Abstract. The United Kingdom Chemistry and Aerosols (UKCA) chemistry–climate model is used to quantify the differences in chemical environment for surface O₃ for six major industrial regions across China in summer 2016. We first enhance the UKCA gas-phase chemistry scheme by incorporating reactive volatile organic compound (VOC) tracers that are necessary to represent urban and regional-scale O₃ photochemistry. We demonstrate that the model with the improved chemistry scheme captures the observed magnitudes and diurnal patterns of surface O₃ concentrations across these regions well. Simulated O₃ concentrations are highest in Beijing and Shijiazhuang on the North China Plain and in Chongqing, lower in Shanghai and Nanjing in the Yangtze River Delta, and lowest in Guangzhou in the Pearl River Delta despite the highest daytime O₃ production rates in Guangzhou. NO_x / VOC and H₂O₂ / HNO₃ ratios indicate that O₃ production across all regions except Chongqing is VOC limited. We confirm this by constructing O₃ response surfaces for each region changing NO_x and VOC emissions and further contrast the effectiveness of measures to reduce surface O₃ concentrations. In VOC-limited regions, reducing NO_x emissions by 20 % leads to a substantial O₃ increase (11 %) in Shanghai. We find that reductions in NO_x emissions alone of more than 70 % are required to decrease O₃ concentrations across all regions. Reductions in VOC emissions alone of 20 % produce the largest decrease (−11 %) in O₃ levels in Shanghai and Guangzhou and the smallest decrease (−1 %) in Chongqing. These responses are substan-

tially different from those currently found in highly populated regions in other parts of the world, likely due to higher NO_x emission levels in these Chinese regions. Our work provides an assessment of the effectiveness of emission control strategies to mitigate surface O₃ pollution in these major industrial regions and emphasises that combined NO_x and VOC emission controls play a pivotal role in effectively offsetting high O₃ levels. It also demonstrates new capabilities in capturing regional air pollution that will permit this model to be used for future studies of regional air-quality–climate interactions.

1 Introduction

Surface ozone (O₃) has become the main cause of atmospheric pollution in the summertime in China since 2013 and is particularly severe in industrial areas of China such as the North China Plain (NCP), the Yangtze River Delta (YRD), the Pearl River Delta (PRD) and the Sichuan Basin where precursor emissions are high (Li et al., 2019a). The 90th percentile of the maximum daily 8 h average (MDA8) O₃ concentration in 30 of 74 major cities of China exceeded the National Ambient Air Quality Standard (100 ppb) in the summer of 2017 (Wang et al., 2017; Lu et al., 2018; Silver et al., 2018; Li et al., 2019b; H. X. Lu et al., 2019). During 2013–2017, the national Air Pollution Prevention and Control Action Plan successfully reduced emissions of fine particulate

matter (PM_{2.5}) and nitrogen oxides (NO_x = NO + NO₂) in China by 33 % and 21 %, respectively (Zheng et al., 2018). However, the reduction in NO_x emissions has led to an increase in O₃ levels in polluted areas due to the non-linear chemistry of O₃ and reduced titration of O₃ by NO (Li et al., 2019a; Wang et al., 2019). Volatile organic compounds (VOCs) are also important O₃ precursors, and emissions of these have increased across China over the same period, exacerbating O₃ pollution (Zheng et al., 2018). VOC emissions are believed to have decreased in megacity regions such as Beijing (Cheng et al., 2019), but the resulting O₃ decrease is likely to have been offset by the O₃ increase due to reduced NO_x emissions. This poses a challenge to mitigate surface O₃ pollution. Therefore, the balance of emission controls on NO_x and VOC is critical to decreasing O₃ levels in these regions. Meteorological processes also affect O₃ formation through temperature, humidity, clouds, precipitation and biogenic emissions, and a number of papers have studied meteorological impacts on O₃ over China (Gong and Liao, 2019; Liu and Wang, 2020; Shi et al., 2020). However, emission controls are the primary strategies used to reduce O₃ pollution, and we focus on these for this study, as their effectiveness for different regions has not been fully investigated.

O₃ is a secondary photochemical pollutant in the troposphere that can be produced rapidly through oxidation of its precursors NO_x, VOCs and carbon monoxide (CO) in the presence of sunlight. Power plants, industry, residences and transport are the main anthropogenic sources of NO_x and VOC emissions (Monks et al., 2015; M. Li et al., 2018). Isoprene is the principal biogenic VOC and is released from trees, plants and crops (Sindelarova et al., 2014). O₃ formation is mainly initiated through oxidation of VOC species by hydroxyl radicals (OH). The resulting organic peroxy radicals (RO₂) and hydroperoxyl radicals (HO₂) can convert NO to NO₂ without destroying O₃. O₃ is then created from the combination of O(³P) atoms, formed from photolysis of the resulting NO₂ and oxygen (O₂) (Sillman, 1999; von Schneidemesser et al., 2015; Wang et al., 2017). Under low-NO_x conditions, HO₂ radicals may combine to produce hydrogen peroxide (H₂O₂). However, at high NO_x concentrations, nitric acid (HNO₃), peroxy nitrates (RO₂NO₂) and organic nitrates (RONO₂) are easily formed as NO_x reacts with OH and RO₂. These species are the main sinks of radicals and NO_x and are readily removed from the atmosphere by deposition or exported to remote areas (Horowitz et al., 1998). Therefore, increasing NO_x concentrations increase O₃ production but also accelerate the formation of NO_x sinks, leading to less efficient O₃ formation. In addition, direct titration of O₃ by NO becomes increasingly important at higher levels of NO_x. There is hence a transition in the magnitude of O₃ production from low- to high-NO_x conditions. This turnover is dependent on the local chemical environment and in particular on the relative abundance of NO_x and VOCs (Sillman, 1995; Kleinman et al., 1997; Thornton et al., 2002; Kleinman et al., 2005; Sillman and West, 2009).

A variety of O₃ sensitivity indicators have been proposed to characterise the O₃ response to changing precursor emissions. The simplest of these are based on the concentration ratios of the precursors, NO_x / VOCs, or of their oxidation products, H₂O₂ / HNO₃ (Sillman, 1995). O₃ concentrations increase with NO_x emissions and are not sensitive to VOC emissions in a NO_x-limited regime when NO_x concentrations are relatively low (Sillman et al., 1990). However, in a VOC-limited regime, O₃ levels may increase with decreasing NO_x emissions, which is common in urban areas with high NO_x emissions, and this is reflected in high NO_x / VOC or low H₂O₂ / HNO₃ ratios. Critical values of these indicators of O₃ sensitivity vary by region and by season (Sillman, 1995; Liu et al., 2010; Xing et al., 2019). Most major industrial regions in China are believed to be VOC limited, and rural areas are NO_x limited or in a transition regime (Jin and Holloway, 2015; Wang et al., 2017). O₃ production efficiency (OPE) is another important metric to evaluate the impacts of NO_x emissions on O₃ concentrations (Liu et al., 1987; Kleinman et al., 2002). This is defined as the number of O₃ molecules produced per molecule of NO_x oxidised. Low OPE values are typically associated with high-NO_x conditions and indicate that there is less O₃ produced from a given amount of NO_x. OPE values generally increase as NO_x emissions decrease, reflecting greater O₃ production per molecule of NO_x oxidised at lower NO_x levels.

In this study, we develop new capabilities in a global-scale model by incorporating higher-VOC chemistry, allowing the model to represent the oxidation environment in major industrialised regions in China. We focus on the spatial and temporal variation of daytime O₃ in this study. We first evaluate the performance of this global chemistry–climate model in simulating regional O₃ across large industrialised regions. We use O₃ sensitivity indicators to compare and contrast the chemical oxidative environment across these different regions in China to identify emission control measures that would be most beneficial to reduce O₃ pollution levels. Using a global model novelly allows us to compare the impact of emission control measures in China with those in other major industrialised regions across the world. The value of this approach is that the same model set-up can be used to assess the impact of future emission and climate scenarios, studies of tropospheric and stratospheric O₃ influences, and comparisons of O₃ in different parts of world.

The configuration of the model used in this study is described in Sect. 2, along with its development and application to surface O₃ in China. We evaluate the model performance in reproducing the diurnal cycles of surface O₃ and NO₂ in Sect. 3, and we investigate the O₃ chemical environment in China, including O₃ precursor concentrations and sensitivity ratios in Sect. 4. We calculate the local O₃ production rates, O₃ loss rates, NO_x loss rates and OPE in Sect. 5. We then quantify the O₃ responses to changing NO_x and VOC emissions in these regions and investigate the requirements of emission controls to reduce O₃ levels in each region in

Sects. 6 and 7. To provide a global context we compare and contrast the effectiveness of emission control strategies with that in other parts of the world in Sect. 7 and present our conclusions in Sect. 8.

