NOTICE OF PROJECT CLOSEOUT

	Closeout Notice Original Closeou	Date it Sta	01/19/90 rted ******
Project No. E-16-679	Center No.	R6651	-0A0
Project Director STRAHLE W C	School/Lab	AE	
Sponsor NATL SCIENCE FOUNDATION/GENERAL			<u> </u>
Contract/Grant No. CBT-8901292	Contract E	ntity	GTRC
Prime Contract No.			
Title PROOF OF CONCEPT IN PRESSURE CORRELAT	ION MEASUREMENT IN	TURBU	LENT FLOWS
Effective Completion Date 891231 (Performan	ce) 900331 (Report:	s)	
Closeout Actions Required:		Y/N	Date Submitted
Final Invoice or Copy of Final Invoice Final Report of Inventions and/or Subco Government Property Inventory & Related Classified Material Certificate Release and Assignment Other	ntracts Certificate	N Y N N N	
Subproject Under Main Project No			
Continues Project No			
Distribution Required:			
Project Director Administrative Network Representative GTRI Accounting/Grants and Contracts Procurement/Supply Services Research Property Managment Research Security Services Reports Coordinator (OCA) GTRC Project File OCA/CSD	Y Y Y Y Y Y Y N		i.

NOTE: Final Questionnaire sent to PDPI.

INTRODUCTION

5

Under a prior NSF program (CBT-8414906) measurements were attempted of two troublesome turbulence correlations by a combined use of Rayleigh scattering, laser velocimetry (LV) and dynamic Pitot tube baraometry. These correlations are the pressure-strain and pressure-scalar gradient correlations. They enter in a description of turbulent stress transport and scalar transport when calculating turbulence fields at the level of second While the PI was able to show some time ago that order closure. pressure-velocity and pressure-scalar correlations could be measured directly by such techniques, the rate of strain field and scalar gradient field require the measurement of a spatial derivative. It was found that the accuracy of measurement in the gradient was simply not great enough to extract the desired information.

The pressure fluctuation, however, exactly obeys a Poisson equation which may be solved in terms of the density and velocity fluctuations and the mean flow field quantities. In principle, therefore, only velocity and density measurements are required to determine the pressure and its correlation against any quantity of interest. The fundamental problem, however, is that the solution comes out as an integral of a Green's function times space-separated correlations of density against itself, density against velocity and velocity against itself; the integral is over all of space. The questions of a) time required to conduct the necessary measurements, b) convergence of the integral in light of the fact that it contains a singularity, and c) accuracy of the result needed to be addressed in order to proceed with an ambitious program. Another issue concerned usual commercial laser equipment. These laser velocimeters always want the probe volumes of two independent velocity components to intersect. Consequently, a device had to be invented to space separate the beams and still retrieve the signals. The development of such a device was started on the prior program and completed on this program.

RESULTS

All objectives were achieved on the program. Appended to this report is a paper submitted to the 23rd Symposium (International) on Combustion which contains all the results of the program. The following results were achieved:

 A device to space-saparate and arbitrarily rotate any component of the LV was developed and demonstrated;

(2) Using a cold turbulent round jet, it was demonstrated that, in fact, only a few space-separated correlations of the velocity measurement were needed for acceptable accuracy;

(3) No convergence problems of the integral occured, and, in fact, the fact that it is a singular integral actually helped in extracting results;

(4) Unexpectedly, new, powerful models for the pressure-velocity correlation emerged;

(5) The role of the density fluctuation in forcing a pressure fluctuation became clarified.

The appended paper is intended as the final report. The results suggest that the pressure-strain and pressure-scalar gradient correlations in hot flow can now be attacked.

ABSTRACT

Examination is made of the correlation between pressure and velocity fluctuations in both cold and reacting turbulent flows. This correlation which accounts for pressure diffusion in turbulence transport equations, is shown to be extremely important physically and not well treated in the past. Experiments on confined and unconfined cold flows and unbounded premixed flames are examined and found to suggest new modeling approaches to this correlation. These suggestions are completely borne out by analytical examination of the Poisson equation for pressure which exactly describes the pressure fluctuation. Under certain restrictions on the flow type, new models are developed for the correlation of interest. These models are shown to compare favorably with experiment and a new experimental technique for nonintrusive pressure measurement is presented.

