2}+\cdots+\sigma_{u_{k}}^{2}+2\left(\sigma_{u_{1} u_{2}}+\sigma_{u_{1} u_{3}}+\cdots+\sigma_{u_{k-1} u_{k}}\right)
$$

In our case the estimate $\bar{Y}$ can be considered to be the sum of $k$ random variables, each of which is the product of two random variables.

$$
u_{h}=\frac{n_{h}}{n} \bar{y}_{h}
$$

Thus,

$$
\begin{aligned}
\sigma_{\bar{y}}^{2} & =\sigma_{\sum_{h=1}^{k}}^{2} \frac{n_{h}}{n} \bar{y}_{h} \\
& =\sigma_{\frac{n_{1}}{n} \nabla_{1}}^{2}+\frac{\sigma_{n}}{2} \bar{y}_{2}+\cdots+\sigma_{n_{k}}^{2} \bar{y}_{k} \\
& +2\left\{\sigma_{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{2}}{n} \bar{y}_{2}\right)}^{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{3}}{n} \bar{y}_{3}\right)}+\cdots+\sigma_{\left(\frac{n_{k-1}}{n} \bar{y}_{k-1}\right)\left(\frac{n_{k}}{n} \bar{y}_{k}\right)}\right.
\end{aligned}
$$

But

$$
\frac{\sigma_{n_{h}}^{n}}{2} \bar{y}_{h}=\bar{Y}_{h}^{2} \sigma_{\frac{n_{h}}{n}}^{2}+\left(\frac{N_{h}}{N}\right)^{2} \sigma_{\bar{y}_{h}}^{2}+\sigma_{\frac{n_{h}}{n}}^{2} \sigma_{h}^{2}
$$

Substituting:

$$
\begin{aligned}
& \sigma_{\bar{y}}^{2}=\left\{\bar{Y}_{1}^{2}{\underset{\frac{n_{1}}{n}}{2}}_{\sigma^{2}}+\left(\frac{N_{1}}{N}\right)^{2} \sigma_{\bar{y}_{1}}^{2}\right\}+\left\{\bar{Y}_{2}^{2} \sigma_{\frac{n_{2}}{n}}^{2}+\left(\frac{N_{2}}{N}\right)^{2} \sigma_{\bar{y}_{2}}^{2}\right\}+ \\
& \cdots+\left\{\bar{y}_{k}^{2}{\underset{\frac{n_{k}}{n}}{2}}_{\sigma^{2}}^{\cdots}\left(\frac{N_{k}}{N}\right)^{2} \quad \sigma_{\bar{y}_{k}}^{2}\right\} \\
& +2\left\{\sigma_{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{2}}{n} \bar{y}_{2}\right)}+\sigma_{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{3}}{n} \bar{y}_{3}\right)}+\right.
\end{aligned}
$$

$$
\begin{aligned}
& \left.\cdots+\sigma_{\left(\frac{n_{k-1}}{n} \bar{y}_{k-1}\right)\left(\frac{n_{k}}{n} \bar{y}_{k}\right)}\right\}+\sum_{h=1}^{k}{\frac{\sigma_{n}^{n}}{2}}_{\sigma_{\bar{y}_{h}}^{2}}^{\sigma^{2}} . \\
& \text { Similarly, } \\
& \begin{aligned}
a_{\bar{y}^{*}}^{2}= & \sigma^{\sigma}{ }_{k=1}^{2},
\end{aligned} \\
& \text { where } \\
& u_{h}^{*}=\frac{N_{h}}{N} \bar{y}_{h} . \\
& \sigma_{\bar{y}^{*}}^{2}=\left(\frac{N_{1}}{N}\right)^{2} \sigma_{\bar{y}_{1}}^{2}+\left(\frac{N_{2}}{N}\right)^{2} \sigma_{\bar{y}_{2}}^{2}+\cdots+\left(\frac{N_{k}}{N}\right)^{2} \sigma_{\bar{y}_{k}}^{2} \\
& +2\left\{0_{\left(\frac{N_{1}}{N} \bar{y}_{1}\right)\left(\frac{N_{2}}{N} \bar{y}_{2}\right)}+\sigma N_{1} \frac{N_{1}}{N} \bar{y}_{1}\right)\left(\frac{N_{3}}{N} \bar{y}_{3}\right)+ \\
& \left.\cdots+\sigma{ }_{\left(\frac{N_{k-1}}{N} \bar{y}_{k-1}\right)\left(\frac{N_{k}}{N} \bar{y}_{k}\right)}\right\},
\end{aligned}
$$

but

$$
\begin{aligned}
& \sigma N_{h-1} \\
&\left(\frac{N_{h-1}}{N}\right)\left(\frac{N_{h}}{N} \bar{y}_{h}\right)=E\left(\frac{N_{h-1}}{N} \bar{Y}_{h-1}-\frac{N_{h-1}}{N} \bar{Y}_{h-1}\right)\left(\frac{N_{h}}{N} \bar{Y}_{h}-\frac{N_{h}}{N} \bar{Y}_{h}\right) \\
&\left.=E\left\{\left(\frac{N_{h-1}}{N}\right)\left(\bar{Y}_{h-1}-\bar{Y}_{h-1}\right)\right\} \frac{N_{h}}{N}\left(\bar{Y}_{h}-\bar{Y}_{h}\right)\right\} \\
&=\left(\frac{N_{h-1}}{N}\right)\left(\frac{N_{h}}{N}\right) E\left(\bar{Y}_{h-1}-\bar{Y}_{h-1}\right)\left(\bar{Y}_{h}-\bar{Y}_{h}\right)
\end{aligned}
$$