2 Materials and methods

2.1 Model description, development and application

The United Kingdom Chemistry and Aerosols (UKCA) model is a state-of-the-art chemistry and aerosol model that simulates atmospheric composition from the troposphere to the upper stratosphere. It is coupled to the Met Office Hadley Centre's Global Environment Model (HadGEM) family of climate models, all of which are based on the UK Unified Model (MetUM) (O'Connor et al., 2014). It is also the atmospheric composition component of the UK Earth System Model (UKESM) (Sellar et al., 2019). Version 10.6.1 of UKCA is used in this study, coupled with the Global Atmosphere 7.1 (GA7.1) configuration (Walters et al., 2019) of HadGEM3 (Hewitt et al., 2011). The spatial resolution is N96L85 with 1.875° by longitude and 1.25° by latitude, and there are 85 terrain-following hybrid height layers with a model top at 85 km. The model time step is 20 min for meteorology, and chemistry is calculated every hour. Wind speed and temperature are nudged with ERA-Interim reanalyses from the European Centre for Medium-Range Weather Forecasts (ECMWF) every 6 h (Dee et al., 2011). Sea surface temperature and sea ice fields are prescribed with the climatology mean of 1995–2004 (Reynolds et al., 2007).

The stratosphere–troposphere (Strat-Trop) gas-phase chemical scheme is used to simulate the inorganic odd oxygen (O_x), hydrogen ($HO_x = OH + HO_2$), and NO_x chemical cycles; oxidation of CO and VOCs; chlorine and bromine chemistry; and heterogeneous processes on aerosols (Archibald et al., 2020). The Global Model of Aerosol Processes (GLOMAP) aerosol scheme is used with a two-moment pseudo-modal aerosol dynamics approach to simulate sulfate, sea salt, dust, black carbon, and both primary and secondary organic aerosol (Mann et al., 2010). Interactive photolysis is represented with Fast-JX, which derives photolysis rates between 177 and 750 nm (Neu et al., 2007).

Global chemistry–climate models typically include simplified gas-phase chemistry schemes representing a limited number of species to mitigate high computational demands. Major long-lived VOC species are selected, and more reactive VOC species are typically omitted from the chemistry scheme (Young et al., 2018). Eight discrete emitted VOC species – formaldehyde (HCHO), ethane (C_2H_6), propane (C_3H_8), acetaldehyde (CH_3CHO), acetone ($(CH_3)_2CO$), methanol (CH_3OH), isoprene (C_5H_8) and monoterpene ($C_{10}H_{16}$) – are simulated in the Strat-Trop chemistry scheme of UKCA. This selection is appropriate

for simulating the global burden of O_3 but is less suitable for simulating O_3 concentrations in high-emission areas. In industrial regions of China, large abundances of more reactive VOCs such as alkenes and aromatics make substantial contributions to O_3 production (Wu and Xie, 2017; Tan et al., 2019; Liu et al., 2020). To address this, we incorporate more reactive classes of VOC including alkenes, higher alkanes and aromatics, represented by propene (C_3H_6), butane (C_4H_{10}) and toluene (C_7H_8) respectively in the chemistry scheme (Atkinson et al., 2006; Folberth et al., 2006). This permits a more realistic simulation of photochemically active environments and allows rapid O_3 formation in high-VOC-emission regions to be captured. The improved chemistry scheme includes 101 species, 244 bimolecular reactions, 26 uni- and termolecular reactions, 70 photolytic reactions, 5 heterogeneous reactions, and 3 aqueous-phase reactions for the sulfur cycle.

We perform model simulations for 2016 and focus our results on summer (June–July–August, JJA). We spin up the model for 4 months and then simulate the full year nudged with ERA-Interim reanalysis data for 2016. The new capabilities of the model allow us to investigate regional O_3 chemical environment in industrial regions of China in the model. The relatively coarse resolution of the model may lead to biases in surface O_3 associated with numerical diffusion (Wild and Prather, 2006; Stock et al., 2014; Fenech et al., 2018; Mertens et al., 2020), but we note that the lifetime of O_3 makes it a regional-scale pollutant except very close to high-emission sources (Valari and Menut, 2008; Hodnebrog et al., 2011; Biggart et al., 2020). This study demonstrates the first application of this improved chemistry scheme to high-emission regions worldwide and lays the foundation for more detailed studies of the interactions between air quality and climate in a global chemistry–climate model under future scenarios.

2.2 Emissions

The anthropogenic emission inventory of Hemispheric Transport of Air Pollution (HTAP) for 2010 is used for the globe outside China (Janssens-Maenhout et al., 2015). The Multi-resolution Emission Inventory for China (MEIC) is used to provide emissions over China for 2013 (Li et al., 2017). We apply independent diurnal and vertical profiles to each emission sector (industry, power plants, transport and residences) according to European Monitoring and Evaluation Programme (EMEP) emissions (Bieser et al., 2011; Mailler et al., 2013). Biogenic VOC (BVOC) emissions are calculated interactively through the Joint UK Land Environment Simulator (JULES) land-surface scheme in UKCA (Pacifico et al., 2011). The Global Fire Emissions Database (GFED4) is used for biomass burning emissions (van der Werf et al., 2010). Other aspects of the emissions used are as described in Archibald et al. (2020).

Table 1. Number of measurement sites and grid cells in the six industrial regions.

Region	No. of measurement sites	No. of grid cells
Beijing	46	4
Shijiazhuang	28	2
Shanghai	58	2
Nanjing	45	1
Guangzhou	45	1
Chongqing	25	1

Given the rapid changes in anthropogenic emissions across China, we adjust NO_x , VOCs, CO, sulfur dioxide (SO_2), black carbon (BC) and organic carbon (OC) emissions in MEIC from 2013 to 2016 by applying national and urban emission scaling factors. NO_x emissions decreased by 18.8%, and VOC emissions increased slightly by 1.1% between 2013 and 2016 across China (Zheng et al., 2018). NO_x and VOC emissions are estimated to have decreased by 24.2% and 12.8% respectively in Beijing and surrounding areas between 2013 and 2016 (Cheng et al., 2019). We apply the Beijing scaling factors to major industrialised regions, reflecting tighter emission controls in these developed urban regions, and use national scaling factors across the rest of the country.

2.3 Selected regions and observations

We focus on six heavily populated regions with high emissions within the major industrialised regions in China. These include Beijing and Shijiazhuang on the North China Plain (32–40° N, 114–121° E), Shanghai and Nanjing in the Yangtze River Delta (28–33° N, 118–123° E), Guangzhou in the Pearl River Delta (21–25° N, 111–115° E), and Chongqing in the Sichuan Basin (28–32° N, 103–108° E); see Fig. 1. Anthropogenic NO_x and VOC emissions are high in these regions (Fig. 2) due to rapid industrialisation, urbanisation and socio-economic development. Model grid cells that include observation stations located in each of the urban and rural regions are selected to be representative of these regions; see Table 1. For comparison with observations, we calculate a grid-weighted mean according to the number of measurement sites in each model grid cell for the region.

We use observed hourly concentrations of air pollutants including O_3 and NO_2 from the surface monitoring networks of China, obtained from the public website <https://www.cnemc.cn/> (last access: 22 October 2020), which mirrors data from the Chinese National Environmental Monitoring Centre (CNEMC) <http://www.cnemc.cn/> (last access: 22 October 2020). A total of 450 measurement stations in China started operating in 2013, growing rapidly to 1670 stations by 2019.

3 Model evaluation of surface O_3 and NO_2

We evaluate the diurnal variation in simulated surface O_3 and NO_2 concentrations against summertime observations for JJA, 2016, for the six industrialised regions (Figs. 3, 4). In general, the diurnal variation of observed O_3 is matched relatively well, and the correlation coefficients are relatively high; see Table 2. Mean concentrations for O_3 and NO_2 over the lowest three model layers (from the surface up to 130 m) are also compared with observations. In the daytime, differences between the surface and three lowest layers are small due to efficient mixing in the planetary boundary layer (PBL). The height of the nocturnal PBL is typically underestimated in the model, leading to overestimated NO_x concentrations and hence underestimated O_3 concentrations at nighttime due to excessive O_3 titration by NO (André et al., 1978; Petersen et al., 2019; Zhao et al., 2019). Figure 3a shows a large difference in nighttime O_3 concentrations across the three layers, reflecting stable conditions that allow NO_x to accumulate at the surface. Simulated surface O_3 concentrations therefore tend to be underestimated at nighttime. In addition, nighttime heterogeneous uptake of nitrogen on aerosols remains highly uncertain due to the complexity in estimating uptake coefficients for different aerosol composition/mixing states (Lowe et al., 2015; Tham et al., 2018). In UKCA, the lack of nitrate aerosol in the aerosol scheme may result in a lower uptake of nitrogen (Archibald et al., 2020), particularly in regions with high NO_x emissions. Therefore, there may be a bias in the heterogeneous removal of nitrogen, potentially leading to higher NO_2 and lower O_3 concentrations at nighttime. In contrast, the peaks in daytime O_3 concentrations are captured relatively well, reflecting efficient O_3 production in the high-VOC environment.

