Abstract—**Since the early 2000's, the Internet topology has been an attractive and important research topic, either for developing data collection mechanisms, and for analyzing and modeling the network. Beside traditional aspects of the Internet topology (i.e., IP interface, router, and AS levels), recent researches focused on intermediate promising visions of the topology, namely Point-of-Presence (PoP) and subnets (i.e., a set of devices that are located on the same connection medium and that can communicate directly with each other at the link layer).**

This paper focuses on network subnet discovery by proposing a new tool called `TreeNET`. One of the key aspects of `TreeNET` is that it builds a tree representing the way subnets are located with respect to each other. This tree allows `TreeNET` to obtain additional information on the network, leading to better analysis of the collected data. In this paper, we demonstrate the potential of `TreeNET` through the evaluation of its key algorithmic steps and the study of measurements collected from the PlanetLab testbed.

I. INTRODUCTION

The Internet is made of a vast set of heterogeneous and interconnected entities enabling the communication between millions of machines. Typically, this network is described as a graph where nodes refer to IP interfaces, routers, or autonomous systems (ASes) and edges depict their relations [1]. For now fifteen years, advanced mechanisms have been developed to collect data revealing the topology of the Internet at those different levels [2]. However, recent researches have suggested to extend the view of the traditional Internet topology to Point-of-Presence (PoP) [3], [4] and sub-networks [5], [6], [7], [8]. This paper follows this line of research by proposing a new tool named `TreeNET` dedicated to the Internet topology discovery integrating sub-network information.

A *sub-network* (or, simply, *subnet*) refers to a set of devices that are located on the same connection medium and that can communicate directly with each other at the link layer [9]. The subnet level is a way to enrich router level maps with subnet level connection information [5]. Subnet discovery presents some similarities with alias resolution [10]. Indeed, alias resolution follows the goal of aggregating several IP addresses (appearing in various traces) of a router into a single identifier. Similarly, subnet detection aims at identifying multiple links (appearing to be separate) and at combining them to represent their single hop connection medium (point-to-point or multi-access) [7]. Considering subnet maps instead of classical IP interfaces, routers, or ASes level maps is a way to deepen our understanding of the Internet topology, in particular topological features of ISP networks.

Previously, techniques have been proposed to obtain information on subnets. One can cite for instance IGMP prob-ing [11] that can be used to detect subnets [12]. But due to filtering done by operators, it becomes less and less usable in practice [13], making this inference technique outdated. The most promising approach proposed recently relies on `TraceNET` [5]. This tool works as `traceroute` [14] in the sense that it detects subnets on a given path between a source and a destination. Building on this tool, the same authors developed `ExploreNET` [8] in order to improve `TraceNET` by discovering individual subnets rather than subnets on an end-to-end path. `ExploreNET` also presents techniques for sampling subnets in a targeted domain and inferring their global characteristics (such as mean subnet degree, subnet prefix length distribution, etc.) [6]. However, `ExploreNET` does not provide any guarantee on the soundness of the inferred subnets or any metric to evaluate them. Furthermore, it tends to fragment large subnets into several smaller (and incomplete) ones.

In this paper, we introduce `TreeNET`, a new tool dedicated to the collection and manipulation of subnet topology information.[1] This tool overcomes the issues mentioned above by introducing a refinement phase and a classification of the inferred subnets for qualitative evaluation purposes. Moreover, `TreeNET` also introduces a tree-like structure able to show how subnets are located with respect to each other with the help of Paris `traceroute` [15]. Using specific interfaces found in subnets and the way they are located in the network, our tool is also able to achieve router inference through alias resolution techniques, eventually leading to a complete router – subnet representation of the targeted network.

In order to assess the performance of `TreeNET`, we thoroughly study a private academic ground truth network and several ASes. All networks are analyzed with both `TreeNET` and `ExploreNET` for the sake of comparison and we demonstrate that `TreeNET` provides more accurate results than the state of the art. In addition to this comparative study, we also assess our alias resolution method on a publicly available dataset [16].

The remainder of this paper is organized as follows: Sec. II describes in details `TreeNET`, our tool for discovering sub-network topology of a targeted domain; Sec. III evaluates the performance of `TreeNET` and compares it to the state of the art tool (i.e., `ExploreNET`); finally, Sec. IV concludes this paper by summarizing its main achievements and discussing potential future research directions.