Since the sampling in any cell $h$ is assumed independent of the sampling in other cells, the deviation of the estimate $\bar{y}_{h-1}$ from the cell mean $\overline{\mathrm{Y}}_{\mathrm{h}-1}$ is independent of the deviation of the estimate $\bar{Y}_{\mathrm{h}}$ from the cell mean $\bar{Y}_{h}$ for all $h$, that is $\rho=0$. Thus the equation for $a_{\bar{y}^{*}}^{2}$ simplifies to:

$$
\begin{aligned}
\dot{\sigma}_{\bar{y}^{*}}^{2} & =\left(\frac{N_{1}}{N}\right)^{2} a_{\bar{y}_{1}}^{2}+\left(\frac{N_{2}}{N}\right)^{2} \frac{\sigma_{\bar{y}_{2}}}{}{ }^{2}+\cdots+\left(\frac{N_{k}}{N}\right)^{2} a_{\bar{y}_{k}}^{2} \\
& =\sum_{h=1}^{k} \frac{N_{h}^{2}}{N^{2}} \sigma_{\bar{y}_{h}}^{2}
\end{aligned}
$$

which agrees with Cochran's result shown earlier. But the objective here is to compare $\frac{\sigma_{y}^{2}}{y}$ with $\frac{\sigma_{\bar{y}}^{2}}{2}$. Therefore, substituting the last result in the equation for $\sigma_{\bar{y}}^{2}$, we have

$$
\begin{aligned}
& \sigma_{\bar{y}}^{2}=\sigma_{\bar{y}^{*}}^{2}+\bar{Y}_{1}^{2} \sigma_{\frac{n_{1}}{n}}^{2}+\bar{Y}_{2}^{2} \frac{\sigma_{n_{2}}^{2}}{n}+\cdots+\bar{Y}_{k}^{2} \sigma_{\frac{n_{k}}{n}}^{2} \\
& +2\left\{\sigma_{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{2}}{n} \bar{y}_{2}\right)}+\sigma_{\left(\frac{n_{1}}{n} \bar{y}_{1}\right)\left(\frac{n_{3}}{n} \bar{y}_{3}\right)}+\right. \\
& \left.\cdots+\sigma_{\left(\frac{n_{k-1}}{n}\right.} \bar{y}_{k-1}\right)\left(\frac{n_{k}}{n} \bar{y}_{k}\right), \sum_{h=1}^{k} \sigma_{\frac{n_{h}}{n}}^{2} \sigma_{\bar{y}_{h}}{ }^{2} \\
& =\sigma_{\bar{Y}^{*}}^{2}+\sum_{h=1}^{k} \overline{\mathrm{Y}}_{h}^{2} \sigma_{\frac{n_{h}}{n}}^{2}+2 \text { (covariance terms) } \\
& +\sum_{h=1}^{k} \sigma_{\frac{n_{h}}{n}}^{2} \sigma_{\bar{y}_{h}}^{2} .
\end{aligned}
$$

Considering any one of the covariance terms,

$$
\begin{aligned}
& \sigma_{\left(\frac{n_{h}}{n} \bar{y}_{h}\right)\left(\frac{n_{i}}{n} \bar{Y}_{i}\right)=} E\left(\frac{n_{h}}{n} \bar{Y}_{h}-\frac{N_{h}}{N} \bar{Y}_{h}\right)\left(\frac{n_{i}}{n} \bar{y}_{i}-\frac{N_{i}}{N} \bar{Y}_{i}\right) \\
&= E\left\{\left(\frac{n_{h}}{n} \bar{y}_{h}\right)\left(\frac{n_{i}}{n} \bar{y}_{i}\right)-\left(\frac{n_{h}}{n} \bar{Y}_{h}\right)\left(\frac{N_{i}}{N} \bar{Y}_{i}\right)\right. \\
&\left.-\left(\frac{N_{h}}{N} \bar{Y}_{h}\right)\left(\frac{n_{i}}{n} \bar{y}_{i}\right)+\left(\frac{N_{h}}{N} \bar{Y}_{h}\right)\left(\frac{N_{i}}{N} \bar{Y}_{i}\right)\right\} \\
&= E\left\{\left(\frac{n_{h}}{n} \bar{y}_{h}\right)\left(\frac{n_{i}}{n} \bar{y}_{i}\right)\right\}-\left(\frac{N_{i}}{N} \bar{Y}_{i}\right) E\left(\frac{n_{h}}{n} \bar{Y}_{h}\right) \\
&-\left(\frac{N_{h}}{N} \bar{Y}_{h}\right) E\left(\frac{n_{i}}{n^{\prime}} \bar{y}_{i}\right)+\left(\frac{N_{h}}{N} \bar{Y}_{h}\right)\left(\frac{N_{i}}{N} \bar{Y}_{i}\right) \\
&= E\left\{\left(\frac{n_{h}}{n} \bar{y}_{h}\right)\left(\frac{n_{i}}{n} \bar{y}_{i}\right)\right\}-\left(\frac{N_{h}}{N} \bar{Y}_{h}\right)\left(\frac{N_{i}}{N} \bar{Y}_{i}\right) \\
&= E\left\{\left(\frac{n_{h}}{n} \cdot \frac{n_{i}}{n}\right)\left(\bar{y}_{h} \bar{y}_{i}\right)\right\}-\left(\frac{N_{h}}{N} \cdot \frac{N_{i}}{N}\right)\left(\bar{Y}_{h} \bar{Y}_{i}\right)
\end{aligned}
$$