INTRODUCTION

In the analysis of turbulent flows at the level of two equation closure or stress transport modeling, there always appear correlations between pressure and velocity and their gradients which give modeling difficulty¹. The most primitive form of the correlation and its most often seen expansion into three terms is

$$\overline{v_{i}^{"}}_{j}\frac{\partial p}{\partial x_{j}} = \frac{\partial}{\partial x_{j}}\left(\overline{v_{j}^{"}}_{j}^{p}\right) + \overline{v_{i}^{"}}\frac{\partial p}{\partial x_{j}} - \overline{p'}\frac{\partial v_{i}^{"}}{\partial x_{j}}$$
(1)

The first term on the right side of Eq. (1), the gradient of the pressure velocity correlation, often suffers outright neglect in modeling; however, it has long been known in free shear flows^{2,3} and has been shown in recent years in premixed flames^{4,5}, that this term cannot be neglected. Moreover, in direct numerical simulation, albeit at relatively low Reynolds numbers, it has been shown that this term can play a dominant role in energy transport in reacting flows^{6,7}. The quantity $\overline{p'v_i^n}$, the pressure velocity correlation, is the item of interest in this paper. While the correlation has been known to be important there appear to be no reliable models for it in the literature, and its measurement has been difficult.

In variable density flows an exact Poisson equation for the pressure fluctuation may be developed from the continuity and momentum equations^{1,8}. It is

$$\frac{\partial^{2} p'}{\partial x_{j} \partial x_{j}} = \frac{\partial^{2} p'}{\partial t^{2}} - 2 \frac{\partial^{2} (\rho' \tilde{v}_{j} v''_{j})}{\partial x_{i} \partial x_{j}} v''_{j} - \frac{\partial^{2} (\rho' \tilde{v}_{j} \tilde{v}_{j})}{\partial x_{i} \partial x_{j}} \tilde{v}'_{j}$$
$$- \frac{\partial^{2} (\rho v''_{j} v''_{j} - \overline{\rho v''_{i} v''_{j}})}{\partial x_{i} \partial x_{j}} - 2 \frac{\partial^{2} (\rho \tilde{v}_{j} v''_{j})}{\partial x_{i} \partial x_{j}} v''_{i}$$
(2)

The only approximation in Eq. (2) is that viscous terms have been neglected for good cause; pressure is primarily influenced by the large energy containing eddies of a turbulent flow whereas viscous action occurs at small scales.

Equation (2) is formidable, and working with it has been avoided by modelers because of its complexity¹. However, recent experience by the authors in evaluation of past data and in the generation of new data suggests a return to use of Eq. (2), because in some flows it appears that only a few terms (in fact, one term) are important. The use of Eq. (2) to generate new models for the pressure velocity correlation is one purpose of this paper. The second purpose is to verify these models by examination of past and new experimental results. Along the way a new nonintrusive method of measuring the pressure velocity correlation.

ANALYSIS

Flows far away from boundaries will be considered such that a solution to Eq.(2) may be written in terms of the free space Green's function

$$G(x_i, y_i) = 1/(4\pi R), \qquad R = [(x_i - y_i)(x_i - y_i)]^{1/2}$$

with the summation convention employed. The solution for p' is then multiplied by v_i'' and averaged to yield the pressure velocity correlation

$$\overline{p'v_{j}''} = \int dV(y_{j}) G(x_{j}, y_{j}) \left[F_{p}(y_{j}) + F_{v}(y_{j}) \right] v_{j}''(x_{j})$$
(3)

with F_{ρ} being the first three terms on the right of Eq. (2) and F_{V} being the last two terms. This generally separates the correlation into parts involving the density fluctuation and velocity correlations, although, for completeness, the fourth term should also be split because ρ stands alone and is equal to $\bar{\rho}$ + ρ^{1} .

$$\overline{p^{12}}(x_{i}) = \left[\int dV(y_{i}) G(x_{i}, y_{i}) [F_{p}(y_{i}) + F_{v}(y_{i})] \right]^{2}$$
(4)

With the x_i values specified, y_i are the variables over which the integration is being taken, so space separated two point correlations of density-velocity, velocity and density are required to evaluate Eqs. (3) and (4). Double and triple correlations are required.