II. TREENET

This section introduces `TreeNET`, our new tool for revealing subnets. We first provide a broad overview of how `TreeNET` works (Sec. II-A), before introducing the vocabulary associated to the tool (Sec. II-B). We also detail in the remaining sections the four different steps of `TreeNET`, namely the network pre-scanning (Sec. II-C), the subnet inference (Sec. II-D), the tree construction (Sec. II-E), and the router inference (Sec. II-F).

A. Overview

`TreeNET` is a topology discovery tool that infers the subnets of a targeted network and relies on them to infer the whole topology (at the router and subnet level), or more precisely the whole visible topology (i.e., containing all the interfaces that are responsive to probes). To do so, it follows four steps that we briefly describe in the next paragraphs.

First of all, `TreeNET` performs a *network pre-scanning* which consists in listing every potential IP interface of the targeted domain, using its IPv4 prefix as input. All listed interfaces are then probed in order to only consider responsive interfaces during the subsequent steps for the sake of efficiency.

Then, `TreeNET` moves to the *subnet inference* step which aims at identifying the subnets inside the targeted domain. These subnets typically encompass all the IP interfaces which were responsive during pre-scanning. To do so, `TreeNET` relies on the inference mechanisms provided by `ExploreNET` in order to list all potential subnets. In addition, `TreeNET` performs refinements over the measured subnets in order to ensure their soundness when they seem incomplete or partial. Both approaches require additional probing, hence the need for filtering only responsive IP interfaces in the first step. The subnet inference step ends when all responsive IP addresses from the previous step have been considered.

Next, during the *tree construction* step, `TreeNET` builds a tree depicting the way subnets are located with respect to each other. This tree is built using Paris `traceroute` [15] towards every inferred subnet, as a set of `traceroute` paths from a same vantage point typically forms a directed acyclic graph (at worst) or a tree (at best). The tree is rooted at the `traceroute` vantage point and the leaves are the inferred subnets themselves.

Finally, the *router inference* step relies on the location details obtained thanks to the tree structure to apply alias resolution techniques [10], eventually leading to the discovery of routers providing access to the measured subnets.

At the end, the tree with inferred routers describes the full router – subnet topology discovered by `TreeNET` when targeting the initial domain. The code of `TreeNET` is freely available at `https://github.com/JefGrailet/treenet`.

B. Terminology

From the perspective of a single vantage point, a subnet can be seen as a set of N responsive interfaces (all being part of a continuous block of M hypothetical interfaces) made of three important components, all of them being depicted in Fig. 1. First, the *Ingress router* refers to the last router crossed by a packet before reaching the subnet of interest. Second, the *Contra-Pivot interface* is the IP interface belonging to the subnet that is located on the Ingress router (black circles on Fig. 1). Finally, the *Pivot* interface refers to any other IP interface in the subnet, all located at the same hop count (gray squares on Fig. 1).

By definition, the Contra-Pivot interface is located at the hop count required to reach a Pivot interface minus one. As such, the Contra-Pivot interface demarcates the subnet under exploration. Finally, in order to ease the subnets location, we introduce the notion of *Neighborhood* as a location bordered by a set of subnets located at, at most, one hop from each other. From a physical point of view, subnets bordering a same neighborhood should be connected through one router or a mesh of Layer-2/Layer-3 devices.

C. Network Pre-scanning

The very first step of `TreeNET` consists in listing all IP addresses of the targeted domain, either provided as single addresses, either as IPv4 prefixes. After a shuffling step, which prevents `TreeNET` from probing consecutive addresses during the next steps (to mitigate network delays), each listed address is probed to check its liveness. Multi-threading is used to make this step as fast as possible.

Due to networking issues, some addresses might not reply during this first probing phase. This is why `TreeNET` conducts a second pre-scanning phase during which the timeout delay used in the first phase is doubled to get as many responsive addresses as possible. An optional third pre-scanning phase can also be conducted.

When a probed address replies within the expected delay, it is saved in a structure we will refer to as the *IP dictionary*. It stores all responsive IP interfaces and related data, such as the timeout delay which was used when it first replied. All next

probes targeting this interface will use this timeout delay to guarantee new responses.