But the sampling proportion $n_{h} / n$ is independent of the stratum mean $\bar{y}_{h}$, since the sample is random with respect to the various strata.

$$
E\left\{\left(\frac{n_{h}}{n} \cdot \frac{n_{i}}{n}\left(\bar{y}_{h} \cdot \bar{Y}_{i}\right)\right\}=E\left(\frac{n_{h}^{n}}{n^{2}}\right) E\left(\bar{y}_{h} \bar{y}_{i}\right)=\left(\bar{Y}_{h} \bar{Y}_{i}\right) E\left(\frac{n_{h}^{n} n_{i}}{n^{2}}\right)\right.
$$

Thus,

$$
\sigma_{\left(\frac{n_{h}}{n} \bar{Y}_{h}\right)\left(\frac{n_{i}}{n} \bar{Y}_{i}\right)}=\left\{E\left(\frac{n_{h} n_{i}}{n^{2}}\right)-\left(\frac{N_{h} N_{i}}{N^{2}}\right)\right\} \bar{Y}_{h} \bar{Y}_{i}
$$

Assuming that the sum of the covariance terms discussed above is nonnegative or at least that the absolute value is small relative to

$$
\sum \bar{Y}_{h}^{2} \sigma_{\frac{n_{h}}{n}}^{2}+\sum_{n=1}^{k} \frac{\sigma_{n_{h}}^{2}}{n} \sigma_{\bar{Y}_{h}}^{2}, \quad \sigma_{\bar{y}}^{2} \geq \sigma_{\bar{y}^{*}}^{2}
$$

The results for the estimate $\nabla^{*}$ are equally applicable to the case where the data are subjected to after-the-fact stratification.

In the case of observational data, it is noted that although each factor level combination may be equally possible, caution must be exercised in treating observational data due to the fact that management decision, operator practice, or indifference may result in a condition such that each factor-level combination is not equally likely in the data. The process may tend to operate at certain factor-level combinations more often than at others. Some factor-level combinations may not be represented in the data at all.

The estimate $7^{*}$ does not require the assumption of independence between $n_{h} / n$ and $\bar{y}_{h}$. That is, the validity of the use of after-the-fact stratification and the estimate $\bar{Y}^{*}$ are not endangered by the lack of randomness, with respect to factor-level combinations, of observational data. As indicated by the presence of the covariance term $P_{X y} \sigma_{x} \sigma_{y}$ in the equation for $\sigma_{x y}^{2}$, the variance of the product of two random variables, the estimate $\bar{Y}$ is not free of the assumption of independence between the sample proportion $n_{h} / n$ and the cell sample mean $\bar{y}_{h}$. A less restrictive assumption is sufficient when
using the estimate $\overline{\mathrm{y}}^{*}$. That is, the observations need only be random with respect to the particular cell or factor-level combination within which they fall.

In summary, the above discussion of a method for weighting the cell variances in order to arrive at an unbiased estimate of the overall surface variance suggests the use of $N_{h} / N$.

In order to arrive at this weighting factor, each value between the largest and smallest observed value for each candidate variable is assumed to be equally possible. Thus, if a factor is segmented into four levels of equal intervals, each level is considered equally possible. For two-factor combinations, each cell's weighting factor is determined by the ratio of its area $\left(N_{h}\right)$ to the area of all cells (N). That is, each cell is weighted according to the proportion of the total surface area, measured in a horizontal plane, which is included within the class limits of that cell. Further discussion and specific examples are given in Chapter VII.

A discussion of the physical means lised to massage the observational data follows in Chapter VI.

CHAPTER VI

## THE COMPUTER, SYMBOLIC PROGRAMMING AID, AND TEST DATA USED

The arithmetic required in calculating means and variances for each possible two-way factor-level combination during the screening stage of industrial experimentation is best accomplished by electronic digital computers.

A Burroughs 220 Datatron system was made available for this study by the Rich Electronic Computer Center, a division of the Engineering Experiment Station, Georgia Institute of Technology. The Burroughs 220 is a general-purpose, stored program, sequentially controlled, decimal computer system.