In general, for a variable density flow, Eqs. (3) and (4) are very complicated. However, because they will apply to the experimental flows to follow, consider a flow with the following restrictions:

- a. The correlation terms involving density fluctuations against the velocity are small compared with terms involving only velocity correlations.
- b. The turbulence intensity is sufficiently small (say 10%) so that triple correlations of velocity are small compared with the product of a mean velocity and a double velocity correlation.
 - c. The flow has a dominant single flow direction (say, a jet). This direction is direction 1.

In such a case, Eq. (3) reduces to a single term, where the position point x_i will be taken as the origin without loss of generality. After noting a fortuitous property of Favre averaging that $\overline{p'v_i'} = \overline{p'v_i'}$ and $\overline{v_i''v_i'} = \overline{v_i'v_i'}$, the result is

$$\overline{\mathbf{p'v_j^{i}}}(\mathbf{o}) = 2 \int d\mathbf{V}(\mathbf{y_j}) \ \mathbf{G}(\mathbf{o},\mathbf{y_j}) \ \frac{\partial}{\partial \mathbf{y_j}} \left[\overline{\mathbf{p}} \widetilde{\mathbf{v}_1} \ \frac{\partial}{\partial \mathbf{y_1}} (\overline{\mathbf{v_j^{i}}} (\mathbf{y_j}) \overline{\mathbf{v_j^{i}}}(\mathbf{o})) \right]$$
(5)

In the above, use has been made of the fact that continuity makes $\overline{\rho}v_{i}$ divergence-free. The mean square pressure equation will only so simplify if, in addition, the density fluctuation is small, in which case

$$\overline{p^{\prime 2}}(o) = \left[2 \int dV(y_i) G(o, y_i) \frac{\partial}{\partial y_j} \left[\overline{p} \widetilde{v}_1 \frac{\partial}{\partial y_1} v'_j(y_i) \right]^2$$
(6)

These expressions can be evaluated if the shape of the correlation curves are known. Notice immediately, however, that the expressions are dimensionally homogeneous with respect to length. The result can depend on shape but not on any turbulent length scale, <u>per</u> <u>se</u>. Now concentrate on the case where the velocity fluctuation is in the same direction as the primary flow velocity, $v_i'=v_1'=u'$. Make the following two restrictions in addition to those above:

d. Shear stresses are small compared with normal stresses either because one

is near an axis of symmetry or in a low shear region of the flow.

e. The mean density and velocity product varies only weakly over the

distance required for the integral to converge.

The integrand of Eq. (5) will now only have one important term involving the velocity correlation, it is

$$\frac{\partial}{\partial y_{m}} \bar{\rho} \tilde{v}_{1} \frac{\partial}{\partial y_{1}} \overline{v'_{m}(y_{i})u'(o)}$$

A crucial move is to apply the divergence theorem once and move the y_m derivative to the Green's function and pull the mean density-velocity product out from under the derivative. The mean density-velocity product may then be pulled out of the integral under restriction e above. Now make the assumption of an axially symmetric flow, measurement near the axis of symmetry, and a two-scale Gaussian correlation function

$$\overline{u'(y_1)u'(o)} = v^2(o) e^{-\alpha y_1^2} e^{-\beta(y_2^2 + y_3^2)}$$
(7)

experimentally realizable, as will be seen below. Using Eq. (7) in Eqs. (5), the result for the axial velocity-pressure correlation is

$$\overline{\mathbf{p}^{\prime}\mathbf{u}^{\prime}} = -2\overline{\rho}\widetilde{\mathbf{v}}_{1} \quad \upsilon^{2} \quad \mathsf{SK}_{1} \tag{8}$$

where the shape factor is, for $\beta/\alpha > 1$, which is the usual case

$$S = \frac{1}{1-\beta/\alpha} \left[1 + \frac{1/2}{\sqrt{\frac{1}{1-\alpha/\beta}}} \ln \frac{1-\sqrt{1-\alpha/\beta}}{1+\sqrt{1-\alpha/\beta}} \right]$$

This is remarkable in its simplicity. The constant K_u , supposedly around unity, is intended as a calibration constant to be obtained experimentally and to account for errors introduced if Eq. (7) is not obeyed precisely.