As unresponsive IP interfaces do not appear in the dictionary, they will not be probed again during the next `TreeNET` steps, such as subnet inference, where all potential IP interfaces of a subnet under exploration are considered, one at a time. Therefore, by listing only responsive IPs with a preliminary multi-threaded step, `TreeNET` buys time for subsequent algorithmic steps.

D. Subnet Inference and Refinement

After the end of the pre-scanning phase, `TreeNET` infers all subnets containing the IP addresses in the IP dictionary by relying on the subnet inference techniques implemented in `ExploreNET`. The algorithm starts by probing a given target address (with ICMP ECHO requests, naked or wrapped in UDP or TCP) and estimating its distance from the vantage point as a TTL value. Then, it builds a small subnet (/31 or /30) which encompasses it, sending additional probes on close IP addresses (e.g., which differs by one bit in the two last bits) with the same TTL as the one required to reach the initial target. This first step also considers adjustments of the TTL value used while probing IP addresses other than the target in case the initial target address was a Contra-Pivot interface.

The next step consists in growing the initial subnet by iteratively decrementing its prefix length while checking that the new addresses are indeed part of it. This verification step involves additional probing during which the TTL of the probe packets varies to confirm the position of the targeted IP addresses. `ExploreNET` eventually stops growing a subnet in two distinct scenarios. In the first scenario, `ExploreNET` discovers that a new address is not part of the subnet (e.g., second Contra-Pivot interface, interface located at the Pivot TTL plus one, etc.). In such a case, it increments the subnet prefix length by one and returns it together with the list of its responsive interfaces. The second scenario happens when, at a given iteration, the total amount of responsive interfaces within the new subnet is below a threshold value that depends on the current prefix length. Then, `ExploreNET` stops iterating and returns the subnet with its prefix length incremented by one and the list of its responsive interfaces. Upon receiving the final subnet as inferred by `ExploreNET`, `TreeNET` also merges the result with previously inferred subnet(s) which cover(s) the same address ranges to ensure the uniqueness of each subnet at the end of the inference.

It is important to understand that, when a large subnet lacks of responsive interfaces, `ExploreNET` tends to fragment it into several smaller subnets containing groups of responsive interfaces with only one of them containing a valid Contra-Pivot interface, meaning that only this subnet can be considered as sound. To overcome this issue, `TreeNET` introduces a refinement phase which aims at ensuring any inferred subnet features a valid Contra-Pivot interface. The idea of the refinement phase is the following: `TreeNET` takes subnets that miss a Contra-Pivot and adjusts their sizes in order to find it. This consists in iteratively decrementing the prefix

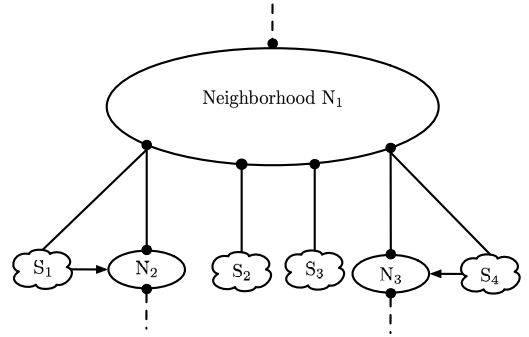

Fig. 2. Topology from Fig. 1 seen as a tree – horizontal arrows highlights the subnets acting as links between two routers.

length of the incomplete subnet and probing the new addresses with the TTL that matches the hypothetical hop count of the Contra-Pivot interface. This refinement by *expansion* stops as soon as one or several Contra-Pivot candidates are found, or when the subnet starts overlapping other measured sound subnets whose TTL to reach Pivot interfaces is different from the one to reach a Pivot in the subnet being expanded. It also stops when the subnet becomes larger than a /20, as no /19 were observed with neither `ExploreNET` neither `TreeNET`. The fact that a subnet can have several Contra-Pivot candidates can be due to networking issues (e.g., redirections) or network policies, such as routers having a back-up interface for a subnet in case the first one failed. The absence of visible Contra-Pivot interface is most probably due to networking issues. In a sense, `TreeNET` applies a *best effort* policy while refining subnets.