Daily mean O_3 concentrations for Beijing, Shijiazhuang, Shanghai and Guangzhou are reproduced well with relatively small biases ($\sim 10\%$; see Table 2). Simulated daily mean O_3 concentrations are highest (> 40 ppb) for Beijing, Shijiazhuang and Chongqing; lower in Shanghai and Nanjing (< 40 ppb); and lowest for Guangzhou (~ 30 ppb). Although daily mean O_3 concentrations are captured relatively well, as seen in Figs. 3a and 4a, daytime maximum O_3 concentrations are overestimated, associated with underestimated NO_2 concentrations. This overestimation is largest in Shijiazhuang, where the underestimation of daytime NO_2 concentrations is larger than other regions. We find that there is a systematic bias in Chongqing, where simulated O_3 levels are higher than observations. Chongqing is a mountainous inland region with complex topography that cannot be fully resolved, and surface O_3 here is thus representative of higher surface altitudes leading to a systematic bias high compared with observations (Su et al., 2018) and a corresponding bias low for NO_2 concentrations. In addition, simulated O_3 increases from biogenic emissions in the Sichuan Basin are much larger in summertime than other regions (X. Lu et al., 2019), and uncer-

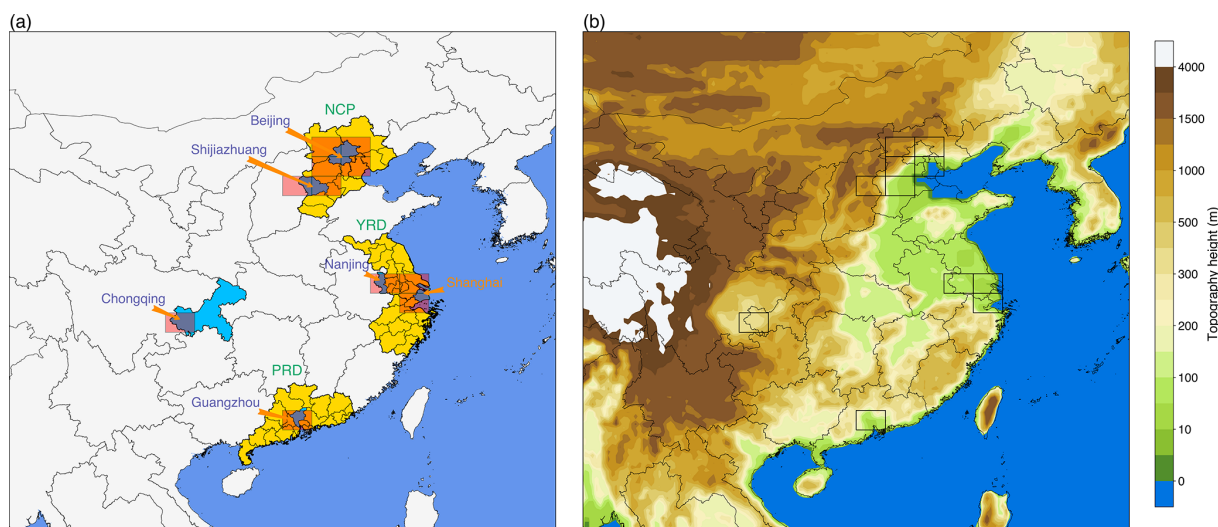

Figure 1. Map of China showing (a) the key provinces (yellow) representing the NCP, the YRD, and the PRD and locations of the six regions (blue) – Beijing, Shijiazhuang, Shanghai, Nanjing, Guangzhou and Chongqing – and UKCA model grid cells co-located with these regions (red); and (b) elevations across the whole of China.

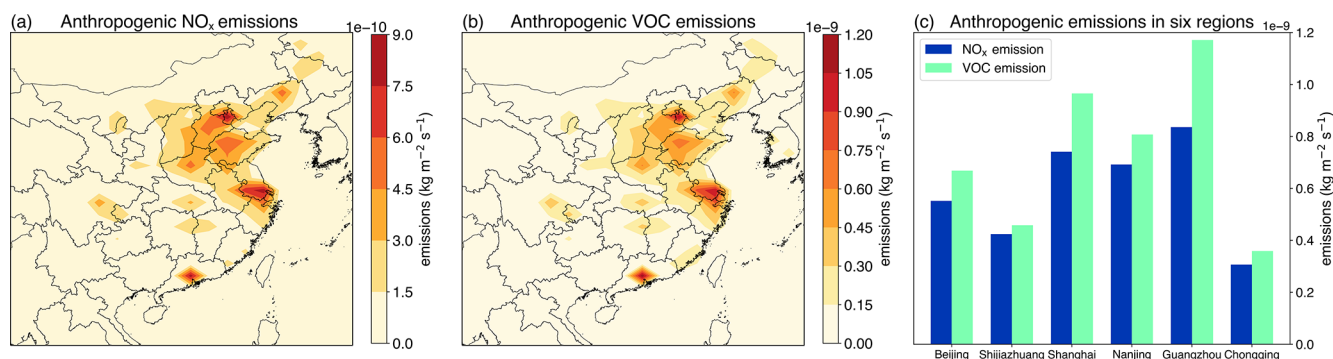

Figure 2. Spatial distributions of anthropogenic NO_x and VOC emissions ($\text{kg m}^{-2} \text{s}^{-1}$) across China (a, b) and grid-weighted averaged emissions for the six regions within the four major industrialised regions (c) in JJA, 2016.

tainty in these emissions may contribute to the biases. Given our use of reliable meteorological reanalysis data, we note that meteorology is not the main influence on the model biases. We therefore investigate O_3 chemical environments in different regions to explore regional differences below.

The diurnal patterns in NO_2 concentrations can also be captured as reflected by high levels at nighttime and low levels in the daytime for all regions. Daytime NO_2 concentrations can be reproduced relatively well, with a small underestimation. This underestimation may lead to overestimated O_3 concentrations in a VOC-limited regime and underestimated O_3 in a NO_x -limited regime. While underestimated NO_x concentrations may reflect underestimated NO_x emissions, it is more likely to arise from the effects of dilution on NO_x . High emissions in these regions are diluted over a large grid cell, resulting in lower NO_2 concentrations in the daytime. This is offset by high NO_2 concentrations in the PBL at nighttime as discussed above. The diurnal variation of NO_2

concentrations is hence stronger in the simulations than the observations (Fig. 4a).

Figures 3 and 4 also show the frequency distribution of observed and modelled hourly O_3 and NO_2 concentrations. The simulated peaks in the distributions of O_3 and NO_2 are underestimated compared to observations for all six regions, reflecting the larger diurnal variation in the simulations. The diurnal variation is more closely simulated for O_3 concentrations (correlation coefficient $r > 0.7$) than for NO_2 concentrations. The Chongqing region has the closest correlation with observations ($r = 0.83$), which provides evidence that the overestimation of O_3 is systematic as suggested earlier. Overall, the magnitudes (see Table 2) and diurnal patterns (see Figs. 3 and 4) of both species can be simulated reasonably well, with differences between industrial regions clearly captured.

