#### 1 Abstract

The aim of this paper is to unfold the relationship between O and C isotope compositions of modern fresh-water mollusc shells and water in order to refine the basis of interpretation for paleoenvironnemental reconstruction in the sub-Himalayan river basins. Large number of mollusc shells and associated host water from both running water and closed body of water were analysed including intra-shell variability in a few cases.

6 The O isotopic compositions of river waters in the Himalayas and Ganga plain have a large range, from -18‰ in 7 the north of the High range up to -8 to -4 % in the Ganga plain.  $\delta^{18}$ O of rivers are also seasonally variable, 8 especially in foothills rivers whereas the seasonal contrast is smoothed out for main Himalayan rivers having 9 large catchments. O isotopic compositions of bulk shells (Aragonite) vary between -15 and -5 ‰. Average 10  $\delta^{18}O_{Ara}$  values are consistent with precipitation at equilibrium with host waters at a temperature range of 20-25 11 °C suggesting that shell growth may be favoured during non-monsoon conditions. Shells collected along main 12 Himalayan rivers have  $\delta^{18}$ O values uniformly distributed within -11 and -6 ‰ reflecting the minimal seasonal 13 contrast shown by these rivers. In contrast, O isotopic compositions of shells from foothills rivers vary only by 4 14 %. This shows that, depending on the type of river where the molluscs grow, the information in term of  $\delta^{18}$ O 15 amplitude will be different for identical climatic conditions. In closed or pond water bodies significant 16 enrichment in <sup>18</sup>O due to evaporation is observed.

17 The C isotopic compositions of river dissolved inorganic carbon (DIC) decrease downstream from 0 to -10 18 ‰ reflecting input of soil derived alkalinity and plant productivity in the river.  $\delta^{13}$ C of shells are systematically 19 lower than compositions calculated for equilibrium with river DIC indicating that in addition to DIC, a 20 significant fraction of carbon is derived from metabolic sources. Intra-shell  $\delta^{13}$ C are stable compared to the 21 seasonal variability of DIC suggesting that the pool of organic carbon changes throughout year.

#### 23 Keywords

C and O isotopes, fresh-water molluscs, modern rivers, Himalaya, Ganga, seasonality, running water versus pond
 water.

- 26
- 27 1. Introduction
- 28

29 Carbon and oxygen isotope compositions of carbonate skeletons have been extensively used for reconstructing 30 past environmental parameters (e.g. Lowenstam and Epstein, 1954; Woodruff et al., 1981; Shackleton, 1986; 31 Miller et al., 1987). From a study of marine mollusc shells and their ambient marine waters, Lécuyer et al. (2004) 32 demonstrated that the oxygen isotope compositions of shells from most fossil mollusc species are suitable to 33 estimate past seawater temperatures. In river systems, mollusc shells represent remarkable sources of 34 geochemical information and allow to document seasonal variations through detailed analysis of growth layers 35 (e.g. Abell, 1985; Fritz and Poplawski, 1974; Dettman et al., 1999; Kaandorp et al., 2003). Nonetheless, only few 36 studies provide stable isotope data of laboratory-reared or natural shells along with their ambient waters 37 (Grossman and Ku, 1986; Margosian et al., 1987; Weidman et al., 1994; Klein et al., 1996).

38 Some studies have focussed on the reconstruction of paleo-environmental conditions in the Gangetic plain using 39 fossils from the plain and Siwaliks (Garzione et al., 2000a; Dettman et al., 2001; Sharma et al., 2004; Gajurel et 40 al., 2003). These studies reveal a large variability in stable isotope compositions through time, and importantly 41 large seasonal cycle. Clearly, fossil records of fresh water mollusc represent a rich source of information to 42 document past evolution of river system. Our objective is to refine the basis of interpretation of oxygen and 43 carbon isotope compositions of fresh-water molluscs for paleoenvironemental reconstruction in the sub-44 Himalayan river basin. For that purpose, we collected modern mollusc samples across a wide range in elevation, 45 from the Ganga Plain to the highest physiographic zones. Waters in the Himalayan rivers and in closed or 46 ponded bodies of water exhibit seasonal changes in temperature and stable isotope (C and O) compositions (Galy 47 and France-Lanord, 1999; Garzione et al, 2000b). Therefore, we sampled several modern mollusc species from 48 streams/rivers and closed bodies of water of Himalayan Valleys and Ganga plain together with host water 49 samples and ambient temperature records to unfold the relationship between shell composition and water 50 parameters. In this paper, we compare water bodies in different geographical settings that differ primarily in the 51 size and elevation of their catchments: the Main Himalayan rivers draining complete Himalayan sections from 52 Tibet to the floodplain, small rivers originating from the Himalayan foothills, the main stream Ganga, and some 53 lakes, ponds and North Himalayan rivers.

54

- 55
- 56

57 Three large rivers emerge from the Nepalese Himalayan belt and flow to the Ganga plain within ~300 58 km wide basin (Fig. 1): the Kosi, Narayani/Gandak and Karnali/Ghaghara rivers, in eastern, central and western

2. Setting: modern Himalayan drainage system and climate

59 Nepal respectively. They drain a large part of Himalaya extending from North Himalaya (altitude 2500-4000 m 60 above mean sea level) through High Himalaya (>4000 m), Lesser Himalaya (300 to 3000 m) and Siwaliks (150-61 1400 m) to the Ganga plain (less than 150-200 m). The headwaters of these large rivers are fed by melt water from snow and glaciers. All of them, except the Arun, make 90° turns, flowing either eastward or westward 62 63 before crossing the Mahabharat Range, north of the trace of the Main Boundary Thrust (MBT). They then, flow 64 axially, sub-parallel to the MBT for more than 100 km and turn southward through the areas of structural 65 weakness to emerge in to the Ganga plain (Hagen, 1969; Seeber and Gornitz, 1983; Gupta, 1997). The Kosi, 66 Narayani and Karnali rivers have high average annual water discharge (varying between 1500 to 2000  $\vec{m}/s$ ) 67 (Sinha and Friend, 1994; DHM, 1998) and drain more than 75 % of the area of the Himalaya of Nepal. Their 68 sediment bed load form large modern alluvial megafans in the Ganga plain (Wells and Dorr, 1987; Sinha and 69 Friend, 1994). A few small rivers originate in the Lesser Himalaya, Siwalik foothills and within the Ganga plain. 70 They merge with the major rivers in the plain. They have smaller discharge and form interfans between the 71 megafans of the large rivers in the plain (Sinha and Friend, 1994). All the rivers of Nepal are tributaries of the 72 Ganga River. The main tributaries of the Ganga River originate from Himalaya although some flow from the 73 Indian shield representing less than 20% of the total Ganga discharge (Rao, 1979).