A remark is necessary concerning Eq. (8). While the left side is invariant to a Galilean transformation, the right side does not appear to be so, containing the mean velocity. In the flows to be considered, a Galilean transformation on the flow will require that the hardware also undergo the uniform translation that the fluid does. That is, for example, for a flame anchored on the end of a burner tube, the tube must be moved if the fluid is translated. Consequently, the mean velocity is a <u>relative</u> velocity measured with reference to hardware causing the flow.

Although the manipulations are somewhat different for the transverse velocity-pressure correlation, similar calculations yield

$$\overline{\mathbf{p}'\mathbf{v}'} = -\mathbf{K}_{\mathbf{v}}\overline{\mathbf{p}}\widetilde{\mathbf{v}}_{1} \ \overline{\mathbf{u}'\mathbf{v}'}$$
(9)

so that this correlation should track the shear stress. It was, in fact, this observation from experimental data^{2,3} that led the authors to pursue the above line of reasoning. Since the shear stress is not appreciable until one is substantially off the axis of symmetry, however, the assumptions made in deriving Eq. (9) are not as well satisfied as those made in deriving Eq. (8). Therefore, some greater error as compared with experiment can be expected.

Equation (6) is very cumbersome to carry out in the same detail as with the pressure velocity correlations. However, if $\alpha=\beta$, a tedious calculation yields for the mean square pressure in a constant density flow

$$\overline{p^{12}} = \frac{8}{3} \, \overline{\rho}^2 \, \overline{V}_1^2 \, \upsilon^2 \tag{10}$$

Since this manipulation started out as an equation for pressure, it is reasonable that the shape factor and the correction constant in Eq. (8) belong to the

pressure, and an <u>ad hoc</u> correction to Eq. (10) to account for $\alpha \neq \beta$ and possible inaccuracies in the approach is postulated as

$$\overline{p'^2} = (K_{u}S)^2 \quad \frac{8}{3} \ \overline{\rho}^2 \widetilde{V}_{1}^2 \ \upsilon^2$$
(11)

Under the constant density conditions necessary for <u>both</u> Eqs.(8) and (11) to be valid, a correlation coefficient may be calculated for the axial velocity-pressure correlation. Remarkably, and in accord with experiment below, it is a constant

$$r_{pu} = \frac{\overline{p'u'}}{(\overline{p'^{2}})^{\frac{1}{2}} \cup} = -.625$$

EXPERIMENTAL

Four experimental flows will be considered - two cold and two hot. They are:

#1. A fully developed turbulent pipe flow of air at nearly one atmosphere, the details of which are located in Refs. (9) and (10). Velocity and its fluctuation were measured by hot film anemometry and pressure and its fluctuation were measured by frequency-compensated dynamic Pitot barometry. Conditions for the above equations to be valid existed from the pipe centerline to the three-quarter radius point.

#2. A premixed propane-air turbulent flame stabilized on a 2.54 cm diameter burner tube. The configuration is as shown in Fig. 1 and the equivalence ratio was 0.8. This flow is documented in Refs. (5) and (11). Velocity was measured by laser velocimetry (LV) and temperature was measured by frequency-compensated thermocouple thermometry as calibrated against Rayleigh scattering measurements. Pressure was measured by dynamic Pitot barometry, but here also compensated for probe tip temperature effects. The adiabatic flame temperature was 2000K, the tube (cold) exit plane velocity was 6.18 m/s and the surroundings were open still air. This and the #1 flow provide the dominant information on the pressure

Fic, I

velocity correlation.

#3. The same burner as in flow #2, but with stoichiometric methane-air. The adiabatic flame temperature was 2250K and the exit plane velocity was 4.67 m/s. While velocity and pressure were measured as with flow #2, temperature (density) was measured by Rayleigh scattering. Reference (12) contains the details of measurement. This flow served primarily as a check flow on a conclusion below as to the weakness of the correlation between velocity and density, although some conclusions concerning pressure velocity correlation will be drawn from this flow.

0

Fig 2

#4. The same burner hardware as in flows #1 and #2, but operated in cold flow. The mirror apparatus shown in Fig. 2 was built in order to rotate and space-separate the two LV probe volumes to measure the necessary space-separated correlations in Eq. (2). One component of the 5w Argon-ion laser was unmolested and velocity was measured in the backscatter mode while the molested component used forward scattering. This technique was to verify that a nonintrusive velocity correlation measurement could be substituted for the usual intrusive Pitot pressure measurement. The measurements were carried out about a volume centered on the axis at z/D=4 where the mean axial velocity was 3.69 m/s and the mean square axial velocity fluctuation was .119 (m/s)².