The fact that a subnet can feature a single, several, or no Contra-Pivot motivates the introduction of a classification which can be used to assess the accuracy and soundness of the measurements. It is worth noticing here that IP addresses can respond with TTL that does not match the expected Pivot TTL or Contra-Pivot TTL. We will refer to such addresses as *outliers* and our classification takes into account such cases. Each subnet is therefore labeled as *Accurate* (i.e., it features a single Contra-Pivot interface and no outlier), *Odd* (i.e., it features two or more Contra-Pivot interfaces and/or some outliers), or *Shadow* (i.e., no valid Contra-Pivot interface could be found, with or without outliers).

Furthermore, when a subnet is classified as *Accurate*, each missing IP address that was responsive during pre-scanning is added to this subnet in order to have a list of live interfaces as complete as possible for each subnet. Finally, *Shadow* subnets are expanded until they collide with sound (i.e., *Accurate* or *Odd*) subnets at the very end of the subnet inference. The purpose of this last refinement is to obtain an upper bound on their size.

E. Tree Construction

Once the targeted domain has been completely analyzed, `TreeNET` performs Paris `traceroute` measurements towards each inferred subnet, using a Pivot interface as destination.

Having routes to every subnet provides knowledge on how they are located with respect to each other. Taking benefit of such an additional information, `TreeNET` builds a tree rooted at the vantage point and whose leaves are the measured subnets. Each internal node of depth N is labeled with an interface that appears at the Nth position in one or several traces. The immediate result of this construction is that internal nodes actually represent Neighborhoods. Moreover, the labels of internal nodes can be used to identify the subnets that act as a link between two routers: one has simply to check that a label belongs to a subnet occurring at the same depth. To illustrate this construction, Fig. 2 shows the same topology as shown in Fig. 1 but as a tree, with the horizontal arrows highlighting the subnets acting as links between two routers.

In order to be faithful to the measured topology, the tree should reduce the impact of routing issues caused by traffic engineering (e.g., load balancing [17]). For example, several subnets sharing the same Ingress router should have routes of the same length with the same last replying interfaces, but differences can still occur on the rest of the routes. As a consequence, the tree could feature several branches for these subnets and partial representation of their Neighborhood, rather than having a single branch at the end of which one can obtain a complete representation of the Neighborhood bordering those subnets. To avoid this situation, `TreeNET` allows internal nodes to have more than one label in such a way that the Neighborhood information in deeper nodes is not lost. As a result, internal nodes with multiple labels constitute no longer a single Neighborhood but rather a superposition of several Neighborhoods. For the sake of simplicity, we will refer to these nodes as *multi-label nodes*. Post-processing of the fully built tree can however isolate Neighborhoods of a multi-label node from each other.

The process of the tree construction is fully described in Algorithm 1. Starting with an empty tree, the algorithm inserts sequentially new subnets in two steps. The first one consists in finding the *insertion point* defined as the deepest internal node that shares a common label (line 11). In `TreeNET`, this step is efficiently implemented using additional data structures to avoid visiting the whole tree. Once the insertion point has been found, all missing internal nodes (if any) and the leaf corresponding to the subnet are inserted (lines 3 – 10). The second step consists in moving from the insertion point to the root of the tree while inserting new labels whenever the route differs from current information stored in the tree (lines 12 – 23). In particular, for each node, if the label from the route of the new subnet already appears in another internal node of the tree at the same depth, it is merged with the current node (lines 19 – 21). The final result is a tree in which every label should appear only once.

Fig. 3 illustrates the tree construction on a toy example. Given the topology shown in Fig. 3(a), possible Paris `traceroute` to subnets S_1, S_2, and S_3 could be $\{1, 2, 4\}$, $\{1, 3, 5\}$, and $\{1, 3, 4, 6\}$ respectively. The insertion of S_1 and S_2 is then rather simple, as Fig. 3(b) shows. Fig. 3(c) and 3(d) illustrates how the insertion of S_3 occurs. The insertion point

22:        $P \leftarrow P$.getParent()
23:    **return**

---

is obviously the node having the label 4. As the parent node does not have the label 3, such a label is added; however, label 3 already appears in the tree, therefore the branch is merged with the node containing both labels 2 and 3. In the final tree, all non-null (i.e., not 0.0.0.0) labels appear only once.