74 Our river water samples represent a wide range of climate with a characteristic pattern of temperature. 75 In the central Ganga plain average minimum and maximum temperatures are 8 and 21 °C for November-76 February and 27 to 33 °C for March-June (Sharma et al., 2004). Surface air temperature records for more than 16 77 years (DHM, 2002) near the northern margin of the Ganga plain and in the Dun Valleys show more or less 78 similar climate with monthly maximum average temperatures of 36 °C for the April to September period 79 (summer) and 26 °C for the October to March period (winter). Tansen, Pokhara and Kathmandu in Lesser 80 Himalaya have mean values of 28 °C, 30 °C and 29 °C during the summer period and 20 °C, 23 °C and 22 °C 81 during the winter period. In North Himalayan valley (Jomsom), the mean annual minimum and maximum 82 temperatures are 5.3 °C and 17.5 °C, respectively.

Nepal receives about 80 % of the total annual precipitation during the June-September monsoon (DHM, Average annual precipitation in North Himalayan valley (Jomsom) is 257 mm. High annual rainfall (>3000 mm) occurs in the Arun and Indrawati river headwaters (High Himalaya). The average wet and dry season precipitations in Pokhara are 3934 and 157 mm, respectively. The highest annual precipitation is recorded in the Pokhara valley, which les within the catchment of the Narayani River system while the Karnali River system is located in a lower precipitation area (<2000 mm) (DHM, 2002). The Ganga plain and Dun Valleys

- 89 (Siwalik foothills) receive average precipitation of 1760-69 mm and 1875-99 mm during wet-dry periods,
- 90 respectively. The Ganga plain (in India) receives annual rainfall of 800-2000 mm (Sinha and Friend, 1994).
- 91

#### 92 **3.** Sampling strategy and fauna

93

94 The sampling area covers (24° 30' N28° 50' N) latitude and (83° E-88° 30' E) longitude while the 95 altitude ranges from 17 to 3576 m (Fig. 1). We collected freshwater modern molluscs from a wide range of 96 habitats including river shores, lake shores, ox-bow lakes and isolated ponds situated within North Himalaya, 97 Lesser Himalaya and Dun valleys, and the Ganga alluvial plain and Bangladesh delta plain. The sampled 98 specimens from the Ganga plain and Himalayan valleys can be easily identified (Subba Rao, 1989; Subba and 99 Ghosh, 2000; Nesemann et al., 2001) and represent two genera from Bivalvia class and ten genera from 100 Gastropoda class whose widespread genus are Bellamya sp. and Melanoid sp. (Fig. 2). They include living and 101 dead specimens. Mollusc's habitat water samples (host water) were collected while habitat water temperature 102 (ambient temperature), pH and air temperature were also recorded during sampling for most locations. The 103 favoured habitat of molluscs in this study are low current environment and closed or ponded environments. In 104 the case of ponds, fresh water as well as stagnant water samples were collected to examine the possible effect of 105 atmospheric exchange and evaporation on the carbon and oxygen isotopic compositions of the biogenic 106 carbonate. At several locations, members of different species were taken in order to examine the variability in 107 shell chemistry of different taxa living in the same environment, caused by different physiological effects and 108 growth periods.

109

- 110 4. Analytical techniques
- 111
- 112 *4.1 Water*

113

114 Meteoric water samples were collected daily at Kathmandu using a PVC collector. Special care was 115 taken to avoid evaporation. The fact that all samples lie close to the global meteoric water line confirms the 116 reliability of the sampling. When daily precipitation was lower than 1 mm we did not collect any sample. River 117 water samples were filtered on site through  $<0.2\mu$ m nylon membranes and stored in polyethylene bottles free of 118 air. The carbon isotopic compositions of dissolved inorganic carbon ( $\delta^{13}C_{DIC}$ ) were measured on CO<sub>2</sub> released by acidification with H<sub>3</sub>PO<sub>4</sub> in vacuum. Aliquots of 15 to 20 ml were injected into the reaction vessel through a septum. The CO<sub>2</sub> released after acidification was extracted while water was trapped as ice (-80 to -50°C). The outgassing procedure was repeated three times in order to extract most of the DIC from the water. Total CO<sub>2</sub> released was measured manometrically for DIC concentration and analysed for <sup>13</sup>C/<sup>12</sup>C ratio using a modified VG 602D isotope ratio mass spectrometer. Results are expressed as  $\delta^{13}C_{\text{DIC}}$  relative to PDB and the overall reproducibility is ± 0.3‰.

125 The oxygen isotopic composition of host water samples ( $\delta^{18}O_W$ ) were analysed using the classical CO<sub>2</sub> 126 equilibration method of Epstein and Mayeda (1953). One cm<sup>3</sup> of water was equilibrated in a vacuum container 127 sealed with a septum with CO<sub>2</sub> at 900 mbar and 25 °C ±0.1 °C. <sup>18</sup>O/<sup>16</sup>O ratios are expressed as  $\delta^{18}O_W$  relative to 128 V-SMOW and overall analytical reproducibility is ± 0.1 ‰.