Consider first flow #1, where in Ref. (10), with a more rudimentary theory, a formula similar to Eq. (8) was derived. For a pipe flow the ratio of longitudinal to transverse integral length scales is about 4, so that the ratio of β to α is about 16 leading to a shape factor of about .07. Excellent agreement of theory and experiment is achieved with both Eqs. (8) and (11) for K_u about 2. This agreement extends over three fourths of the tube radius, after which wall effects become important. In these experiments $\overline{p'v'}$ was not measured. The correlation coefficient for $\overline{p'u'}$ was a remarkable constant of -0.6 (see the theoretical value above). One reason for the excellent agreement between theory

and experiment for this flow is that it closely satisfies all restrictions in the development of the theory, and the axial velocity profile is quite flat over the transverse dimensions of agreement.

Fig. 3

311.4

Fig.5

Considering next hot flows #2 and #3, the profiles on the centerline for the mean axial velocity and mean density are shown in Fig. 3. For both flows most of the heat release on the centerline takes place for z/D between 2 and 4. Both flames have the unconfined flame characteristic that the mean velocity on the centerline is almost a constant, because there is no strong axial pressure gradient. The density is highly variable, however. Using a result to be obtained later on flow #4, the longitudinal to lateral length scale is roughly about 2, yielding a shape factor of about .17. With $K_u=2$ a comparison of $\overline{p'u'}$ computed from Eq. (8) is made with the experimental values in Fig. 4. The agreement is quite good, even through the flame zone.

The agreement is somewhat surprising and probably arises because of one peculiar fact for these two flames. For these <u>unconfined</u> flames the correlation between density and velocity is exceptionally $low^{5,11,12}$. While the density fluctuation itself may be of the order of 40% of the cold density, the correlation coefficient against velocity is only of the order of 0.1. This feature of the unconfined flame does not usually hold up in confined flames because there are strong mean velocity gradients. But here the correlation is so low that the theoretical assumptions made in throwing out the density fluctuation terms appear valid.

It is not true, however, that $\overline{p'}^2$ can be computed from Eq. (11) for these flames. The density fluctuation effect does not disappear for this quantity, as mentioned above. To illustrate this fact experimental and theoretical (computed from Eq. (11)) rms pressure fluctuation results are shown on Fig. 5. While the agreement is good upstream and downstream of the flame zone, there is a dramatic rise in p' in the flame zone. This can only occur because of the density

fluctuation effects. Also shown in Fig. 5 is the density fluctuation for both flames (notice the scale change for the hottest flame which has substantially higher fluctuation in density than does the colder flame). There is a substantial displacement of the peak in density fluctuation from the peak in pressure fluctuation which is somewhat unexpected. However, this may arise from some peculiarity in the theory, if it could be carried out including the density fluctuation effects. This will be left for future work.

In Fig. 6 is shown a theoretical-experimental comparison for the transverse velocity-pressure correlation. The theory uses Eq. (9) with $K_v=1$ and the experimental result is from flow #2. The agreement is quite good, but the comparison is made at z/D=6, which is quite far downstream from the flame zone. Although not shown, the p'v' correlation in the flame zone also tracks the shear stress, as demanded by Eq. (9), but K_v would have to be about 6. There must be some problem in the theoretical assumptions in the flame zone concerning the p'v' correlation, although at least the shape of the radial variation in this quantity appears to be correctly predicted.

A problem in usual turbulence modelling¹ is now clear. The diffusion of pressure energy is at least as large as the usual modelling of the diffusion of turbulence kinetic energy and should be so considered. While the current results are gained under certain restrictions on the flow type and cannot be considered completely general, the fact remains that typical $k-\varepsilon$ modelling has to be modified. This conclusion is also drawn in Refs. (6) and (7).