As implied in the previous paragraph, the routes obtained with Paris `traceroute` are not always complete, i.e., they feature 0.0.0.0 interface(s) along the way. As `TreeNET` does not consider these labels while looking for the insertion point, this leads to one branch per distinct interface following a 0.0.0.0 interface. While this does not affect deeper internal nodes, this can lead to splitting a large internal node into several ones. Specially when the interface is labeled as 0.0.0.0 due to a delay or a black-listing of the vantage point by that interface, preventing it from replying to any subsequent probe. This typically occurs with the first hops to a remote network (which are often common to all routes): some routes will feature the proper interface(s) while others will not.

To mitigate this issue, `TreeNET` always starts building the tree using only subnets that feature a complete route (i.e., with no occurrence of 0.0.0.0). Then, before inserting any subnet with an incomplete route, `TreeNET` finds the most similar route already stored in the tree and replaces 0.0.0.0 interface(s) of the incomplete route with the interface(s) at the same index(es) in the selected route.

F. Router Inference

A fully built tree provides a good knowledge of the topology, as it gives an idea of how many interfaces border
Fig. 3. Example of the tree constructed by Algorithm 1 on a toy example.

(a) Example topology   (b) Insertion of S_1, S_2 (c) Insertion of S_3 (d) Insertion of S_3 (2)

an internal node, which is either a Neighborhood, either a superposition of Neighborhoods. Given $\#L$ the amount of labels of a node, $\#S$ the amount of children subnets, $\#I$ the total amount of labels from child internal nodes, and $\#C$ the amount of *crossed* subnets (i.e., subnets which contain the label of a child internal node), the amount N of interfaces an internal node is given by

$$N = \#L + \#I + \#S - \#C. \tag{1}$$

The amount of labels $\#L$ can be assimilated to the number of interfaces through which packets enter the Neighborhood(s), while $\#I + \#S - \#C$ refers to the number of outgoing interfaces.

Not only the tree provides an idea of the number of interfaces of each internal node, but it also gives some of these interfaces. The labels themselves are interfaces, but moreover, subnets classified as *Accurate* during subnet inference feature a valid Contra-Pivot interface which, by definition, is the interface of a router. *Odd* subnets also feature at least one valid Contra-Pivot. Therefore, for each internal node, one can list all labels and each Contra-Pivot of each child *Accurate* or *Odd* subnet. Then, one can use an alias resolution technique on them to infer one or several routers. After that, internal nodes do not need to be abstracted as Neighborhoods (or superimpositions) any longer, and one can build a full router – subnet topology of the measured network. The alias resolution also helps to disambiguate multi-label nodes, as interfaces of routers belonging to distinct (superposed) Neighborhoods should never be associated together.

In `TreeNET`, the router inference consists in a combination of three different alias resolution techniques: Ally [18], IP-ID counter velocity check (which is reminiscent of Radar-Gun [19]), and reverse DNS association.

For every interface of an internal node/Neighborhood, `TreeNET` collects `i` IP-IDs (`i` is at least three) and evaluates the wall clock time (in microseconds) between the acquisition of each ID, leading to `i - 1` delays. While the wall clock time might not be necessarily faithful to the delay between the generation of two IP-IDs on a remote device, it is a

Fig. 4. Schematic view of the data used for the velocity range technique.

reasonable and exploitable estimation. In addition to the IP-IDs and delays, the reverse DNS for each IP address is also retrieved when available.

Once all the aforementioned data has been collected for every interface, the association process starts. When IP-IDs and associated delays are available, `TreeNET` first considers association by Ally. The idea of Ally is very simple: one probes a first interface, retrieves an IP-ID `x`, then obtains another IP-ID `y` from a second interface, and a third ID `z` from the first one. If the inequality `x < y < z` with `z - x` being reasonably small is verified, one can assume both probed interfaces actually belong to the same router. Therefore, in the context of `TreeNET`, one just has to find a triplet of IP-IDs from two distinct interfaces which form a succession to use Ally. To locate IP-IDs chronologically, each collected ID has an associated *token*, an integer unique to each probe that is given by a counter incremented each time a token is drawn.

However, the IP-ID counters can evolve quite fast, therefore mitigating the efficiency of Ally in many cases. To overcome this issue, the second technique implemented in `TreeNET` rather estimates the velocity of each counter for each interface (the three IP-ID mentioned above) and associates interfaces together when their velocity is similar, which is the same idea as RadarGun [19]. This is why delays between getting each IP-ID are being collected.