This system has a magnetic-core internal storage of 500044 -bit words which use the $8,4,2,1$ binary code for each tea-decimal-digit-plus-sign-digit-position word. In addition to various input, output, and auxiliary components, this system includes six magnetic tape units which read and write at the rate of 25,000 characters per second.

One of the most impressive characteristics of digital computers is their operating speed. The Burroughs 220 requires approximately 200 millionths of a second to add two numbers. Thus, analyses requiring multitudinous computations which would preclude consideration when utilizing manual resources may become practical through the use of electronic computers.

The task of translating the desired computations into a language which the computer can understand is called coding or programming. A program is a list of instructions which provide an orderly explanation to the computer of each individual operation it is to perform. The instructions comprising a computer vocabulary usually include the basic arithmetic operations of addition and subtraction, through which multiplication and division are available; operations permitting the transfer of data between designated locations in the computer; and operations controlling input and output equipment. Various other more complex operations which are used frequently may be included in the computer vocabulary.

Difficulty in communicating with the computer was greatly reduced through the use of the Burroughs Algebraic Compiler, generally referred to as Algol. This, in essence, is a set of instructions available for use on the 220 which permit the machine to accept symbolic programs, written in almost plain language, and convert these into machine language programs. A description of the evolution and status of Algol is available elsewhere. (28; 29)

Prior to translation into an Algol program, the problem was reduced to a graphical diagram, often referred to as a flow chart, of the general sequence of operations necessary to arrive at the desired output. The flow chart is included as Appendix A.

Through the use of an Algol reference manual (30), the problem was then translated into the symbolic Algol program shown in Appendix B.

The data used to test the program were obtained from quality control logs of four textile plants. The response variable of interest was warp contraction, expressed as a percentage. In the process of weaving cloth, lengthwise and widthwise yarns are interlaced. The lengthwise yarns, individually known as ends, are called the warp. The widthwise yarns are called the filling and individually referred to as picks.

When the yarns interlace to form cloth, they bend around one another. This bending is known as crimp and tends to shorten the horizontal span of a given length of yarn. The amount of this crimp is often referred to as the per cent contraction. This is simply the horizontal length of yarn after interlacing divided by the length of the same yarn prior to the interlacing, all multiplied by one hundred.

This dependent variable was chosen because of the high order interactions of the various variables which were thought to affect the warp contraction. The diameters of both the lengthwise and widthwise yarns were thought to influence the contraction. The number of ends per unit of length widthwise and the number of picks per unit of cloth length were also suspected as affecting warp contraction.

The nature of the relationships between the factors was unknow. However, a positive correlation between the diameters of the warp ends and filling picks and also between the number of ends and picks per unit of perpendicular length was suspected. A negative correlation between the number of ends and the diameter of these yarns was
anitcipated. A similar correlation was expected for the filling yaras. In addition, the frequency of interlacings was thought to affect the dependent variable.

Data regarding other candidate variables - some discrete, such as the mill at which the data originated, and some continuous, such as the width of the cloth - were also available from the plant logs and were considered as "candidate" factors.

Each continuous factor was segmented into four equal intervals, each of which was assigned a discrete level number. Each observation was then classified according to the appropriate level of each continuous and discrete variable.

In two cases the number of observations falling into the highest numbered level was small relative to that level's proportionate share ( 25 per cent) of the total of 170 observations. In view of the desirability of obtaining two-way and possibly three-way factor-level combinations, reasonably even distribution of observations among the levels was felt necessary. Consequently, in these two cases the intervals were redetermined so as to render the interval in the region of few observations larger than the other intervals by a factor of two or three.

For example, the range of the continuous variable picks per inch was 26 to 131. In setting up equal intervals Table 5 was obtained.

Since the eight and four observations in levels three and four respectively provide only limited possibilities for further meaningful

Table 5. Original Intervals for the Factor Picks/Inch

|  | Interval | Number of <br> Observations |
| :---: | :---: | :---: |
| Level 1 | $26-52$ | 90 |
| Level 2 | $53-78$ | 68 |
| Level 3 | $79-104$ | 8 |
| Level 4 | $105-131$ | 4 |

subdivision into four two-factor-level combinations, the intervals were recalculated as shown in Table 6.

Table 6. Adjusted Intervals for the Factor Picks/Inch

|  | Interval | Relative <br> Interval Size | Number of <br> Observations |
| :---: | :---: | :---: | :---: |
| Level 1 | $26-43$ | 1 | 59 |
| Level 2 | $44-61$ | 1 | 83 |
| Level 3 | $62-79$ | 1 | 16 |
| Level 4 | $80-131$ | 3 | 12 |

This is tantamount to dividing the continuous variable into six intervals and pooling the upper levels for analysis purposes.

Table 7 shows the description of class intervals for each of the 15 "candidate" factors considered in the testing of the computer pragram.