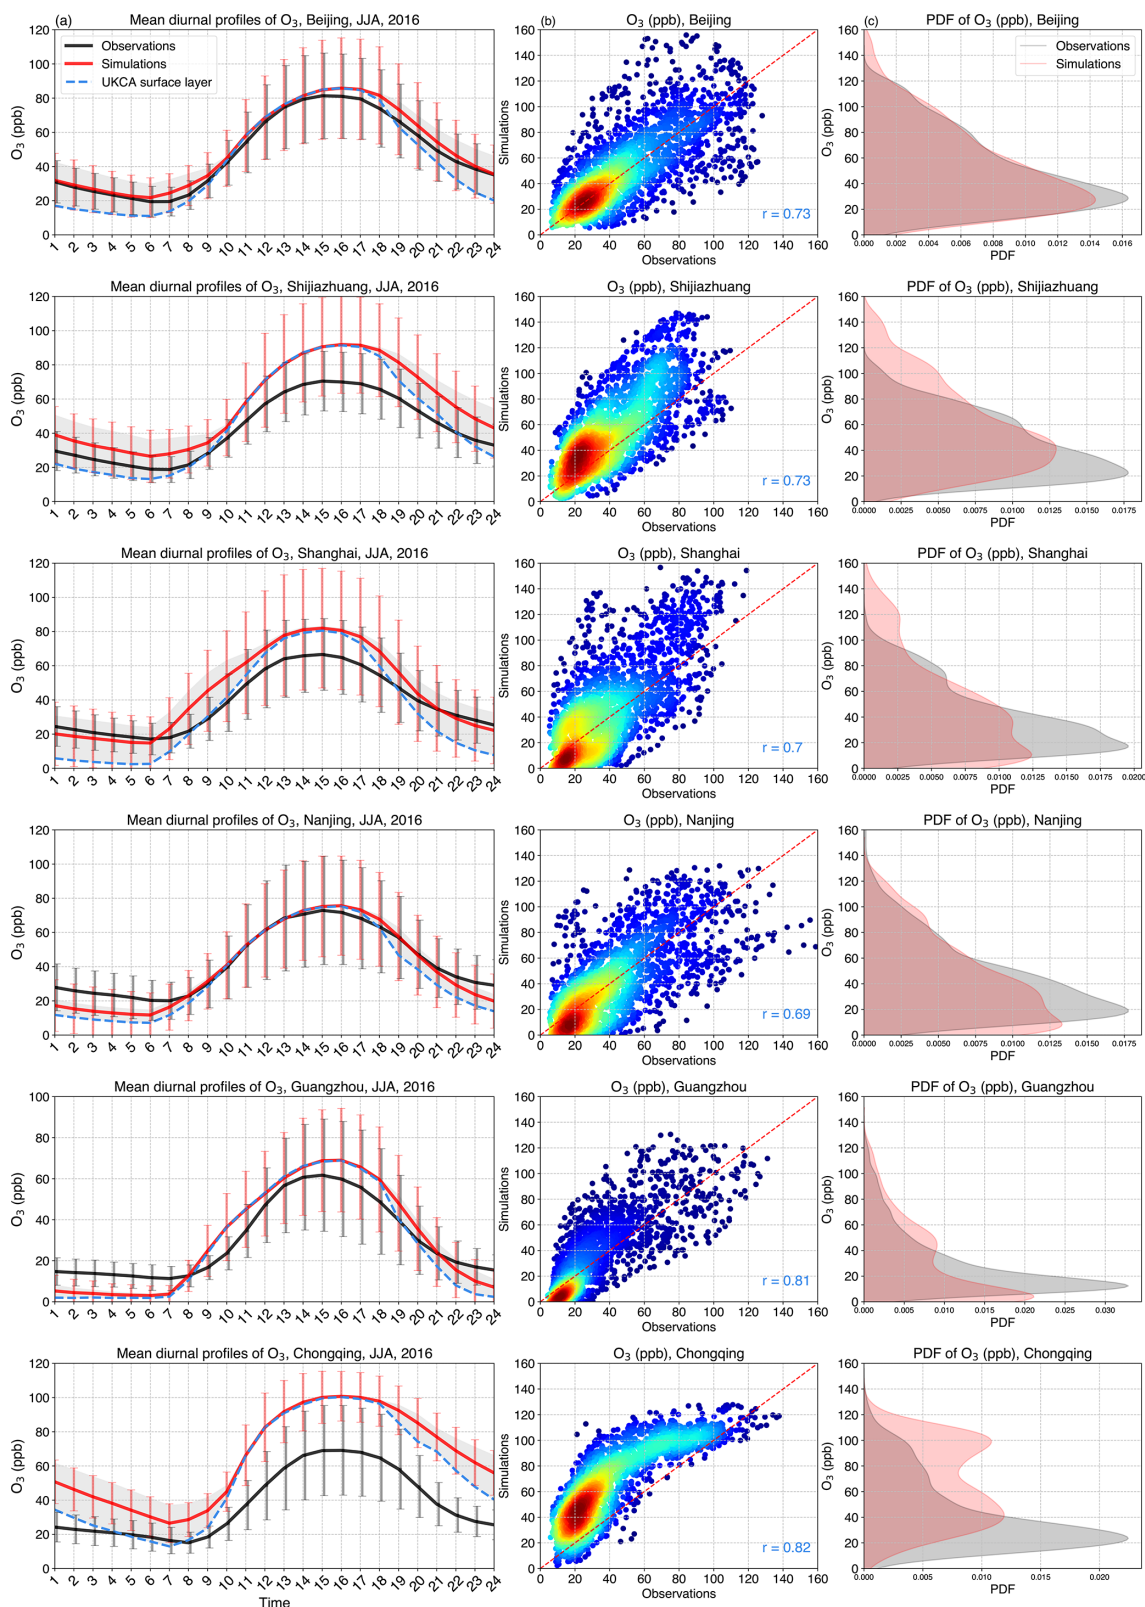

Figure 3. Comparison of observed and modelled O₃ concentrations for the six industrialised regions in JJA, 2016, China. **(a)** Mean diurnal cycles of observed and modelled O₃ concentrations (ppb). The shaded area represents the spread across the lowest three model layers. Error bars denote 1 standard deviation of hourly O₃ concentrations across all days. **(b)** Observed and modelled hourly O₃ concentrations (ppb; three lowest model layers) and correlation coefficient values r . **(c)** Probability density function (PDF) of O₃ concentrations (ppb) for modelled and observed hourly values.

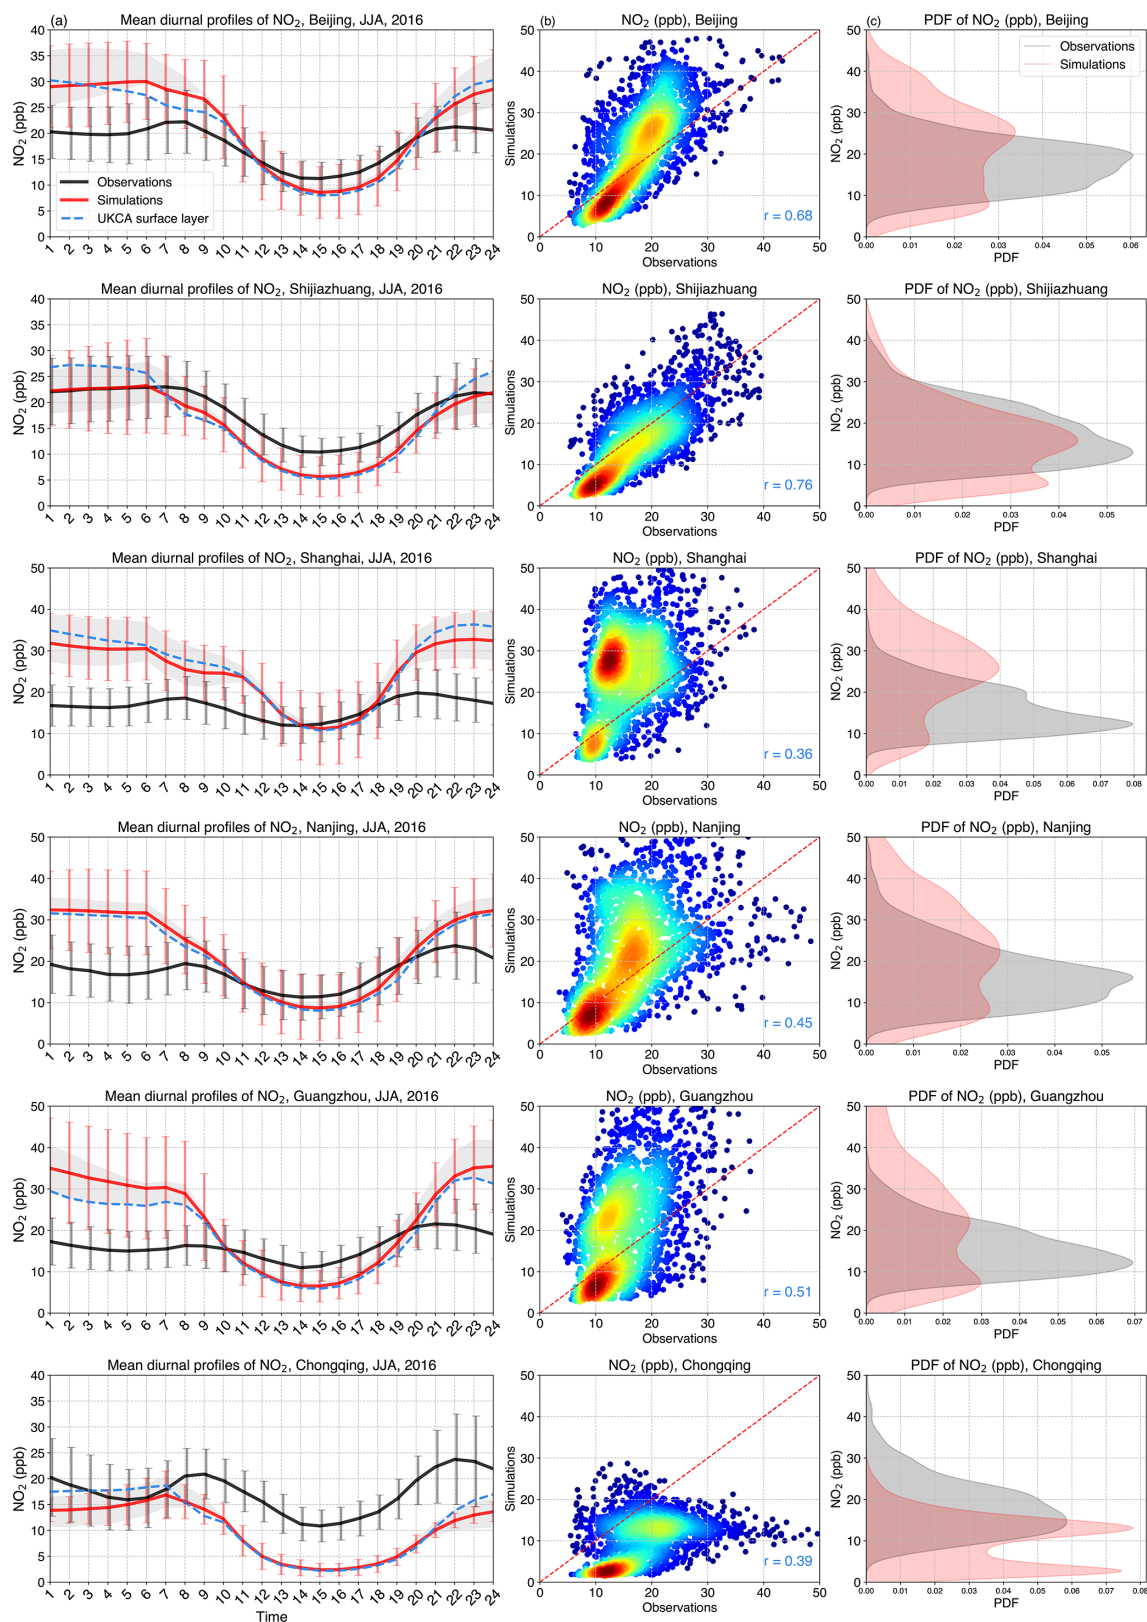

Figure 4. Comparison of observed and modelled NO₂ concentrations for the six industrialised regions in JJA, 2016, China. **(a)** Mean diurnal cycles of observed and modelled NO₂ concentrations (ppb). The shaded area represents the spread across the lowest three model layers. Error bars denote 1 standard deviation of hourly NO₂ concentrations across all days. **(b)** Observed and modelled hourly NO₂ concentrations (ppb; three lowest model layers) and correlation coefficient values r . **(c)** PDF of NO₂ concentrations (ppb) for modelled and observed hourly values.