However, the velocity of a counter is not constant and fluctuates, and to model this, `TreeNET` does not compute a single velocity per interface but rather a range of velocities, with a velocity being computed for every pair of consecutive IP-IDs. Moreover, as IP-ID counters are encoded on 16 bits, they can rollover on a regular basis, and it is not unlikely to have two or more rollovers for interfaces belonging to routers dealing with large traffic. For every pair of consecutive IP-IDs (denoted as i and $i+1$ and the delay between those IP-IDs is

denoted d_i), we consider a variable x_i to model the amount of rollovers. In Fig. 4, we illustrate the data involved in our alias resolution technique based on IP-ID counter velocity and the variables for each pair of consecutive IP-IDs.

To be able to compute coherent velocities, one must find a value for every x_i such that the velocities are reasonably close to each other. Our approach consists in assigning a value from 0 to a maximum (e.g., 50) to x_0 and, for each value, resolving $i - 2$ equations to find every x_i with i being greater than 0. The equation is the following

$$\frac{i_1 - i_0 + 65535 \times x_0}{d_0} = \frac{i_{i+1} - i_i + 65535 \times x_i}{d_i}. \quad (2)$$

As it is possible to have the inequality $i_{i+1} < i_i$ due to a rollover between the first IP-ID of the pair and the second one, we replace $-i_i$ by $+(65535 - i_i)$ when this occurs to accurately express the amount of times the counter was incremented.

Since it is extremely rare to find an integer, non-zero solution for every x_i, we rather solve such equations in the real domain and round the results afterwards. If all solutions are positive and if the rounding error (i.e., the difference between the rounded result and the real value) is below a threshold (e.g., 0.35), the rounded solutions are kept, otherwise the next value for x_0 is being considered until the maximum. If the maximum value is reached without finding a solution, we consider the counter to have an *infinite* velocity, represented by the range [0, 65535].

If an integer value is found for every x_i, the velocities are obtained with the following formula:

$$v_i = \frac{i_{i+1} - i_i + 65535 \times x_i}{d_i}. \quad (3)$$

Of course, if i_i is greater than i_{i+1}, the term $-i_i$ is again replaced with $+(65535 - i_i)$.

The final step consists in retrieving the maximum and minimum velocity obtained for the IP addresses. Afterwards, interfaces are associated if their respective ranges of velocity overlap. As we observed several ranges being very close to each other without overlapping, we added a tolerance value (e.g., 0.3) which slightly extends the largest range such that it overlaps close ranges. Finally, it is worth noting we always associate together interfaces for which the velocity is computed as *infinite* (i.e., [0, 65535]).

If neither Ally nor the velocity range technique can be used, reverse DNS association is considered. It is worth noting that if IP-IDs are available and if the two previous techniques rejected the association, reverse DNS is not considered. In other words, reverse DNS is the last resort technique. The technique itself is very simple: splitting the DNS of two IP interfaces at dots, they will be associated if and only if they have the same amount of components and if only the first ones differ between both IP addresses. We did not elaborate our reverse DNS technique further because of the need for additional inputs, such as the naming conventions found in a particular network.

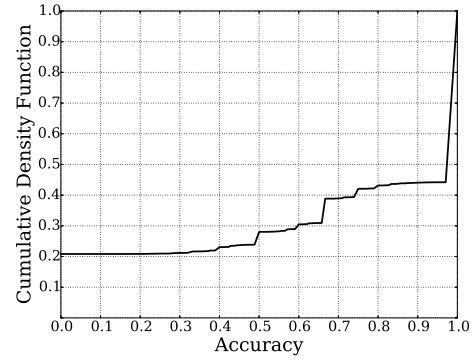

Fig. 5. Preliminary performance results for our alias resolution scheme.

III. EVALUATION

In this section, we evaluate the performance of `TreeNET`. We first provide preliminary results for our three alias resolution scheme (Sec. III-A) and, next, we compare subnet inference of `TreeNET` with `ExploreNET` (Sec. III-B) on a ground truth and several ASes. We also mention some preliminary results which could guide future study of the measured ASes (Sec. III-C). Subnets and aliases collected during our measurement campaign are freely available: `https://github.com/JefGrailet/treenet/tree/master/v2/Measurements`

A. Alias Resolution

To assess our alias resolution scheme described in Sec. II-F, we relied on a dataset provided by iPlane [16]. It is made of a list of 57,806 routers with their aliases as observed in iPlane `traceroute`. Aliases are determined by using standard IP-ID technique and identical return TTLs when probed at the same time. It should be noted that this dataset is updated every two months and that our GitHub repository provides the dataset which was available at the time of our measurements.