Hydrogen isotopic compositions of water samples were measured using a GV-Isoprime mass spectrometer coupled to an elemental analyzer. 3  $\mu$ l of water were injected over Cr reactor at 1100°C under He flux and analysed in continuous flow mode. D/H ratios are expressed as  $\delta$ D relative to V-SMOW and overall analytical reproducibility is better than  $\pm 2 \%$ .

133

134 *4.2 Mollusc shells* 

135

Mollusc shell samples were cleaned in distilled water with ultrasound to remove adhered sediments and organic debris. Before micro sampling, shell outer periostracum, which is composed of organic coloured layers, were removed by scraping with the help of manual drilling bit to expose white prismatic layer. Intra-shell samples were taken all along the profile parallel to the growth lines of intact shell. Typical width of growth layers is 0.5 to 2 mm. Whole shell samples are either whole shell grinded for small specimens (one mm) or, for larger ones, a slice perpendicular to the growth line covering the entire life span of the specimen.

For experimental analyses, three individual representative average samples of a *Bellamya bengalensis* were treated in three different ways: one powder sample was vacuum roasted for one hour at 380 °C and another sample was heated in plasma O<sub>2</sub> cold asher for one night to volatilize shell organic compounds and the third one was not treated. These procedures did not produce any remarkable variation (Table 1). The samples were reacted under vacuum with ~100 % phosphoric acid at 25  $\pm$  0.1 °C (McCrea, 1950). Isotopic analyses of the released CO<sub>2</sub> were performed in a modified mass spectrometer model VG 602. Carbon and oxygen isotopic ratios of aragonite are expressed as  $\delta^{13}C_{Ara}$  and  $\delta^{18}O_{Ara}$  relative to PDB. Following common practice for aragonite shell

149 analyses (e.g. Dettman et al, 1999; Lecuver et al, 2004) we did not apply any correction specific for aragonite 150 and used the standard correction for calcite. Ten to fifteen repeated analyses of calcite international standards 151 over the analytical period are : NBS-18  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  ‰, NBS-19  $\delta^{13}C = -5.02 \pm 0.04$  ‰ and  $\delta^{18}O = -23.06 \pm 0.13$  $2.00\pm0.04$  ‰ and  $\delta^{18}O = -2.15\pm0.13$  ‰, IAEA -CO-1  $\delta^{13}C = 2.47\pm0.04$  ‰ and  $\delta^{18}O = -2.46\pm0.09$  ‰, IAEA -CO-1 152  $8 \delta^{13}C = -5.74 \pm 0.07$  ‰ and  $\delta^{18}O = -22.79 \pm 0.1$  ‰. Overall reproducibility is  $\pm 0.1$  ‰. 153 154 Shell mineralogy was examined using X-Ray diffraction in which only aragonite was observed for 155 whole shell powders (n=3). The carbonate content of shells was calculated from manometrically measured CO<sub>2</sub> 156 yields after complete reaction with phosphoric acid. Carbonate contents ranged from 95% to 99%. 157 158 5. Results 159 160 5.1 Isotopic composition of waters 161 162 Hydrogen and oxygen isotopic composition of waters ( $\delta D_W$ ,  $\delta^{18}O_W$ ) and carbon isotope ratio of DIC  $(\delta^{13}C_{DIC})$  are listed in table 2. Sample locations are listed in appendix 1 and 2. Additional isotopic data from 163 164 Ramesh and Sarin (1992), Jenkins et al. (1987) and Galy and France-Lanord (1999) have also been included. 165 The  $\delta^{18}O_W$  values of rivers, lakes and ponds in the Himalayas and Ganga plain show a large range as seen in

166 figures 3 and 4 for different zones (North Himalaya, High Himalaya, Kathmandu Valley, Phewa Lake (Pokhara), 167 foothills, Main Himalayan rivers and Main Ganga River in the plain). Himalayan rivers display a strong 168 dependence on elevation with  $\delta^{18}O_W$  around -18 % to the north of the High range up to -8 to -4 % in the Ganga 169 plain. Such a variability has already been reported by Ramesh and Sarin (1992) and Garzione et al. (2000b). The 170 large-scale variations observed from High Himalaya to the Ganga plain are controlled by the combined effects of 171 elevation, orographic precipitation and temperature. Orographic precipitation drives a strong Rayleigh 172 distillation, which tends to deplete the clouds remaining over the north Himalaya in the heavy isotope. In 173 parallel, temperatures strongly decrease from the plain to the high range amplifying this trend.

174  $\delta^{18}O_W$  of rivers are also seasonally variable. Monsoon rain can be 4 ‰ lower than precipitation during 175 the dry season as obviously observed in foothills rivers (Fig. 4). Over the whole basin,  $\delta^{18}O$  of monsoon rains are 176 markedly lower compared to precipitations during the rest of the year. This is well documented in the Gangetic 177 plain and is related to the "amount effect" or intensity of precipitation (Rozanski et al., 1993; Bhattacharya et al., 178 2003). Our record of precipitation at Kathmandu over the year 2001-02 (appendix 3, Fig. 5) shows a similar 179 seasonal evolution. For Kathmandu, the  $\delta^{18}$ O values of precipitation are close to 0% and even positive 180 throughout the dry season, after which they drop abruptly to the range of -5 to -15‰ at the onset of the monsoon 181 season. The variation is clearly correlated with the intensity of precipitation. The weighted average  $\delta^{18}$ O values is 182 -7.9 ‰ for the whole year and that of the monsoon period is -10.6 ‰. This sharp seasonal contrast is smoothed 183 in the river signal, especially for large area catchments as observed for the Ghaghara, Narayani-Gandak and Kosi 184 rivers. For the Narayani-Gandak, which is most extensively monitored, the difference between dry and wet 185 seasons does not exceed 3 %. In the floodplain, the Ganga shows a clear seasonal contrast in the western part up 186 to Patna (Fig. 3b). Dry season compositions are between -6 to -4 ‰ whereas during monsoon they vary between 187 -8 to -10 %. This difference results from both the lower  $\delta^{18}$ O values of monsoon precipitation and the greater influx of Himalayan water during the monsoon as the  $\delta^{18}$ O of precipitation is lower in the Himalaya than on the 188 189 plain. At the outflow in Bangladesh, the Ganga is usually ~-10 ‰ during monsoon. Values as high as -7 ‰ have 190 been reached during the 2004 monsoon, probably due to large rainfall amounts on the Ganga Plain during that 191 period. The Gomti (Table 2), which is a plain fed river, appears stable and is around -7 ‰ throughout the year. 192 This stability is probably related to a discharge of local groundwater (Bhattacharya et al., 1985; Sinha and 193 Friend, 1994).