Table 2. Comparison of modelled and observed daily mean surface O₃ and NO₂ concentrations for the six industrial regions in JJA, 2016, China.

Region	Obs. (ppb)	Sim. (ppb)	Bias ppb/%	RMSE (ppb)	Correlation <i>r</i>
O ₃					
Beijing	47.7 ± 22.1	43.4 ± 27.7	−4.4 (9.1 %)	8.1	0.77
Shijiazhuang	42.9 ± 18.4	47.6 ± 28.7	4.7 (10.9 %)	11.6	0.78
Shanghai	38.3 ± 17.5	34.4 ± 28.8	−3.9 (10.2 %)	12.7	0.77
Nanjing	42.6 ± 18.9	35.9 ± 24.9	−6.8 (15.8 %)	9.8	0.71
Guangzhou	29.8 ± 18.3	28.0 ± 25.9	−1.8 (−6.1 %)	9.4	0.81

Chongqing	17.4 ± 3.8	10.9 ± 6.3	−6.4 (37.1 %)	8.0	0.43

4 Differences in chemical environment

Spatial distributions of modelled daytime concentrations of O₃, NO_x, VOCs and O₃ sensitivity ratios (NO_x / VOCs and H₂O₂ / HNO₃) are shown in Fig. 5 to illustrate the differences in chemical environment for the six regions. We use the standard definition of the maximum daily average 8 h (MDA8) ozone metric and consider this same time period for other species, which we refer to hereafter as daytime concentrations. For the sensitivity ratio NO_x / VOCs, we consider the sum of anthropogenic and biogenic daytime VOC concentrations.

Figure 5a shows high daytime O₃ levels (> 80 ppb) across northern China, eastern China and the Sichuan Basin in JJA, 2016. O₃ levels in the PRD (~ 40 ppb) are much lower despite high emissions, likely due to transport of clean air from the South China Sea associated with the East Asian summer monsoon (Zhao et al., 2010; S. Li et al., 2018). Areas with high anthropogenic NO_x and VOC concentrations generally coincide with high-emission regions (Figs. 2, 5b, c). High daytime NO_x concentrations (> 12 ppb) are simulated in Beijing and Shijiazhuang, Shanghai, and Nanjing. Chongqing has the lowest NO_x concentrations of 3–6 ppb due to relatively low NO_x emissions. High anthropogenic daytime VOCs concentrations are simulated across the main industrial regions, in particular in Shanghai with the highest levels (> 12 ppb; Fig. 5c).

The distribution of biogenic VOC concentrations (including isoprene and methanol) differs from that of anthropogenic VOCs (Fig. 5c, d). There is a strong latitudinal gradient, reflecting differences in climate and the spatial distribution of vegetation (Li et al., 2013). The highest biogenic VOC levels are simulated in south-eastern China where deciduous and mixed broadleaf trees are the main source of

biogenic VOCs. The YRD, the PRD and the Sichuan Basin have higher biogenic VOC concentrations than the NCP. Chongqing has the highest biogenic VOC levels of the regions considered here. However, higher biogenic VOC levels are found south of China in Laos, Vietnam and Cambodia.

High NO_x / VOC ratios and low H₂O₂ / HNO₃ ratios typically indicate VOC-limited O₃ production. The transition between VOC- and NO_x-limited regimes is typically about 0.25 for the NO_x / VOC ratio and about 0.2 for the H₂O₂ / HNO₃ ratio (Liu et al., 2010; Xing et al., 2019). From these two thresholds for the O₃ sensitivity ratios, it can be seen that VOC-limited regions cover most areas of the NCP, parts of the YRD including Shanghai and Nanjing, and Guangzhou in the PRD (Fig. 5e, f). All six regions except Chongqing have NO_x / VOCs ratios ≥ 0.6 and H₂O₂ / HNO₃ ratios ≤ 0.18 (Table 3). This suggests that these regions have a chemical environment that is strongly VOC limited. In addition, VOC-limited regimes shown by both indicators are quite similar, showing that these two O₃ sensitivity ratios may be useful to directly diagnose different O₃ sensitivity regimes in China. Regions with high NO_x / VOC ratios and low H₂O₂ / HNO₃ ratios typically occur where NO_x concentrations are high. Overall, these transition values delineate the different O₃ sensitivity regions across China well, showing VOC-limited regimes in the major industrial regions with high emissions. However, we note that these O₃ sensitivity ratios only provide an estimate of the chemical environment, and further, more detailed investigation of O₃ responses to emission changes is required.

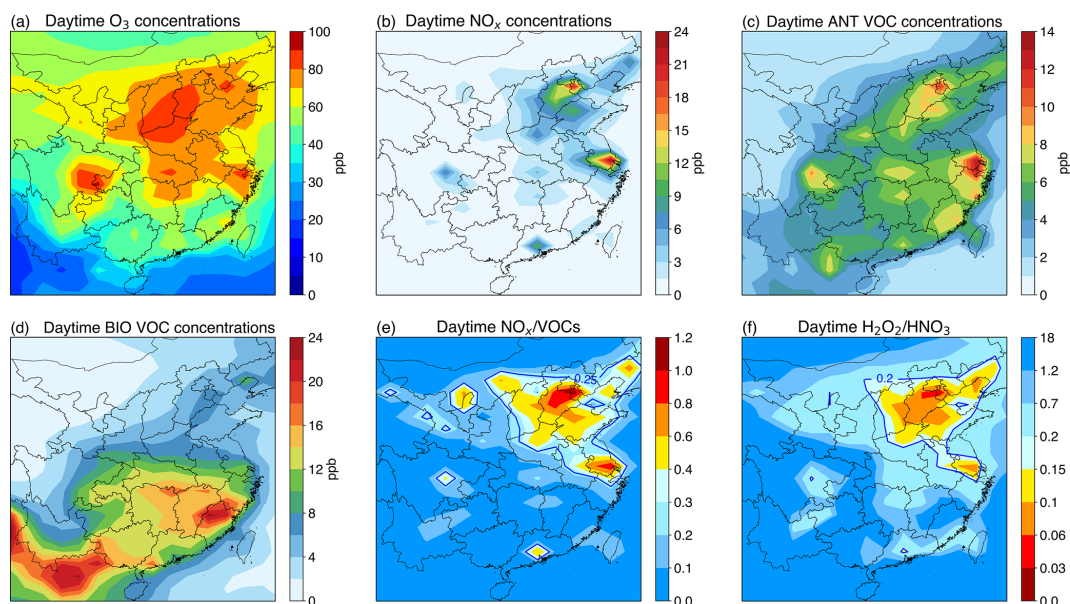

Figure 5. Spatial distributions of simulated surface daytime O_3 , NO_x , anthropogenic VOCs, biogenic VOCs (ppb) (a–d), and two O_3 sensitivity ratios – $\text{NO}_x / \text{VOCs}$ and $\text{H}_2\text{O}_2 / \text{HNO}_3$ (e, f) – in JJA, 2016, China.

5 Differences in local O_3 production rates

In this section, we calculate the daytime production rates for surface O_3 to investigate how the local O_3 production compares across the six regions. We define the net O_3 production rate (ppb h^{-1}) as the gross rate of production of O_3 , $\text{P}(\text{O}_3)$, from the reactions $\text{HO}_2 + \text{NO}$ and $\text{RO}_2 + \text{NO}$ minus the gross rate of loss of O_3 , $\text{L}(\text{O}_3)$, from the reactions $\text{O}^1\text{D} + \text{H}_2\text{O}$,

$\text{O}_3 + \text{OH}$, $\text{O}_3 + \text{HO}_2$ and $\text{O}_3 + \text{VOCs}$. We assume that the pathways above represent the net O_3 production rate under O_3 photochemical steady state between NO and NO_2 , and they are shown as follows:

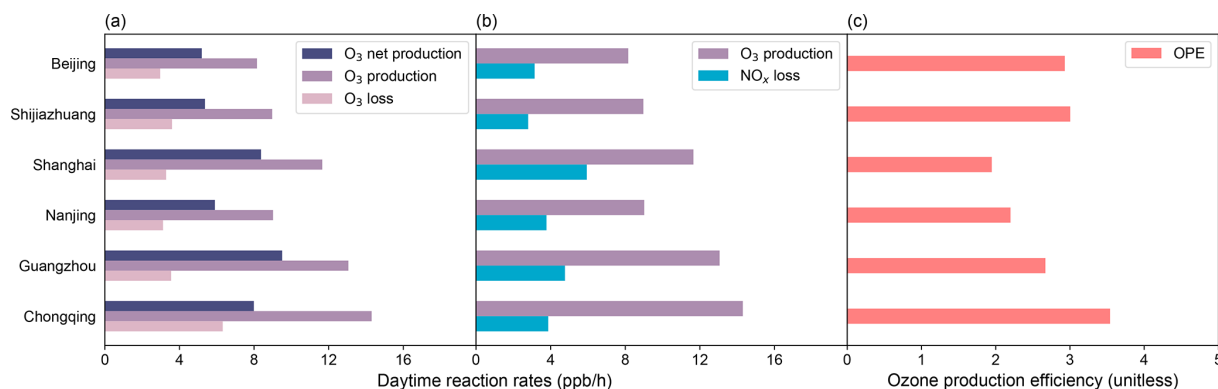

Figure 6. Simulated surface daytime (a) net O₃ production rates, gross O₃ production rates and gross O₃ loss rates (ppb h⁻¹); (b) gross O₃ production rates and NO_x loss rates (ppb h⁻¹); and (c) OPE (unitless) for the six industrial regions in JJA, 2016, China.

$$\begin{aligned}
 \text{Net } P(\text{O}_3) &= P(\text{O}_3) - L(\text{O}_3) \\
 &= k_1[\text{HO}_2][\text{NO}] + k_2[\text{RO}_2][\text{NO}] \\
 &\quad - (k_3[\text{O}(\text{D})][\text{H}_2\text{O}] + k_4[\text{O}_3][\text{OH}] \\
 &\quad + k_5[\text{O}_3][\text{HO}_2] + k_6[\text{O}_3][\text{VOCs}]), \quad (1)
 \end{aligned}$$

where k_i represents the rate coefficient of reaction i .

The loss of NO_x, $L(\text{NO}_x)$, is principally determined by the reactions OH + NO₂, RO₂ + NO₂ and RO₂ + NO, which produce HNO₃, RO₂NO₂ and RONO₂ respectively. OPE is then defined as the number of O₃ molecules produced per molecule of NO_x consumed (Liu et al., 1987).

$$\text{OPE} = \frac{P(\text{O}_3)}{L(\text{NO}_x)} \quad (2)$$

As shown in Fig. 6, local O₃ production varies across the six regions, with O₃ net production rates ranging from 4 to 10 ppb h⁻¹. Simulated daytime net O₃ production rates are highest (> 8 ppb h⁻¹) in Shanghai and Guangzhou mainly due to high precursor emissions, and this is reflected by higher O₃ concentrations in Shanghai than in nearby Nanjing. While O₃ production is high in Guangzhou, the O₃ concentrations are much lower than in other regions, indicating that meteorological impacts in this coastal region are important to transport O₃ produced locally. O₃ net production in Beijing and Shijiazhuang is similar to that in Nanjing (~ 5 ppb h⁻¹). O₃ production in Chongqing is also high, reflecting high radical concentrations (see Table 3) that promote O₃ production despite lower precursor emissions. High photolysis rates $j(\text{O}(\text{D}))$ in Chongqing and Guangzhou contribute to high concentrations of OH radicals (Table 3). O₃ destruction rates are fairly similar (< 4 ppb h⁻¹) across these regions but are higher in Chongqing, offsetting its high O₃ production rates.

The simulated NO_x loss rates (Fig. 6b) show the highest removal of NO_x in Shanghai, where NO_x concentrations are also highest. This influences OPE, which is strongly dependent on NO_x loss, and leads to the lowest OPE in Shanghai

and highest in Chongqing (Fig. 6c). The low OPE in Shanghai and Nanjing shows the low efficiency in O₃ production per molecule of NO_x consumed. However, the OPE values in all six regions are generally lower than those in other remote and rural regions, in agreement with Wang et al. (2018), indicating that high precursor emissions in these regions are the main cause of high surface O₃ concentrations.

6 Response of O₃ to emission controls

We quantify the response of daytime O₃ to emission changes to investigate the relationship between the chemical environment and the magnitude of O₃ changes for the six industrial regions of China. We implement three scenarios applying 20% reductions in anthropogenic NO_x emissions, VOC emissions, and combined NO_x and VOC emissions.

Spatial distributions of simulated daytime surface O₃ responses vary across China (Fig. 7). In the 20% NO_x emission control scenario, substantial O₃ increases (2–10 ppb) can be seen in the NCP, the YRD, and the PRD, and O₃ concentrations decrease (0–8 ppb) in the Sichuan Basin. In the 20% VOC emission control scenario, there are small O₃ changes in most non-industrial regions of China (–1–2 ppb), but O₃ concentrations generally decrease by 1–9 ppb across the NCP, the YRD and the PRD. The Sichuan Basin shows relatively small O₃ decreases. Areas showing O₃ increases in the 20% NO_x emission control experiment match well with VOC-limited areas indicated by the NO_x / VOCs and H₂O₂ / HNO₃ ratios (cf. Fig. 5e, f vs. Fig. 7a), suggesting that all the industrial regions considered here are VOC limited except Chongqing in the Sichuan Basin that is NO_x limited. The determination of O₃ sensitivity regimes here is based on the O₃ responses to decreasing anthropogenic NO_x and/or VOC emissions, and any potential impacts of changing BVOC emissions has not been assessed. Decreasing BVOC emissions may offset the increase in O₃ levels due to decreased NO_x emissions for the NCP, the YRD, and the PRD and would make all regions more VOC limited. We note

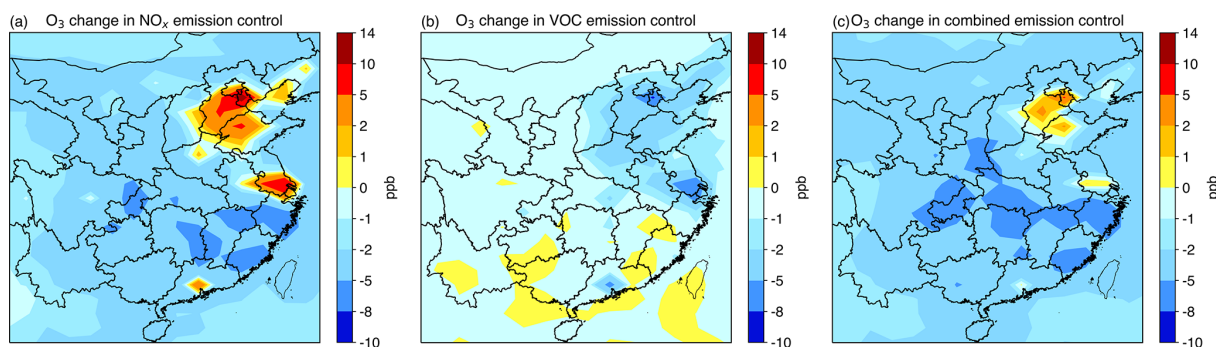

Figure 7. Spatial distributions of simulated surface daytime O_3 concentration changes (ppb) for (a) the 20 % NO_x emission control, (b) the 20 % VOC emission control, and (c) the 20 % combined NO_x and VOC emission control compared to the present-day results in JJA, 2016, China.

Table 4. Simulated daytime mean O_3 concentrations and changes (ppb) in NO_x , VOC, and combined NO_x and VOC emission controls for the six industrial regions in JJA, 2016, China.

Region	Base	NO_x control	Change (%)	VOC control	Change (%)	$NO_x + VOC$ control	Change (%)
Beijing	78.0	84.7	8.6 %	72.5	−7.0 %	79.7	2.2 %
Shijiazhuang	83.5	86.6	3.8 %	80.2	−3.9 %	84.6	1.4 %
Shanghai	70.1	77.8	11.0 %	63.1	−10.0 %	69.4	−1.0 %
Nanjing	66.8	72.4	8.5 %	61.4	−8.0 %	67.8	1.6 %
Guangzhou	60.2	64.8	7.6 %	53.8	−10.7 %	60.4	0.3 %
Chongqing	93.8	89.5	−4.6 %	92.5	−1.4 %	88.5	−5.6 %

that our conclusion of NO_x limitation in Chongqing may be sensitive to our underestimation of NO_2 levels (Sect. 3) and to the higher BVOC emissions in this region, both of which reduce the ratio of NO_x to VOC in the region (Table 3). However, satellite-observation-based studies have also suggested this region as one that is largely NO_x limited, in contrast to the heavily populated coastal regions (Wang et al., 2021).

In general, the greatest O_3 increases in the 20 % NO_x control scenario occur in areas with high precursor concentrations. Shanghai shows the largest O_3 increases (11 %) (Table 4) and has the highest underlying NO_x concentrations (Table 3). O_3 increases in Beijing and Guangzhou are similar ($\sim 8\%$), possibly because of their similar NO_x concentrations. Shijiazhuang in the NCP shows the smallest O_3 increase (4 %) because of its lower NO_x concentrations. In contrast, an O_3 decrease of 4 % is seen in Chongqing, which is NO_x limited. In the 20 % VOC control scenario, the largest O_3 decreases are simulated in Shanghai and Guangzhou (−10 %), while minimal O_3 decreases (−1 %) are simulated in Chongqing. The simulated chemical environment in Chongqing is NO_x limited, and therefore the O_3 changes are not sensitive to VOC emissions.