A final demonstration considers Flow #4, where a nonintrusive indirect measurement of the pressure velocity correlation is concerned. As demanded by Eq. (5), after simplification, what is required is a space separated two point correlation of the axial velocity fluctuation, if the p'u' correlation is required. Shown in Fig. 7 are the measurement points and general nomenclature

Alg. 7

4inle

for the measurements on the axis of Flow #4. The mean velocity, as seen in Fig. 3, has a very weak axial gradient, measurements are made on an axis of symmetry, the transverse velocity is very small, shear stresses are negligible, and, in general, all restrictions on the theory are met. Typical measurements of the radially separated axial velocity are shown in Fig. 8. A composite graph of axial and radial separations, as well as some points skewed to the radial and axial directions is shown in Fig. 9. The correlations are quite symmetric about the origin point, justifying the bi-directional Gaussian approximation to the correlation function used above. The primary contribution to the integral in Eq. (5) comes near the singularity (integrable) of the Green's function and the maximum in the correlation function. Consequently, a Gaussian is fitted to best match the experiments in this region. The result is that $\beta/\alpha = 4$, which is a value used above in determination of K_u. It should be cautioned, however, that this flow is cold.

11

71g.8

The results from Eq. (8), using the space separated measurements, and those from use of the Pitot probe with LV are as follows, with K_{μ} =2:

	Space separated	Pitot-LV			
p'u'	34 Pa m/s	35 Pa m/s			
r _{o'u'}	6 Pam/s	48 Pa m/s			

These results give a renewed confidence in the use of intrusive Pitot barometry. The space separated measurements are extremely time consuming, but act as a check on the intrusive measurements. For the general case in which density fluctuations play a strong role, velocity and density measurements and their correlation would be required by the indirect method, giving strong motivation to use of the intrusive method of measurement.

CONCLUSIONS

10

1. The pressure velocity correlation in both hot and cold turbulent flows is as strong as any other turbulence energy transport term in the physics of energy transport and cannot be neglected.

2. Contrary to popular opinion, the pressure velocity correlations are of the order of the <u>mean</u> velocity times either a normal or shear stress, depending on the direction of the velocity of interest.

An indirect, nonintrusive method of measurement of the pressure velocity 3. correlations has been developed as an adjunct method to check the results of Pitot barometry, LV and Rayleigh scattering. The method rests upon space separated measurements of velocity fluctuations, and, in the general case, space separated measurements of density fluctuations and density-velocity correlations. Under several restrictions on the flows, 4. simple models for the pressure-velocity correlation have been theoretically developed and experimentally verified. While the models are not completely general, they should be applicable to several simple flows, and, in particular, reacting turbulent flows.

NOMENCLATURE

LIST OF CAPTIONS

1.0

- Figure 1. Burner schematic for Flows #2 #4
- Figure 2. System of mirrors used to rotate and shift one of the two laser beams used for velocity measurements.
- Figure 3. Measurements of mean quantities in Flows #2 #4. Mean velocity for Flow #2. ★ Mean velocity for Flow #3. ★ Mean density for flow #2.
 □ Mean density for Flow #3. → Mean velocity near Z/D = 4 for Flow #4. Velocities are mode dimensionaless by the exit plane value.
- Figure 4. Dimensionless axial velocity-pressure correlation, $\overline{p'u'/\rho u^3}$. Comparison of theory (\mathbf{X}) and experiment (\mathbf{m}). Flow #2.
- Figure 5. Dimensionless correlations vs axial distance for Flows #2 and #3.

Mean square pressure, $(p'^{2})\frac{\sqrt{2}}{\sqrt{p}} \overline{u^{2}}$, on the axis of Flow #2

 $(\overline{\rho'}^2) \frac{1}{2} / \overline{\rho}$ for Flow #2. $\Box (\rho' \overline{2}) \frac{1}{2} / \overline{\rho} + 10$ for flow #3. \divideontimes Theoretical

 $(\overline{p^{+2}}) \frac{\sqrt{2}}{\rho} \overline{u^2}$ neglecting density fluctuation.

- Figure 6. Transverse velocity-pressure correlation, $\overline{p'v'}/\overline{p}u^3$, vs radial distance at z/D = 6 for Flow #2. 🗶 Theory. **E** Experiment.
- Figure 7. Experimental configuration for space-separated velocity measurements.
- Figure 8. Radially separated correlation measurements of the axial velocity and the Gaussian fit to the data used in the theory.
- Figure 9. Two dimensional fit to the axial and radial space-separated axial velocity correlation.