It will be noted that factors three and five are the same as
factors four and six respectively, differing only in the class intervals

Table 7. Factor Level Identification

| Factor Description Number |  | Identification |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Level 1 | Level 2 | Level 3 | Level 4 |
| 1 | Fabric <br> (Name of Cloth) | Broad- <br> cloth <br> and <br> Poplin | Print <br> Cloth <br> and <br> Sheeting | Soft Filled <br> Sheeting, Osnaburg, and Misc. Plain Weave | Nonplain Weave |
| 2 | Weave | Plain and Semiplain | Drill | Twill and Semi-regular Drill | Sateen |
| 3 | Ends/Inch <br> (Special) | 32-45 | 46-90 | 91-113 | 114-127 |
| 4 | Ends/Inch | 32-55 | 56-79 | 80-103 | 104-127 |
| 5 | Picks/Inch <br> (Special) | 26-43 | 44-51 | 52-103 | 104-131 |
| 6 | Picks/Inch | 26-43 | 44-61 | 62-79 | 80-131 |
| 7 | Let-Off Motion | Roper | Bartlett | Hunt | - |
| 8 | Plant | Mill A | Mill B | Mill C | Mill D |
| 9 | Loom Type | $40^{\prime \prime} \mathrm{D}$ | $\begin{aligned} & 50^{\prime \prime} \mathrm{X}-2 \\ & 60^{\prime \prime} \mathrm{X}-2 \\ & \text { Misc. } \end{aligned}$ | $46^{\prime \prime} \mathrm{X}-2$ | - |
| 10 | Square Root of Warp Yarn Nbr. (Highly Correlated with Inverse of Yarn Diameter) | $\begin{aligned} & 3.78- \\ & 4.29 \end{aligned}$ | $\begin{aligned} & 4.30- \\ & 4.81 \end{aligned}$ | $\begin{aligned} & 4.82- \\ & 5.33 \end{aligned}$ | $\begin{aligned} & 5.34- \\ & 5.85 \end{aligned}$ |
| 11 | Square Root of Filling Yarn Nbr. | $\begin{aligned} & 2.77- \\ & 3.79 \end{aligned}$ | $\begin{aligned} & 3.80- \\ & 4.82 \end{aligned}$ | $\begin{aligned} & 4.83- \\ & 5.85 \end{aligned}$ | $\begin{aligned} & 5.86- \\ & 6.88 \end{aligned}$ |
| 12 | Loom Speed | 152-164 | 165-176 | 177-188 | 189-200 |
| 13 | Filling Twist Multiple | $\begin{array}{r} 3.13- \\ 3.49 \\ \hline \end{array}$ | $\begin{aligned} & 3.50- \\ & 3.86 \\ & \hline \end{aligned}$ | $\begin{array}{r} 3.87 \\ 4.23 \\ \hline \end{array}$ | $\begin{aligned} & 4.24- \\ & 4.60 \\ & \hline \end{aligned}$ |
| 14 | Cloth Width | $\begin{aligned} & 32.0- \\ & 40.2 \end{aligned}$ | $\begin{aligned} & 40.3 \\ & 48.5 \end{aligned}$ | $\begin{aligned} & 48.6- \\ & 56.7 \end{aligned}$ | $\begin{aligned} & 56.8- \\ & 65.0 \\ & \hline \end{aligned}$ |
| 15 | Yards of Cloth per Pound | $\begin{aligned} & 0.92- \\ & 1.88 \end{aligned}$ | $\begin{aligned} & 1.89 \\ & 2.85 \end{aligned}$ | $\begin{aligned} & 2.86- \\ & 3.82 \end{aligned}$ | $\begin{aligned} & 3.83- \\ & 5.77 \end{aligned}$ |

shown in Table 7. These factors will be discussed in the next chapter.

Each of the 170 observations was coded for the applicable level of each factor. The end result was the representation of each observation as a l6-dimensional vector, where the first through the fifteenth dimensions represent the level of the 15 "candidate" factors, each having three or four levels. The sixteenth dimension is the continuous response variable. As an illustration, a coded observation is shown in Table 8.

Table 8. Example of Sixteen-Dimensional Coded Observational Vector
$\begin{array}{llllllllllllll}1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14\end{array} 15$
$\begin{array}{llllllllllllllllll}\text { Level } & 4 & 2 & 3 & 4 & 3 & 4 & 2 & 4 & 3 & 4 & 4 & 4 & 3 & 3 & 2 & 3.90\end{array}$

Thus, for the observation shown in Table 8 (observation number 35 in the data), a response of 3.90 was observed when factor one was at level four (not a plain weave fabric) and factor two was at level two (a drill weave) and factor three at level three (ends per inch between 91 and 113), and so forth.

A listing of all 170 coded observation vectors is included as Appendix $C$.

## CHAPTER VII

## RESULTS

The program developed in this study, in general terms, permits the Burroughs 220 Datatron System to accept data cards, one for each observation on the response variable with each card coded for the appropriate level of each candidate variable, and to calculate the number of observations, mean, sum of squares, and variance in each level of each factor. These initial computations provide the desired information for oneway factor-level classification.