194 During the dry season, evaporation in the floodplain can significantly affect the O and H isotopic 195 compositions (Krishnamurthy and Bhattacharya, 1991; Ramesh and Sarin, 1992). This is shown by compositions 196 lying below the meteoric water line in a  $\delta^{18}$ O vs.  $\delta$ D diagram (Fig. 6). We observe a similar trend for Ganga 197 water in May 2004 (Table 2) whereas Main Himalayan rivers such as the Ghaghara, Gandak and Kosi show no 198 significant effect of evaporation. Monsoon compositions in the floodplain show no shift from the meteoric 199 waterline. Similarly, North Himalayan rivers and Kathmandu Valley rivers show no evidence for evaporation 200 (Fig. 6) except for minor catchments in the Kathmandu Valley during monsoon (Jenkins et al., 1987). Finally, we 201 observe major effects of evaporation for ponds located in the floodplain and Himalaya (Fig. 6). It is important to 202 document these effects as ponds are quiet environment favourable to the development of gastropods.

203  $\delta^{13}C_{DIC}$  values of river water are also highly variable (Table 2, Fig. 7). They have very high values in the 204 North Himalaya around 0 ‰ and decrease downstream toward values around -5 to -8 ‰ for the Main Himalayan 205 rivers. In Northern Himalaya where biological activity is limited, sulfuric acid released by sulfur oxidation is a 206 significant source of acid for carbonate dissolution (Galy and France-Lanord, 1999). It produces DIC close to 0 207 ‰ without noticeable contribution of soil organic CO<sub>2</sub> since most carbonates are of marine origin. Downstream 208  $\delta^{13}C_{DIC}$  values become significantly lower (between -5 to -10 ‰) reflecting input of soil derived alkalinity in the 209 river (Galy and France-Lanord, 1999). However, in High Himalaya, hot springs enriched in alkalinity derived 210 from outgassing of metamorphic CO<sub>2</sub> towards surface contribute to maintain relatively high  $\delta^{13}C_{DIC}$ . Due to carbonate precipitation and CO<sub>2</sub> outgassing, these springs have very high  $\delta^{13}C_{DIC}$  up to +15 ‰ and, when mixed 211 212 with river water, tend to increase their  $\delta^{13}C_{DIC}$ . Altogether, about 10 % of the riverine DIC in Himalaya could be 213 derived from thermal spring activity (Evans et al., 2004). Siwaliks drainage basins have lower  $\delta^{13}$ C values 214 around -8 to -10 %. The main Himalayan tributaries of the Ganga (Gandak and Kosi) have  $\delta^{13}C_{DIC}$  values around 215 -7 to -9 ‰. In the Ganga plain, the Ganga varies from relatively high values in the West (-3 to -6 ‰) to more 216 depleted values around -6 to -10 % downstream under the combined influence of (1) Himalayan river input, (2) 217 increase of silicate weathering in the soils of the floodplain and (3) increased plant productivity in the eastern 218 part of the Gangetic plain.

Except for a few cases, there is a systematic difference between monsoon and dry season waters, the latter showing higher  $\delta^{13}C_{DIC}$  (Table 2). This difference varies between 0 and 5 ‰ and derives from complex controls between origin of water (Himalayan vs. plain) and time of residence of water in soils. It is noticed that the variability is relatively large in Bangladesh (Fig 8). The Ganga  $\delta^{13}C_{DIC}$  values during the monsoon vary from -10 to -7.3 ‰.  $\delta^{13}C_{DIC}$  in the Ganga are well correlated with  $\delta^{18}O$  of water with low  $\delta^{13}C_{DIC}$  being associated with low  $\delta^{18}O_W$ . The latter reflects higher contribution of Himalayan waters.

225

226 5.2 Isotopic composition of aragonite shells

227

All isotopic data are given in table 3 and summarized in figures 4 and 7 in the form of histograms for different geographical environments. Water isotopic compositions are compared to shell aragonite composition. For oxygen, isotopic compositions of water relative to V-SMOW are compared to aragonite composition relative to PDB.

232

233 5.2.1. Bulk oxygen isotopic composition of shells

234

235  $\delta^{18}$ O values of bulk shells vary between -15 and -5 ‰ for running water environment. The lowest value 236 of -15.2 ‰ is associated with low  $\delta^{18}$ O waters from North Himalaya. Samples from ponds display higher values 237 between -8 and +3 ‰ that are related to <sup>18</sup>O enrichment by evaporation in closed system environment. In discussing this data set we define three groups based on the characteristic of the river water isotopic composition. Foothills samples belong to local watershed in the Lesser Himalaya and Siwaliks where waters are characterized by marked seasonality. The Main Himalayan rivers are made up of the samples from the Karnali-Ghaghara, Narayani-Gandak and Kosi from the foothills to their confluence with the Ganga. Their  $\delta^{18}O_W$  values are relatively similar and stable throughout the seasons. The third group consists of main Ganga samples for which waters have higher and more variable  $\delta^{18}O_W$  than Main Himalayan rivers (Fig. 3b). Data of  $\delta^{18}O_{Ara}$  for these three groups are represented in the form of histograms in figure 4.