In addition to separate 20 % reductions in NO_x and VOC emissions, we demonstrate the importance of combined NO_x and VOC emission controls to mitigate O_3 pollution in VOC-limited regions. This effectively offsets the higher levels of O_3 that arise with NO_x emission reductions alone. The O_3

increase in Shanghai is fully offset in the combined emission control (−1 %). While O_3 increases still occur in the other VOC-limited regions, these increases are minimal ($< 3\%$). Reducing both NO_x and VOC emissions decreases O_3 levels in Chongqing by 6 %. Therefore, combined emission controls are necessary to efficiently mitigate O_3 pollution in all these industrial regions, and VOC emission controls should be at least as stringent as NO_x emission controls to address rising O_3 levels in these industrial regions.

7 Effectiveness of emission controls in reducing surface O_3 levels

To provide a more complete exploration of the effectiveness of emission controls, we construct a response surface of summertime daytime O_3 for each region to show the effect of changing NO_x and VOC emissions. We do this by performing a set of 64 model simulations with global anthropogenic NO_x and VOC emissions scaled independently over the range 0 %–140 % in increments of 20 %.

Figure 8 shows the magnitude and direction of O_3 changes in the six regions as NO_x and VOC emissions change. For context, Fig. 8a also shows the simulated daytime O_3 changes between 2013 and 2019 in the Beijing region, assuming that the emission changes observed between 2013 and 2016 continue at the same rate until 2019 (Cheng et al., 2019). We find that simulated O_3 concentrations in Bei-

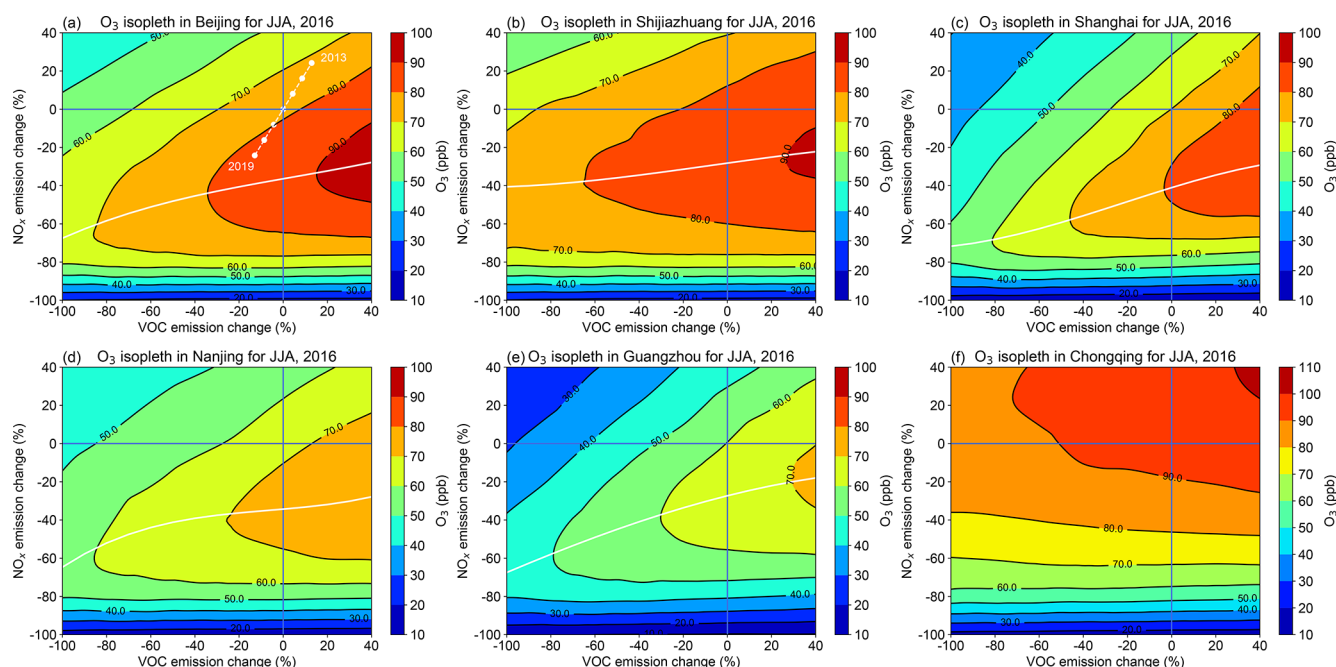

Figure 8. Simulated daytime surface O_3 responses (ppb) to anthropogenic NO_x and VOC emission changes for the six industrial regions across China (a–f) in JJA, 2016. The intersection of the vertical and horizontal lines marks current O_3 levels. White ridge lines mark the peak in O_3 concentrations for given VOC emissions and show the approximate transition between VOC-limited (above the ridge) and NO_x -limited (below the ridge) regimes. White dots in panel (a) represent simulated daytime O_3 levels in the Beijing region in JJA between 2013 and 2019 following estimated NO_x and VOC emission changes.

ing increase from 71.6 ppb in 2013 to 82.6 ppb in 2019, an increase of 1.8 ppb yr^{-1} . This is consistent with observed changes of 1.9 ppb yr^{-1} over this period due to anthropogenic emission changes (Li et al., 2020). The observed daytime O_3 concentrations are 83 ppb in the Beijing region in 2019. This demonstrates that the model captures not only the magnitude and diurnal pattern of O_3 in summer 2016 well but also the observed O_3 changes in recent years.

The patterns of O_3 response seen in the VOC-limited regions (Fig. 8a–e) are similar, such that decreases in NO_x emissions from their current levels increase O_3 concentrations. Large O_3 increases occur in Shanghai and Beijing, highlighting that it is not beneficial to reduce NO_x emissions unless VOC emissions are also reduced. Large reductions ($\sim 40\%$) in NO_x emissions are required to shift the chemical environment from VOC limited to NO_x limited for these two regions. The large decrease in O_3 in Shanghai and Guangzhou when reducing VOC emissions indicates that the efficiency in lowering O_3 levels by decreasing VOC emissions is high in these regions. In contrast, the efficiency of VOC emissions alone in reducing O_3 levels is lower in Shijiazhuang and Chongqing.

Figure 9 shows the O_3 responses in each region to changes in NO_x emissions, VOC emissions, and combined NO_x and VOC emissions, which represent cross sections through the O_3 response surfaces shown in Fig. 8. It is difficult to decrease O_3 concentrations in Shanghai by reducing NO_x

emissions alone because there is a steep rise in surface O_3 ($\sim 15\%$) when NO_x emissions are reduced by 40% from the current state. Decreasing O_3 from current levels requires reductions in NO_x emissions of more than 50% for Shijiazhuang and Guangzhou and more than 70% for Beijing, Shanghai and Nanjing. This suggests that mitigating poor O_3 air quality in these VOC-limited regions through NO_x emission controls alone would require much greater reductions than the 21% reductions in NO_x emissions that are reported to have occurred in China from 2013 to 2017 (Zheng et al., 2018).

O_3 responses to VOC emission changes are smaller and more linear than the responses seen for NO_x emissions changes (Fig. 9a, b). Reducing VOC emissions by 40% gives large decreases in O_3 concentrations (20%) in Shanghai and Guangzhou and smaller decreases ($< 10\%$) in Shijiazhuang and Chongqing (Fig. 9b). Reductions in VOC emissions are key to reducing present-day O_3 concentrations as they effectively offset the rising O_3 levels due to decreasing NO_x emissions (Fig. 9c). Emission reductions of 50% or more are required to reduce O_3 levels for all regions if controls on NO_x and VOC emissions are applied simultaneously.

To place our results in a wider global context, Fig. 10 shows summer daily mean surface O_3 changes over different regions with high emissions in other parts of the world compared with those in China. We consider six major industrialised regions outside of China and select the model

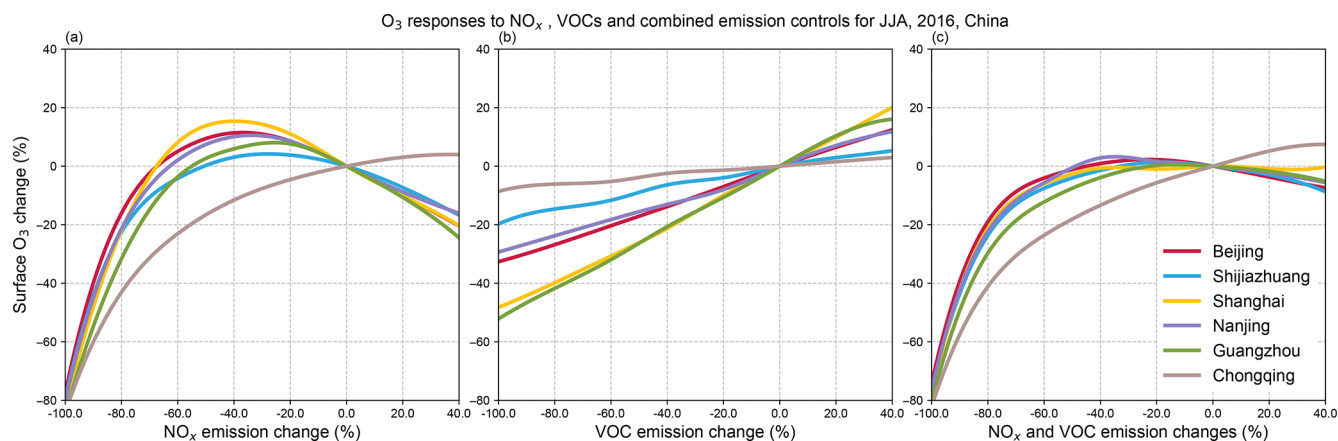

Figure 9. Simulated daytime surface O_3 responses to changes in anthropogenic emissions of (a) NO_x , (b) VOC, and (c) combined NO_x and VOC emissions for the six industrial regions in JJA, 2016, China.