The data concerning observations falling into each level are actually sorted into separate portions of the computer's internal storage, one factor at a time. As the initial one-way calculations are performed, the data associated with the first level of factor one are transferred to magnetic tape, followed in sequence by the observations coded with levels two, three, and four respectively. The computer then considers each of the remaining factors in turn. Thus, as the single factor-level means and variances are calculated, the complete file of data is written on magnetic tape as many times as there are factors being considered. Each time the data are written on tape, they are, in effect, grouped according to the levels of the factor being considered.

To obtain the means and variances for the two-way combinations, the groups of observations, each representing all the observations
classified with a particular level of one factor, are brought back into internal storage one at a time. In this phase, the data from a group are treated in a manner similar to the original file of data. That is, the data in a group are sorted according to the levels of other factorsy one at a time. In order to avoid duplication of calculations, the data for a level of a particular factor, say arbitrarily numbered $w$, are sorted for only those factors designated with a number larger than w. For example, the data for the levels of factor two need not be sorted according to the levels of factor one since. in previous manipulations of the data, groups for the levels of factor one were subdivided according to the levels of factor two.

The second series of sortings provides the opportunity for calculating the number of observations, mean, sum of squares, and variance of the dependent variable for each two-way factor-level combination.

At the option of the user, the data may again be placed on magnetic tape in groups which represent the observations falling into cells formed by each two-way combination of factor levels. As before, these may be passed through the arithmetic unit of the computer in order to obtain, through the same sorting action, the means and variances for each possible three-way combination.

The results of these data manipulations and calculations may be printed out or punched into card form at the option of the user. The form of these results is as shown in Appendix D.

The two-factor combination results become more meaningful to the experimenter when presented in the form of $a b \times c$ table, where
$b$ and $c$ are the number of levels into which the candidate factors are subdivided. As discussed in Chapter IV, by considering the table as a surface viewed from above. and by considering the values within the table as representing the estimated heights of the surface above each cell of the table, a mental image of the estimates of the surface emerges.

The variance surfaces for each two-factor combination were considered first. A $4 \times 4$ or, where applicable, a $4 \times 3$ table for each two-factor combination was filled by using the appropriate cell variances which had been calculated and printed out as discussed earlier.

The estimate of overall surface variance was determined by weighting each within cell variance, as outlined in Chapter $V_{\text {g }}$ by $N_{h} / N$ which was determined by the ratio of the area of the $h^{\text {th }}$ cell relative to the total area of all cells included in the table and for which at least two observations were available. In so doing. it was assumed that each value of a candidate variable between the highest and the lowest observed values was equally possible. For discrete variables, each observed level was assumed equally possible.

For example, the class intervais for factor ten were equal and the class intervals for factor twelve were approximately equal, as shown in Table 7. The development of cell weighting factors for this factor combination is shown in Table 9.

Since each cell in this factor combination is approximately equally possible. the cell weighting factors are approximately equal.

Table 9. Cell Weighting Factors ( $N_{h}$ ), Combination of Factors Ten and Twelve

Since all factor-level combinations are not necessarily represented by two or more observations, relative weighting factors were used. In the case shown in Table 9 where each cell was approximately equally possible, a relative weighting factor of unity was used for each cell.

As an example of the case where relative cell weights other than unity were necessary, Tables 10 and 11 show the development of cell weighting factors for the combination of factors six and ten.

A summary of the overall surface variance for each factor combination is show in Table 12. Recall that the smaller the remaining within-cell variance, the greater the variation which may be attributed

to the independent variables forming the combination and to their interaction or to other independent variables correlated with the factors forming the combination. The mean value of the surface variances for all two-factor combinations of which each factor is a part is shown in Table 13. Factor fifteer is associated with the surfaces having the lowest residual variance and is thus suspect as having the largest main effect. This had not been ar:ticipated。 Factors twelve through fifteen had been included merely because the data had been available. Factors four, two, and six exhibited the next smailest mean residual variances.

On the other hand, factors seveng twelve, and thirteen were associated with the surfaces having the largest residual variances. Since the removal of the sum of squares due to the main effects of these variables reduced the overall response surface variance by a small amount relative to the reduction effected by removing the sum of squares of other candidate factors, these factors would be the first to be dropped from consideration by the experimenter, provided he agrees to adopt the conservative criterion of minimizing the maximum possible risk of an incorrect decisiono (31, p. 471, 481)"

Tables 14: 15, and 16 present the estimates of the three response surfaces having the smallest overall within-cell variances among the 105 such two-factor variance surfaces investigated. Each of these surfaces having a relatively small residual variance has factor fifteen as one component of the two-factor combination.

In picturing these tables as surfaces viewed from above, as discussed in Chapter IV, a decrease in the response is noted in each surface as the level of factor fifteen increases.