245 Foothills gastropods show a clear unimodal distribution between -10 and -6 ‰ and centered on -8 ‰. 246 Main Himalayan river gastropods have  $\delta^{18}O_{Ara}$  values uniformly distributed between -12 and -5  $\infty$ . In contrast to 247 foothills samples, this range is greater than and encompasses their host waters ( $\delta^{18}O_W = -10$  to -6 %). Fourteen 248 samples representing three species Bellamya bengalensis, Digoniostoma textum and Indoplanorbis sp. have been 249 taken at the same location on the Ghaghara bank. All of them show higher variability than the whole dataset of 250 the Main Himalayan rivers. No significant difference occurs among the species Bellamya bengalensis, 251 Digoniostoma textum and Indoplanorbis sp. For the Main Ganga stream, most samples cluster between -8 and -5 252 ‰ and only few samples have lower values around -9 ‰. Ten Bellamya bengalensis specimens sampled on the 253 Ganga at Barauni (BR-316) are quite homogeneous between -8.1 and -6 %. Altogether, the average  $\delta^{18}O_{Ara}$  for the 254 Ganga is -6.4 % ( $\sigma$ =1.0), which is significantly higher than that of Main Himalayan rivers at -8.8 % ( $\sigma$ =2.3) or 255 foothills rivers at -7.6 % ( $\sigma$ =1.1). The Gomti river which is draining only the plain, shows values very similar to 256 those of the main Ganga stream with an average value of -7.0 % ( $\sigma=1.0$ ). In the plain, samples from ponds display 257 highly variable  $\delta^{18}O_{Ara}$  values from -8 % up to +3 %. Low values are in the range of river values whereas high 258 values show clear effect of <sup>18</sup>O enrichment due to evaporation of closed water bodies. In the range, samples from 259 the Phewa Lake (Pokhara) which is not significantly evaporated have homogeneous compositions with an average 260  $\delta^{18}O_{Ara}$  at -8.6 % ( $\sigma$ =0.8). The few samples collected in North Himalayan rivers show the lowest  $\delta^{18}O_{Ara}$  between 261 -15 and -8 % consistent with the lower composition of the host waters.

262 263

#### *5.2.2. Carbon isotopic composition of shells*

264

Except one sample from North Himalaya, all  $\delta^{13}C_{Ara}$  of shell samples collected from rivers are between -13 and -4 %. The average  $\delta^{13}C_{Ara}$  is -7.6 % with a standard deviation of 2.0, which shows that the overall variability is low. The highest values are observed in the western Ganga and the rivers with dominant plain input (Gomti and Rapti). On the contrary, the lowest values are observed in the foothills rivers. This group is the only one that significantly 269 differs from the others with an average composition of -9.7 ‰ ( $\sigma$ =2.1). All other groups have average  $\delta^{13}C_{Ara}$ between -7.7 and -6.6  $\infty$ . For all groups analysed, we observe no relationship between  $\delta^{18}O_{Ara}$  and  $\delta^{13}C_{Ara}$ . 270 271 272 5.2.3 Intra-shell compositions 273 274 We analysed four samples to document intra-shell isotopic variations due to seasonal effect during 275 growth. Such variations have been reported for fossil samples of the Ganga plain (Sharma et al, 2004) and of the 276 Siwaliks (Dettman et al. 2001). Data are listed in table 4 and presented in figures 9, 10a and 10b. Both molluscs 277 from the plain (BR-316-10 from the Ganga and BR 337-3 from the Gandak) and bivalve (Btw-2 cor) from the 278 Tinau khola foothills river show marked variations with increasing  $\delta^{18}O_{Ara}$  during shell growth. For these samples 279 the amplitude of the increase is about 3 %. The fact that  $\delta^{18}O_{Ara}$  simply increases and does not return to more 280 negative values suggests that these specimens lived for only one season. Another sample from a foothills river 281 (Chit 1) shows only limited variation of about 1  $\infty$ .  $\delta^{13}C_{Ara}$  values are rather stable and independent of  $\delta^{18}O_{Ara}$ 282 with values around -8 ‰ for both BR-316-10 and Chit-1, and -11 ‰ for Btw-2 cor. 283 284 6. Discussion 285 286 6.1 Oxygen isotope fractionation between biogenic carbonate and water 287 288 Stable oxygen isotopic composition of biogenic carbonate is controlled by both temperature and isotopic 289 composition of environmental water during shell accretion (e.g. Epstein et al., 1953). The measured  $\delta^{18}$ O values 290 of mollusc shells and water and ambient temperature of water are examined to oxygen isotope equilibrium 291 fractionation between carbonate and water. We used the fractionation-temperature relationship of Dettman et al. 292 (1999) that is based on calibration from Grossman and Ku (1986): 293 1000 ln  $\alpha$  = (2.559\*10<sup>6</sup>/T<sup>2</sup>)+0.715 294 where T is the temperature of water in  $^{\circ}$ K and  $\alpha$  is the fractionation coefficient between water (w) and aragonite 295 (Ara). The analysis of  $\delta^{18}O_W$  -  $\delta^{18}O_{Ara}$  relationship ideally requires a detailed record of  $\delta^{18}O_W$  and temperature 296 variations, which is not available for most settings studied here. We calculated  $\delta^{18}O_{Ara}$  from  $\delta^{18}O_W$  for the 297 298 different main settings that we sampled (Bangladesh Ganga, Central Ganga plain, Main Himalayan rivers,

299 foothills rivers). For this purpose, we used all  $\delta^{18}O_W$  data available (Table 2 and Ramesh and Sarin, 1992). For 300 the data of Ramesh and Sarin (1992), no temperatures were available and we used estimates based on standard 301 seasonal temperatures. Figure 11 shows that the Ganga is expected to generate aragonite with marked seasonal 302 change in  $\delta^{18}$ O at least in the Central Ganga plain area where there is a potential variation of ~4 ‰ between the 303 winter and the monsoon seasons. The main Himalayan rivers show lower amplitude than the Ganga as expected 304 from the relative insensitivity of their  $\delta^{18}O_w$ . From this limited data set, no significant difference is expected 305 among these rivers. The Gandak and Kosi appear very similar and the Ghaghara is systematically higher than its 306 two eastern analogs. Foothills rivers are expected to show the highest seasonal contrast in  $\delta^{18}$ O with 6 to 7 ‰ 307 between April and the monsoon.