For each alias (given as a list of interfaces), we run our resolution technique and define an *accuracy rate*, i.e., the size (i.e., amount of interfaces) of the largest alias inferred by `TreeNET` for this list divided by the number of responding interfaces from that list. As a consequence, a value of 1 means that we obtain the same results as iPlane with respect to responsive interfaces. On the contrary, a value of 0 means that we are not able to identify the listed interfaces as aliases at all. Measurements were done on November 19th, 2015, collecting four IP-IDs for each responsive interface.

On the set of 57,806 routers, 26% of them were not responding to our probes. No accuracy rate has been computed on those routers. The accuracy rate for the remaining 74% of the routers is given, as a cumulative distribution function, on Fig. 5. The most important result here is that, in 55% of the cases, our alias resolution provides the same results as the iPlane dataset. The second main result is that, for a bit more than 70% of the dataset, we have an accuracy rate of at least 50%. Those results are promising and we leave as a future work a better characterization of our alias resolution technique and potential improvements of it. In particular, we

plan to elaborate on the amount of collected IP-IDs and the effects of other parameters of our velocity-based technique we previously mentioned.

B. Subnet Inference

In order to evaluate the subnet inference proposed by `TreeNET` with respect to `ExploreNET`, we implemented a slightly edited version of `ExploreNET` using the same input/output schemes as `TreeNET` and targeted different ASes as well as a ground truth network (an academic network for which we have access to the actual topology – access to that network topology is, obviously, not allowed outside the campus) with both of them.

We decided to conduct measurements on three ASes: AS224, AS5400 and AS30781. The first two are comparable regarding the amount of hypothetical IP addresses (a bit more than one million in both cases) but have a different role in the Internet topology: AS224 is a stub AS (i.e., all traffic coming in and out of it goes through a single path) while AS5400 is a transit AS (i.e., it acts as a link between other ASes). AS30781, on the other hand, is another transit AS but of a much smaller scale (with a maximum of 45,824 hypothetical IP addresses), which is interesting for a comparison with AS5400. The datasets we obtained from them are available on `https://github.com/JefGrailet/ treenet/tree/master/v2/Measurements`.

In the case of the ground truth, we were able to check the results with a network administrator, and discovered that 86.3% of our measured subnets were correct in terms of prefix with respect to the actual topology, the problematic results being caused by very specific cases. These difficult cases notably included loop-back interfaces from distinct subnets (sometimes /32 subnets) whose TTL were similar and for which the IPv4 addresses were consecutives, and were therefore considered to be on the same subnet. The inferred routers were also confirmed by the actual network, therefore demonstrating the relevancy of the tree structure and proving again the accuracy of our alias resolution scheme.

To assess the soundness of subnets measured by `TreeNET`, we introduce the notion of *credibility* of a subnet. A subnet is considered as *credible* if less than 10% of its listed interfaces are Contra-Pivot candidates and more than 70% of them are Pivot interfaces, as we consider a subnet cannot be sound if more than 20% of its interfaces are outliers. These numbers are however arbitrary and could be adapted for specific networks where the amount of outliers is assumed to be high. The purpose of this metric is to evaluate if an *Odd* subnet is a good measurement, an *Accurate* subnet being *de facto* credible while *Shadow* subnets are never considered as credible.

Finally, we also use two additional metrics on datasets obtained through `ExploreNET`: *redundancy* and *encompassed* ratios. The redundancy ratio denotes how many subnets in the datasets are equivalent with previously listed subnets, since `ExploreNET` does not merge similar subnets like `TreeNET` does. The encompassed ratio, on the other hand, quantifies how many subnets inferred by `ExploreNET` are strictly smaller than overlapping subnets obtained by `TreeNET`, in order to check if the latter handles large subnets better than the former.