Particular attention is called to the surface represented in Table 16. In addition to a pronounced negative slope as the level of factor fifteen increases, there is also an apparent decrease in the response with an increase in the factor level for factor fourteen in levels one and two of factor fifteen.

|  | Level 4 | 6.77 | 5.69 | 3.73 | 2.74 |

To the writer, this surface was the most interesting of all those estimated due to its implications concerning the nature of the response. The higher levels of factor fifteen indicate lighter weight cloth. A decrease in warp contraction with decreasing cloth weight per yard is indicated by Tables 14, 15, and 16. Factor fourteen is cloth width and the higher levels indiaate wider cloth. Table 16 suggests that warp contraction tends to decrease as the cloth width increases within a given cloth weight classification. These two indications suggest the hypothesis that warp contraction increases with cloth weight per square unit of length.

The variance surface for the combination of factors fourteen and fifteen is show in Table 17 and the number of observations falling into each cell is shown in Table 18.

The generation of means and variances during the computer run makes available to the experimenter a wealth of information useful during the preliminary stages of experimentation. For example, assuming that the experimenter is interested in pursuing a particular hypothesis developed either prior to or during the analysis of observational data, a substantial amount of relatively quantitative information is available. In the example concerning warp contraction which was used to test the computer program, the experimenter would be particularly interested in factor fifteen after a cursory review of the results discussed above. Table 19 demonstrates the additional information which is readily available concerning this factor or any other factor considered in the analysis. From Table 19, the experimenter may plot the response against the midpoint of each interval and thereby obtain an indication of the nature and slope of the response associated with various levels of the independent factor when considered alone.

The estimate of the mean value of the response applicable to any level of any factor may be plotted against the midpoint of that level

| Mean Iwo-Way Variance | 15.23 | 9.73 | 5.06 | 1.01 | 6.40 |

as the result of the data available from the oneway classification. However, the possibility of correlations among the factors cannot be ignored in viewing these data.

Table 19 also provides information concerning the overall variance within each level of factor fifteen when combined with each other factor. Level one of factor fifteen has a larger variance than the other levels. Level four shows a small variance, regardless of the factor with which combined.

The three-way factor combination proved to be impractical for the large number of factors and observations herein used to test the program. The one- and two-way factor combinations, which involved in this test case the calculation of 1740 means and variances (one for each of the four levels of 15 factors in the one-way classification and one for each of the 16 possible factor-level combinations in each of the 105 two-way combinations), required a total of one hour and fifty minutes of computer time.

However, the number of combinations of fifteen factors taken three at a time is 4.33 times greater than when taken two at a time.

$$
C_{3}^{15}=\frac{15!}{3!12!}=\frac{15 \cdot 14 \cdot 13}{3 \cdot 2 \cdot 1}=4.33 C_{2}^{15}
$$

In addition the number of possible factor-level combinations for each three-factor combination increases from 16 to 64 . Consequently, in the writer's opinion, the time required for a three-factor combination
of the test data being used was prohibitive. A one- two and threeway combination of only five factors was run in less than forty minutes during the testing of the program.

To demonstrate a method by which an experimenter may utilize more than four levels for one or more of the candidate factors, the class intervals of factors four and six were arbitrarily modified to create factors three and five respectively. By so doing, the combination of factors three and four, for exampie, is a further modification of the same factor - ends per inch - which is segmented into seven levels instead of four. A three-factor combiration including factors three and four would, ir effect, be a two-factor combination involving seven levels of the factor ends per inch as though represented by a single factor. Table 20 illustrates the modified intervals created by the combination of factors three and four. Table 21 gives the means

Table 20. Creation of a Seven-Interval Factor Through Combination of Two, Four-Level Factors Representing the Same Candidate Variable

| Factor 3 Ends/Inch (Special) | Level 1 | Interval | Factor 4 <br> Erids/Inch |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | Level 1. | Level 2 | Level 3 | Level 4 |
|  |  |  | 32-55 | 56-79 | 80-103 | 104-127 |
|  |  | 32-45 | 32-45 |  |  |  |
|  | Level 2 | 46-90 | 46-55 | 56-79 | 80-90 |  |
|  | Level 3 | 91-113 |  |  | 91-103 | 104-113 |
|  | Level 4 | 114-127 |  |  |  | 114-127 |

and variances for each of the seven levels of the modified factor. By using this approach, the number of levels into which a factor may be segmented for the purpose of this analysis is seven rather than four. In order to take advantage of this method, the number of factors considered must be small enough to permit practical utilization of the three-way combination.

Table 2l. Estimates of Means and Variances for the Seven Levels of the Candidate Factor Ends/Inch Created by Combination of Factors Three and Four

| Interval | Mean | Variance | Combination <br> Factor 3 <br> Level | Factor 4 <br> Level |
| :---: | :---: | :---: | :---: | :---: |
| $32-45$ | 4.51 | 3.81 | 1 | 1 |
| $46-55$ | 5.04 | 10.62 | 2 | 1 |
| $56-79$ | 5.80 | 7.62 | 7.19 | 2 |
| $90-90$ | 7.45 | 6.55 | 2 | 2 |
| $104-113$ | 7.33 | 9.10 | 3 | 3 |
| $114-127$ |  |  | 4.04 | 4 |

## CHAPTER VIII

## CONCLUSIONS AND RECOMMENDATIONS

In summary, through after-the-fact stratification of observational data, through the treatment of candidate variables in pairs as in factorial design, and through utilization of an electronic computer to perform the myriad of calculations, the candidate variables are ranked according to the variation in the response which is removed when the effects of each factor are removed.