grid cell that is most closely co-located with the region. We note that proportional increases in summer daily mean O_3 are larger than that of daytime O_3 increases when NO_x emissions are reduced (see Fig. 9), principally because absolute O_3 concentrations are smaller with the inclusion of nighttime conditions. We find that all selected high-emission regions across the globe outside of China are NO_x limited at the model resolution considered here, such that NO_x emission decreases yield regional O_3 decreases. Current levels of NO_x emissions in these regions are considerably lower than for the industrial regions of China, reflecting the different O_3 sensitivity regimes (Table 5). We note that these results apply to the wide urban regions considered here and that local O_3 sensitivity in some parts of these regions may be different.

Reductions of both NO_x and VOC emissions substantially decrease O_3 levels for these selected regions outside of China, and the magnitude of the O_3 decreases are similar to those found for Chongqing (Fig. 10). Conversely, the magnitude of O_3 decreases when reducing VOC emissions are smaller than all five VOC-limited regions in China. This indicates that O_3 concentrations are less sensitive to VOC emissions in these other world regions due to their lower VOC emissions (Table 5).

Despite lower NO_x and VOC emissions in the regions outside of China, surface O_3 concentrations, particularly in the Seoul and New York regions, are similar to those for China. This highlights that regional O_3 levels also depend on background O_3 concentrations, despite localised NO_x and VOC emissions that lead to different O_3 production regimes. The O_3 levels in European regions, e.g. London and Paris, are lowest, in accordance with the lowest NO_x and VOC emission levels. Overall, these results show that there are substantial differences in the efficiency of emission control scenarios to reduce surface O_3 levels in different parts of the world. For many industrial regions of China, the extended regions are VOC limited, and hence reductions of VOC emissions

Table 5. Anthropogenic NO_x and VOC emissions ($\times 10^{-10} \text{ kg m}^{-2} \text{ s}^{-1}$) and summertime mean surface O_3 concentrations (ppb) in regions across the industrial regions of China and the globe. MEIC emissions of 2013 adjusted for 2016 are used for Chinese industrial regions. HTAP emissions of 2010 are used for other regions of the globe.

Region	NO_x emissions	VOC emissions	O_3 conc.
China			
Beijing	5.5	6.7	43.4
Shijiazhuang	4.2	4.6	47.6
Shanghai	7.4	9.6	34.4
Nanjing	6.9	8.1	35.9
Guangzhou	8.4	12.0	28.0
Chongqing	3.1	3.6	56.0
Global			
Tokyo	2.0	2.6	38.9
Seoul	1.5	2.1	45.5
New York	2.3	3.1	45.3
L.A.	1.1	1.3	40.1
London	1.1	1.5	30.6
Paris	0.8	1.0	32.6

are the key to reducing poor O_3 air quality. For other regions selected in this study NO_x emission reductions are still pertinent to improving O_3 pollution.

8 Conclusions

This study presents the application of the global chemistry–climate UKCA model with an improved gas-phase chemistry scheme including more reactive VOCs to simulate regional summertime O_3 pollution across major industrialised regions in China for the first time. Differences in atmospheric chem-

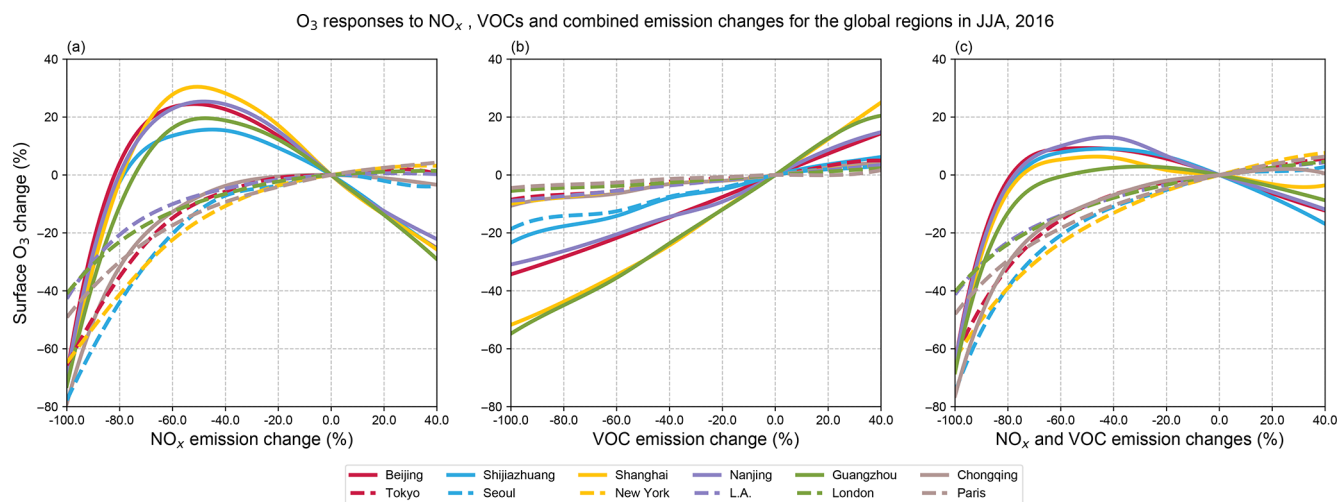

Figure 10. Simulated summer daily mean surface O₃ responses to anthropogenic (a) NO_x, (b) VOC, and (c) combined NO_x and VOC emission changes in regions across the globe: Tokyo, Seoul, New York, L.A., London, Paris (dashed lines) and those in major industrial regions of China (solid lines) in JJA, 2016.

ical environments are investigated, and the effectiveness of different emission control strategies in reducing O₃ concentrations is quantified. The model captures the magnitude, diurnal profiles and diurnal variation of O₃ concentrations across most industrial regions well. We highlight that peak O₃ concentrations can be captured well, indicating that O₃ production can be effectively simulated with more highly active VOC oxidation environments for high-emission regions of China.

Simulated daytime O₃ levels are highest on the North China Plain (Beijing and Shijiazhuang) and in the Sichuan Basin (Chongqing) and are lowest in the Pearl River Delta (Guangzhou). We find that there is a systematic bias in O₃ throughout the diurnal cycle in Chongqing, reflecting the mountainous inland area that is inadequately captured by the topography in the model. The O₃ production rates are highest in the Pearl River Delta compared to other regions. However, its much lower O₃ levels reflect the importance of meteorological impacts in this coastal region. OPE values in these industrial regions are low, indicating that their high O₃ levels are mainly caused by high precursor emissions. Both O₃ sensitivity ratios we apply here (NO_x / VOCs and H₂O₂ / HNO₃) suggest that all the industrial regions except Chongqing are VOC limited. This study hence provides a broad assessment of the O₃ sensitivities for these regions with implications for emission control strategies.

A set of simulations are performed with a range of NO_x and VOC emissions to construct O₃ response surfaces to assess the impacts of different emission control strategies in different regions. Reducing NO_x emissions alone by 20% leads to a substantial O₃ increase (11%) in Shanghai. Reductions in VOC emissions alone of 20% produce the largest decrease (−11%) in O₃ levels in Shanghai and Guangzhou

and the smallest decrease (−1%) in Chongqing. We find that reducing O₃ concentrations across all industrial regions of China would require more than 70% reductions if reducing NO_x emissions alone, and therefore VOC emission controls are important to reduce O₃ levels. We also find that combined emission controls effectively offset high O₃ levels that arise from reduced NO_x emissions alone. These responses are substantially different from those currently found in major highly populated regions in other parts of the world. The results show NO_x-limited O₃ production in these global areas, which also reflects the predominance of heavily populated VOC-limited areas across the industrial regions in China. Therefore, O₃ pollution in the industrial regions of China should be treated as a regional issue, and regional VOC emission control strategies should be considered.

The new capabilities for simulating regional surface O₃ pollution developed here will be helpful for future model studies to investigate the regional O₃ impacts on climate. The magnitude of O₃ changes over recent years in the Beijing region can be reproduced well. There remain model biases in regions with complex topography and high elevation – a common issue for global and regional models. Another source of uncertainty is the rapid change in anthropogenic emissions in recent years in China, which presents a particular challenge for inventory development. Recently, while NO_x emissions have been successfully reduced across many regions in China, changes in VOC emissions have been relatively small, and this has led to an increase in O₃ concentrations in many regions. Regional VOC emission controls are hence urgently needed to maximise the effectiveness in reducing surface O₃ pollution in China.