Our results are presented in Table I. One can immediately notice a striking improvement due to `TreeNET`. It is indeed remarkable how `TreeNET` is able to infer a smaller amount of subnets than `ExploreNET` while covering much more addresses and having a high proportion of *Accurate* subnets. The ratios of incomplete, redundant, and encompassed subnets for each network further demonstrate that the refinements operated by `TreeNET` over the results of `ExploreNET` drastically improves the inferred subnets regarding both credibility (in the broad sense) and coverage of the measured networks.

Furthermore, the introduction of *Odd* subnets in `TreeNET` overcomes a limitation of `ExploreNET`: indeed, the latter assumes that a subnet necessarily owns a single Contra-Pivot interface. Therefore, `ExploreNET` can stop the inference when it discovers two potential Contra-Pivot interfaces at once. Unfortunately, this prevents it from properly inferring a large subnet when there is, for example, a back-up Contra-Pivot interface. It also tends to ignore outliers (e.g., an IP interface located at the Pivot TTL + 1, which can occur due to specific network policies), that could appear in measurements conducted by `TreeNET` due to subnet merging. Thus, not only the refinements help to find sounder subnets, but they also relax the definition of a subnet to some extent and allows the discovery of more exotic network configurations.

C. Preliminary results

Even if the focus of this paper is the description and evaluation of `TreeNET`, we can already provide directions for future analysis of the networks measured with it. In particular, the datasets we collected can be analyzed to compute the distribution of the subnet prefix lengths in each AS and our ground truth. A first look at Fig. 6 already highlights an interesting property: the proportion for each prefix length varies from one network to another, and while /31 and /30 subnets are inevitably the most common ones (as already observed with `ExploreNET` [8]), other prefix lengths are not used in the same manner by each network.

For example, /24 subnets are particularly common in our dataset from AS224, which is a stub AS. An interesting perspective for future research would be to compare the results obtained by `TreeNET` on several stub ASes to determine if the proportion of /24 subnets is a common feature of stub ASes or an AS224 specificity.

However, an in-depth analysis of the data would require more metrics and modeling formalisms suited for router – subnet topologies, which are left for future work.

IV. CONCLUSION

In this paper, we introduced `TreeNET`, a new tool collecting and manipulating subnet topology information to discover the router – subnet topology of a target network. Using as a basis `ExploreNET`, a state of the art subnet inference tool, `TreeNET` adds subnet refinement mechanisms along with a tree-like structure which not only gives an overview of the

	AS224		AS30781		AS5400		Ground truth	
	TreeNET	ExploreNET	TreeNET	ExploreNET	TreeNET	ExploreNET	TreeNET	ExploreNET
# hypothetical IPs	1,115,392		45,824		1,385,472		5,888	
# inferred subnets	3,053	68,635	1,195	6,606	1,769	7,398	124	1,024
# covered IPs	446,750	200,021	21,408	8,228	104,468	11,055	3,956	1,818
Accurate subnets	69.9%	36.7%	76.1%	45.6%	74.0%	39.8%	75.8%	45.3%
Odd subnets	23.8%	/	20.0%	/	12.3%	/	17.7%	/
Shadow subnets	6.3%	/	3.9%	/	13.7%	/	6.5%	/
Credible subnets	88.2%	36.7%	88.0%	45.6%	79.8%	39.8%	84.7%	45.3%
Incomplete subnets	/	63.3%	/	54.4%	/	60.2%	/	54.7%
Redundant subnets	/	56.3%	/	57.7%	/	42.8%	/	49.9%
Encompassed subnets	/	72.5%	/	66.3%	/	63.0%	/	54.3%

network but also eases router discovery via alias resolution techniques.

We were able to demonstrate the benefits of `TreeNET` regarding subnet inference through a comparative study with `ExploreNET` on a ground truth network and several ASes. We also obtained promising results for the alias resolution scheme currently implemented in `TreeNET`, both on our private ground truth and a publicly available dataset provided by iPlane. The datasets we obtained from the mentioned ASes and the aliases list provided by iPlane we used are publicly available on `https://github.com/JefGrailet/treenet` along with the sources of `TreeNET`.

Future works involve in-depth evaluation of `TreeNET` (in particular the efficiency of the pre-scanning phase and the alias resolution scheme compared to RadarGun), large-scale measurement campaigns and in-depth study of our datasets through modeling formalisms suited for router – subnet topologies. We are also planning to use `TreeNET` to elaborate Layer-2 devices inference techniques in the long term.