308

309 6.1.1 Intra-shell data

310

311 Bellamya bengalensis sample BR 316-10 from the Eastern Ganga shows a clear evolution from the apex around -10 % to -7 % towards the aperture (Fig. 9). Comparing these values with the model  $\delta^{18}O_{Ara}$  for Ganga 312 313 (Fig 11), it appears that the lowest  $\delta^{18}O_{Ara}$  of the apex is close to the expected value in the monsoon period. It 314 would imply that the increase in  $\delta^{18}O_{Ara}$  up to -7 % corresponds to the subsequent autumn season. The measured 315 amplitude is however lower than the calculated one and winter composition as high as -4 ‰ is not observed in 316 this sample. It is to be noted that because of the shell shape, the apex that records the monsoon low  $\delta^{18}O_{Ara}$  value 317 represents only a minor proportion of the total shell. As a consequence, the bulk composition is controlled by the 318 autumn aragonite and is around -7.5 %.

319 The articulated bivalve Corbicula sp (Btw-2 cor) sampled from shore sediments of the foothills river (Tinau Khola) shows lower  $\delta^{18}O_{Ara}$  value (Fig. 10b), which is slightly higher than the minimum  $\delta^{18}O_{Ara}$  values 320 321 calculated for the monsoon in foothills rivers. The overall variability in  $\delta^{18}O_{Ara}$  shown by the mollusc is 2.8 ‰, 322 which is lower than the 5-6 ‰ range calculated for foothills rivers. This may reflect a lifespan shorter than the 323 whole year as suggested by the lack of reverse trend of the growth record. Integrating effect of growth may also 324 tend to blur the effective ambient water variability. For the gastropod Brotia sp. (Fig. 10a) sampled from the 325 foothills Rapti river (Chit 1), the recorded  $\delta^{18}O_{Ara}$  values around -8 ‰ are incompatible with the monsoon period 326 in foothills rivers and slightly lower than the range calculated for the winter period. They could reflect growth 327 during the warm period prior to the monsoon.

328

330

Bulk shell data do not allow a detailed analysis of water to carbonate relationship because rivers are seasonally variable and bulk analyses integrate a specific intra-shell variability. Therefore we will analyse each setting separately according to its own characteristics.

In environments where  $\delta^{18}O_W$  is relatively stable such as the Phewa Lake (Pokhara) and the Gomti River in the floodplain,  $\delta^{18}O_{Ara}$  of shells show limited variability around -8.6 ‰ ± 1 and -7.0 ‰ ± 1 respectively. Based on aragonite-water fractionation of Dettman et al. (1999) and on the average  $\delta^{18}O_W$  value, we calculate an apparent temperature of precipitation between 20 and 30 °C which corresponds to major part of the seasonal range of temperatures in these two sites (Fig. 12).

In other environments,  $\delta^{18}$ O values of rivers are more variable and the comparison of water and shell  $\delta^{18}$ O values highlights some characteristics of the different groups (Fig 4). For a given zone, we compare the set of shell data to the  $\delta^{18}$ O<sub>w</sub> values and average temperature of waters at different seasons. Winter temperatures are around 15-20 °C in rivers of foothills and floodplain. For these temperatures, aragonite-water fractionation coefficient is between 1.031 and 1.032 implying that  $\delta^{18}$ O<sup>PDB</sup><sub>Ara</sub> is equal to  $\delta^{18}$ O<sup>SMOW</sup><sub>W</sub> or 1 ‰ lower. Premonsoon and monsoon temperatures are very high around 25-32 °C (aragonite-water fractionation coefficient between 1.028 and 1.030), which leads to  $\delta^{18}$ O<sup>PDB</sup><sub>Ara</sub> being 1 to 2 ‰ lower than  $\delta^{18}$ O<sup>SMOW</sup><sub>water</sub>.

For samples from foothills rivers,  $\delta^{18}O_{Ara}$  are relatively homogeneous around -7 ‰ which is compatible with winter and pre-monsoon waters and conditions. Monsoon waters in these watersheds have significantly depleted compositions which should lead to shells with compositions around -11 to -13 ‰ (Fig. 11). Monsoon compositions are therefore not recorded or represent only a minor proportion of these shells. This could be similar to what is observed for intra-shell variability in sample BR-316-10 where only a small fraction of the shell records monsoon composition.

The group of Main Himalayan rivers shows  $\delta^{18}O_W$  values between -10 and -6 ‰. Using a temperature of 20 °C during winter, and 30 °C during the warm season and monsoon,  $\delta^{18}O_{Ara}$  values of the shells should be between -10 to -8 ‰ during winter and -13 to -10 ‰ during monsoon (Fig. 11). Nineteen samples out of twentyfive are compatible with these ranges of values. More significantly, fifty percent of bulk gastropod data have  $\delta^{18}O$  values lower than -10 ‰, implying that for these samples, most of the aragonite shell was generated during the monsoon period. Six samples have  $\delta^{18}O$  higher than -8 ‰, which are incompatible with any measured range of waters composition and temperatures. While we have no satisfying explanation for these samples, the most 359 plausible one is that they correspond to shells which grew in shallow pools near a riverside which were subject to 360 isotopic enrichment by evaporation. Such shells could then have been transported back in the main river during 361 the high flow of the monsoon.

Ganga samples have bulk  $\delta^{18}O_{Ara}$  that cluster around -6 ‰ which suggests that most of the aragonite has been formed with high  $\delta^{18}O$  waters of the Ganga during winter or pre-monsoon period. Most monsoon Ganga waters have low  $\delta^{18}O$  due to <sup>18</sup>O depleted monsoon precipitation and Himalayan rivers input. Combined with high temperature in the Gangetic plain these conditions should generate aragonite lower than -9 ‰ which is not observed.