The ability to consider up to thirty candidate factors reduces the risk of overlooking an important variable. Hence the latter stages of the experiment are less susceptible to the invitiating omission of an important variable。

It is concluded that for a given commitment of resources to an experimental program, the utilization of the procedure herein developed will minimize the risk of failure of the experiment as a whole.

In addition, the organization and display in tabular form of the estimates of the mean and variance for each factor-level combination of those factor combinations having a relatively small error sum of squares, provide the experimenter with an estimate of the general contour of the response surface over the observed range of the paired factors.

As a result, the experimenter obtains an appreciation for the nature of the response surface. The risk of failing to vary factors
over sufficient ranges and the risk of failing to use appropriate transformations of the candidate variables in subsequent experiments is reduced.

The method herein developed permits the user to lay the data open so as to be able, as Tukey expressed the need, "to see what they look like inside, even though they do not give definite significance levels." (19, p. 172)

The writer's recommendations for further study and investigation may be classified as theoretical and mechanical. Among the former is the determination of optimum class intervals to be used in classifying the observational data so as to obtain the greatest reduction in the residual error. After obtaining an indication of the relative importance of the candidate factors, a more detailed study using various class intervals for the severai variables selected by the experimenter might prove worthwhile.

Secondly, the ever present hazard of correlations between factors hopelessly entangling the real effects gives rise to a need for a method of ranking the candidate factors after excluding the reduction in residual error which is attributable to correlation with a higher ranking factor.

Thirdly, the covariance terms in the final equation for $\frac{\sigma^{2}}{\bar{y}}$ might well be the subject of further investigation so as to permit a more precise statement regarding the relative magnitudes of $\frac{\sigma}{y}$ and $\sigma^{2 *}$ 。

7

From the standpoint of the mechanics of this method of analysis, an automatic means for the elimination of certain factors, based on the results of the two-way classification would reduce the amount of computer time required for performing the calculations associated with all possible three-factor combinations. For example, if an experimenter begins the analysis using $X$ candidate variables, it is conceivable that the program might be so written as to exclude automatically $Y$ of the variables prior to entering the three-factor phase. This exclusion would be based upon the relative ranking of the candidate factors.

An automatic means for displaying weighted cell variances and cell means in addition to the listing of means and variances would also be helpful. In particular, a display of automatically weighted variances in a fashion similar to that of Tables 12, 13, and 19 would be desirable.

APPENDICES

MOW

MRD

REWND Label for the external machine language statement for rewinding a specified tape unit.

Label for the external machine language statement for transferring data from internal storage to a specified tape unit using the specified output declaration.

Label for the external machine language statement for transferring data from a specified tape unit to internal storage using the specified input declaration.

Label for the external statement for a search of a specified tape for the first word of a ten word block (TOTAL) equal to a specified value (SK).

## ARRAYS

(These declarations specify the structure of
a collection of numbers and enable the user to
refer to them with a single identifier.)
Array Identifiers

## Description

DATA (5) A five dimensional vector referring to the 5 word data unit DATA (1), DATA (2), DATA (3), DATA (4), and DATA (5).

TDATA (5) A five dimensional vector referring to the 5 word data unit equivalent to DATA (5). TDATA (5) is used to distinguish output declarations whereas DATA (5) is used in input declarations.

Label
FLOW CHART

Read "TOTAL, IDIN, NBR, MORE."

If the bumper (9999999999) is read, the analysis for each group of data on tape is complete.
Take the remainder obtained dividing IDIN by 100 , consider this value as an integer: add lo The net effect is to increase $F$ by 1 .

Proceed to the next group of data upon completion of analyses on FMAX factors.

Establishes the current identification for the data which which will be put into each pocket.

Commence reading each of the NBR 5 word data units from tape into internal storage.

Add 1 to the number of observations which have been detected as having this level of the factor being considered.

Transfer control to one of four statements depending on the level detected. If the number of observations in one level exceeds the program capacity, detect the difficulty.

Store the 5 word data unit in the appropriate matrix or "pkt."

Calculate, for pocket 1 , the sum of observations on the $X$ variable and also for the $Y$ variable as well as the sum of squares for each.

For each pocket.

Calculate the mean and sum of squares for both response variables.

If the number of observations is less than a predetermined number, bypass the variance calculation.

Calculate the variance for both response variables.

Print the results as specified by the output declaration "RESLT" and in the format specified by "PRINI."

Clears various identifiers to 0 .

Set "SK" equal to "TOTAL" with the last five digits equal to zero.

If the machine operator has set the program control switch number 3 to "ON," print in accordance with the "LONG" declaration and format "PRINI." STOP with 6's showing in the A register.

Tape search for the data group on tape having "TOTAL" equal to "SK." This is the data group currently being analyzed. In effect this positions the tape back to the label of the current data group.

Read in accordance with declaration LBLIN (Label in).