- 367
- 368 6.1.3 Average compositions
- 369

370 One can also compare average compositions of the different geographical groups for both water and 371 shell samples in a  $\delta^{18}O_W$  vs.  $\delta^{18}O_{Ara}$  diagram (Fig. 12). In such a diagram data should align on equilibrium lines 372 depending on temperature. While variability is rather large for most groups, we observe that different groups 373 tend to align along the 20°C equilibrium line which supports a general compatibility with non monsoon 374 conditions. In the same diagram, data for North Himalayan samples show that they reflect significantly lower 375 temperatures. This comparison underlines the differences existing between shells grown in Main Himalayan 376 rivers on one side and Ganga mainstream, foothills and plain rivers on the other side. Main Himalayan rivers are 377 continuously supplied by <sup>18</sup>O depleted High Himalayan watershed resulting in shells with 1-1.5 ‰ lower average 378  $\delta^{18}$ O values than shells from foothills and plain.

379

#### 380 6.2 Carbon isotope fractionation between biogenic carbonate and water

381

382 Gastropods principally uptake carbonate from dissolved inorganic carbon of water to build their shell. 383 Carbon isotopic fractionation between aragonite and  $HCO_3^-$  is  $2.6 \pm 0.6$  between 10 and 40°C (Rubinson and 384 Clayton, 1969; Romaneck et al., 1992). Therefore, the  $\delta^{13}C$  of aragonite should be at least 2 ‰ higher than that 385 of DIC in ambient river water. An examination of our data set shows that this is not the case for most of our 386 samples (Fig. 7). Overall they have  $\delta^{13}C_{Ara}$  equal to or 1 to 2 ‰ lower than that of DIC at sampling site. This is 387 also confirmed by noting that average  $\delta^{13}C$  values of the different groups (Fig. 13) are 2 to 3‰ lower than that 388 expected from DIC values of corresponding river waters.

389 The discrepancy between measured and calculated  $\delta^{13}C_{Ara}$  could be due to non-representative sampling 390 of DIC. But at least in cases of the Ganga and the Narayani-Gandak, seasonnal cover was sufficient to rule out a 391 possible bias of sampling. A second source of bias is related to the speciation of carbon in water. All samples 392 have pH around 8 ±0.55 implying that most of DIC is present as HCO<sub>3</sub><sup>-</sup>. However, these rivers have total DIC, 393 which is 10 to 15 % in excess of the measured alkalinity (Galy and France-Lanord, 1999). This means that a 394 significant proportion of DIC is present as excess CO<sub>2</sub> with  $\delta^{13}C \sim 8$  % lower than that of HCO<sub>3</sub>. The effective 395  $HCO_3^-$  is therefore expected to be about 0.5 to 1 ‰ higher than the measured DIC, leading to higher  $\delta^{13}C$  values 396 in precipitating aragonite and therefore larger discrepancy with measured  $\delta^{13}C_{Ara}$ .

397 The difference between the calculated and observed  $\delta^{13}C_{Ara}$  values is known from earlier studies and is 398 commonly explained by the incorporation of metabolic CO<sub>2</sub> from respiratory sources (e.g. Michener and Shell, 399 1994; Dettman et al., 1999; Aucour et al., 2003). Such C can be provided by digestion of particulate organic 400 carbon (POC) of land origin or phytoplankton of the river. POC in the Ganga rivers has low  $\delta^{13}$ C value around -401 22‰ (Aucour et al., in press) and therefore represents a source of low  $\delta^{13}C$  CO<sub>2</sub>. Phytoplankton  $\delta^{13}C$  is still not 402 documented but is likely to be around -30‰ assuming a DIC-phytoplankton fractionation around 22‰. The 403 proportion of inorganic to organic carbon incorporated in the shell is a matter of debate and several estimations 404 have been developed (McConnaughey et al., 1997; Aucour et al. 2003). Following Aucour et al. (2003) about 30 405 to 70% of total carbon should be of metabolic origin in order to explain our observed shell compositions 406 assuming that POC is the only organic source with  $\delta^{13}$ C of -22‰. Uncertainties are large mostly because each type of site displays a relatively large range of  $\delta^{13}C_{DIC}$  and  $\delta^{13}C_{Ara}$ . These proportions are of course lower if 407 408 phytoplankton is ingested instead of POC.

409 The  $\delta^{13}C_{DIC}$  of rivers tends to be lower during the monsoon period with a typical contrast of 2 to 3 %410 between the monsoon and dry season for both Ganga and Main Himalayan Rivers (Fig. 7). This should generate 411 a seasonal trend in the  $\delta^{13}C_{Ara}$  of shell that is not observed. The Ganga sample BR 316-10 (Fig. 9) for which intra-shell variation of  $\delta^{18}$ O is consistent with a monsoon to dry season evolution does not show a parallel trend 412 413 for carbon isotopes.  $\delta^{13}C_{Ara}$  of this sample is rather stable around -8  $\% \pm 0.5$ . Similarly the Gandak sample BR-414 337-3 does not show any significant change in  $\delta^{13}C_{Ara}$  that could reflect the seasonal evolution of  $\delta^{13}C_{DIC}$  of this 415 river (5 to -8 ‰). This suggests a complex interplay of changes in the source of organic carbon and its 416 incorporation in the shell over the year. One hypothesis is that the seasonal DIC contrast is counterbalanced by a 417 change of the organic carbon sources. During the monsoon, suspended particles concentrations are very high (1 418 to 5 g/l unpublished data) and POC around -22 ‰ dominates the organic pool. On the contrary, during the dry season, suspended particle concentration decline to 0.1-0.2 g/l. This increases the proportion of phytoplankton relative to POC in the organic carbon pool and could balance the increase in  $\delta^{13}C_{DIC}$ . Such hypothesis would allow to maintain a relatively constant proportion of organic carbon during the year around 30 to 50 % of the total carbon.

#### **4** 7. Conclusion and implications for fossil record

The main objective of this study was to determine how oxygen and carbon isotope compositions of mollusc shell can document environmental conditions in the Gangetic plain. For the first time, isotopic characteristics of river water in the Gangetic floodplain have been analysed for their seasonal variability and their relation to the watershed size. This basis allows to determine how shells of freshwater molluscs can record the isotopic compositions of river waters and how far we can relate it to climatic conditions.

430 Two distinct environments for the freshwater molluscs in the Ganga plain are observed. One is related 431 to flowing river and the other is stagnant water mass in isolated ponds. In rivers, average  $\delta^{18}O_{Ara}$  values of shells 432 are found compatible with isotopic equilibrium with the waters at a temperature range of 20 to 25 °C. In contrast, 433  $\delta^{18}$ O values of shells from stagnant water bodies are highly variable and can reach values as high as +3 ‰ due to 434 the effect of evaporation. This effect has been observed in modern and quaternary lake and ponds of the Gangetic 435 plain (Sharma et al., 2004) as well as in the Mio-Pliocene Siwaliks (Dettman et al., 2001). Overall, river 436 molluses have bulk  $\delta^{18}O_{Ara}$  in the range -10 to -6 \%. While one individual specimen may reflect a particular 437 history that appears in disequilibrium with the local river water, the analysis of small population (n>10) shows 438 that average values do reflect the characteristics of the river system. Molluscs from Main Himalayan rivers 439 consistently differ from the other environments surveyed (Ganga, foothills and Plain rivers) in that they have lower  $\delta^{18}O_{Ara}$  derived from the lower  $\delta^{18}O_W$  of these rivers. In the floodplain, the type of watershed therefore 440 441 plays a significant role in the resulting shell isotopic signal. The difference between the two groups is about 2 %. From the mollusc record of Surai khola Siwaliks, Dettman et al. (2001) derived an increase of river water  $\delta^{18}$ O 442 443 during the Mio-Pliocene compared to Middle Miocene. Such change from -12/-8 to -8/-6 ‰ may therefore 444 reflect a change in  $\delta^{18}$ O of precipitation related to climatic evolution as well as a change in the river network.

We also investigated if seasonality information can be derived from the mollusc shells. While the seasonal contrast for  $\delta^{18}$ O of precipitation in one location can reach as high as 10 ‰ (as we reported for Kathmandu), our record of different river systems shows that the rivers had a strong tendency to average this contrast. Main Himalayan rivers show a small contrast of ~ 3 ‰, whereas small rivers originating in the 449 Himalayan foothills vary by 5 ‰ or more. This shows that, depending on the type of river where the mollusc 450 grows, the information in term of  $\delta^{18}$ O amplitude can be different under identical climate conditions. A second 451 limitation is related to the recording by the mollusc itself. None of the specimen that we analysed showed pluriannual record that would allow deriving the whole amplitude of  $\delta^{18}$ O. This suggests that in the fossil record, the 452 453 application of such a tracer will require the analysis of a relatively large number of samples to provide the best 454 specimen. Extreme contrasts are recorded in isolated environments such as ponds. These cannot be used 455 quantitatively to trace past variations of precipitation as there is no control on the extent of evaporation. The minimum  $\delta^{18}O_{Ara}$  certainly documents the wet season as stated by Dettman et al. (2001) but it is difficult to know 456 457 how such system is related to the river environment. We suggest therefore that samples that do not present 458 extreme values due to evaporation should be preferred when possible, in order to be sure to trace rivers and not 459 closed bodies of water or ponds.

460 Finally, the carbon isotope composition of shells is controlled by that of DIC and, for a significant 461 proportion, by carbon derived from metabolic processes. The resulting  $\delta^{13}C$  of shells is 2-3% lower than 462 predicted by inorganic equilibrium with DIC. Shell aragonite has therefore the potential to trace processes that control the  $\delta^{13}C$  of DIC in river water. The evolution of the flora from G to C<sub>4</sub> during the Mio-Pliocene that 463 464 affect the whole Gangetic basin (e.g. Quade et al, 1995) is of course a major event that can be traced. In addition 465 this should increase the  $\delta^{13}$ C of land derived organic carbon and likely that of phytoplankton. DIC is also 466 controlled by lithologies that are weathered in the watershed and changes in the proportion of carbonate to 467 silicate weathering ratio in the Himalaya should also be detectable. Singh et al. (in press) reported  $\delta^{13}C_{DIC}$  for the 468 Brahmaputra and Himalayan tributaries that are 3 to 5 ‰ lower than those of the Ganga or Main Himalayan 469 rivers draining Nepal. This simply reflects the fact that less carbonate rocks are exposed to erosion in Eastern 470 Himalaya.  $\delta^{13}$ C of shells in the Siwaliks record have therefore the potential to trace long term variation of the 471 occurrence of carbonate rocks in the river drainage.

472 Studies of fossil shells in the sedimentary record have the potential to document river water evolution. 473 One option is to rely on bulk compositions avoiding abnormally high  $\delta^{18}$ O values that are clearly related to 474 evaporation. It requires also a statistical approach in order to determine average compositions. Because 475 watershed characteristics control part of the isotopic composition of the shell, efforts should be made to derive 476 river type from complementary sedimentological and geochemical characteristics. The second approach relies on 477 the analysis of intra-shell variations. It has clearly the potential to document the intensity of the seasonal contrast

- 478 provided the river environment has been determined. In this case again, the sedimentological context is essential
- 479 to derive climatological implications.

#### 480 Acknowledgements

This research was funded by the ECLIPSE Centre National de la Recherche Scientifique program. The first author is grateful to the French Minister of foreign affairs (MAE) and French Embassy in Kathmandu for providing scholarship to complete his doctorate degree in France. Dr. Sunil K. Singh (from PRL Ahmadabad) is warmly thanked for his continuous support and expertise during sampling in the Gangetic plain. We thank David Dettman and an anonymous reviewer for their very careful and helpful comments.
