**DIVERSE FORESTS FOR CLIMATE CHANGE:
DROUGHT STRESS TOLERANCE OF SECONDARY
TIMBER SPECIES**

Dissertation

zur Erlangung des mathematisch-naturwissenschaftlichen Doktorgrades

”Doctor rerum naturalium”

der Georg-August-Universität Göttingen

im Promotionsprogramm

Biodiversity and Ecology

der Georg-August-University School of Science (GAUSS)

vorgelegt von

Sebastian Mario Fuchs

aus

Schwalmstadt

Göttingen, Dezember 2020

- Version zur Veröffentlichung, Juli 2021 -

Thesis committee:

- Prof. Dr. Christoph Leuschner, Abteilung Pflanzenökologie und Ökosystemforschung, Universität Göttingen
- Prof. Dr. Dirk Hölscher, Abteilung Waldbau und Waldökologie der Tropen, Universität Göttingen
- Prof. Dr. Bernhard Schuldt, Lehrstuhl für Ökophysiologie und Vegetationsökologie, Universität Würzburg

Examination board:

- Prof. Dr. Christoph Leuschner, Abteilung Pflanzenökologie und Ökosystemforschung, Universität Göttingen
- Prof. Dr. Dirk Hölscher, Abteilung Waldbau und Waldökologie der Tropen, Universität Göttingen
- Prof. Dr. Bernhard Schuldt, Lehrstuhl für Ökophysiologie und Vegetationsökologie, Universität Würzburg
- Prof. Dr. Holger Kreft, Abteilung Biodiversität, Makroökologie und Biogeographie, Universität Göttingen
- Prof. Dr. Hermann Behling, Abteilung Palynologie und Paläoökologie, Universität Göttingen
- Prof. Dr. Erwin Bergmeier, Abteilung Vegetationsanalyse und Phytodiversität, Universität Göttingen

Date of the oral examination: 12.01.2021

SUMMARY

Accelerated climate warming in the past decades and a recent increase in the frequency and severity of summer heat-waves in combination with more irregular summer precipitation challenge silvicultural concepts in Europe's temperate forest region, as some of the main timber species seem to be relatively susceptible to drought and possibly also heat. Notably, Norway spruce (*Picea abies* (L.) H. Karst.) and European beech (*Fagus sylvatica* L.) showed drought-related dieback and vitality losses. For that reason, concepts to admix and promote native, putatively drought-tolerant, minor timber species are gaining growing interest in Central Europe. Norway maple (*Acer platanoides* L.), common hornbeam (*Carpinus betulus* L.), European ash (*Fraxinus excelsior* L.), and small-leaved lime (*Tilia cordata* Mill.) are promising candidates due to their occurrence in the more continental climate of Eastern Europe and scattered knowledge from ecophysiological studies.

The present thesis assessed the drought tolerance of the four aforementioned species in comparison to sessile oak (*Quercus petraea* Matt. Liebl), a well-studied, drought-tolerant, and major timber in Central Europe. A combination of three methodological packages was applied to quantify drought tolerance, namely plant hydraulic traits, fine root inventories and dendroecology. To allow for quantification of the species' plasticity, the assessment was accomplished in a field study along a precipitation transect from putatively optimal to relatively dry conditions (mean annual precipitation range from ca. 900 to 500 mm) around the Harz mountain range in Central Eastern Germany.

Hydraulic efficiency- (xylem conductivity and Huber value) and safety-related traits (xylem embolism resistance, leaf turgor loss point, hydraulic safety margins) were quantified from sun-exposed branches from the uppermost canopy. Although a certain intra-specific trait variability in safety-related traits was observed, the magnitude was small compared to interspecific variability. In contrast, efficiency-related traits showed a high intra-specific trait variability both within populations and within the crowns of single trees. Surprisingly, the observed ITV of all traits was neither driven by climatic or soil water availability, nor by tree height, indicating a complex control of adult trees' hydraulic traits by the environment. *A. platanoides* and *C. betulus* showed very wide safety margins, a highly resistant xylem and higher trait plasticity, whereas *T. cordata* was vulnerable to embolism and operated with consistently narrow margins.

Fine root inventories in the uppermost mineral soil were carried out in spring under ample water supply and after extreme summer drought in 2018, assessing fine root biomass, necromass and morphology. The extent of the root necromass/biomass ratio (N/B) increase and reductions in root tip frequency were used as a measure of the species' belowground sensitivity to water deficits. *Q. petraea* showed the smallest fine root density and was the only species not increasing N/B towards drier sites and without losses of root tips after summer drought, indicating the most conservative and resistant fine root system. The other species showed a more susceptible fine root system with distinctly increased N/B towards drier sites, mostly elevated N/B after summer drought (especially on moister sites), and throughout reduced root tip frequencies in response to drought.

For the dendroecological assessment, climate-growth relationships, their temporal variation, and the resistance and resilience to climatic droughts was analyzed from increment cores for the past 50 years. While growth responded in all four species positively to summer precipitation and negatively to higher summer temperature and climatic aridity, climate sensitivity of growth decreased in the period of 1967-2016. None of the species showed negative growth trends with recent climate warming and drought sensitivity was not higher at drier sites, indicating a considerable acclimation and adaptation potential. The resistance of radial growth to drought was higher in ring-porous species (*F. excelsior*, *Q. petraea*) in comparison to diffuse-porous species (*A. platanoides*, *T. cordata*), but resilience was high in all species.

The findings of the present work and knowledge from literature were combined to a synoptic evaluation of the species' abilities to withstand drought and an integration of the drought response strategies into the isohdry-anisohdry syndrome. *Q. petraea* and *F. excelsior* are strictly anisohydric and highly drought-tolerant, keeping up high productivity under unfavorable water supply. However, *F. excelsior* is severely threatened by the fungus *Hymenoscyphus fraxineus*, causing a pan-European ash dieback and rendering any recommendations for silvicultural planning impossible in the near future. *A. platanoides* is strictly isohydric with high hydraulic safety, accepting temporary reductions of productivity for the sake of a low drought-related mortality risk. *T. cordata* did not prove to be highly drought-resistant overall, but pursues a unique semi-isohydric strategy with high stem and leaf water capacitance, buffering well against mediocre droughts. *C. betulus* showed no drought-resistant fine root system, but fairly drought-resistant hydraulic properties. Early leaf shedding and radial growth stagnation seem to

be safety mechanisms of *C. betulus* in order to provide a certain tenacity in coping with unfavorable conditions.

In comparison to *F. sylvatica* and *P. abies*, all five species seem to be more drought-resistant, and especially *A. platanoides* (in addition to *Q. petraea*) deserves a broader consideration in silvicultural concepts targeted at adapting production forests to climate warming.

1 GENERAL INTRODUCTION

1.1 Climate warming and drought intensification affect forest ecosystems

Anthropogenic global warming already reached about 1°C above preindustrial levels and is estimated to continue to increase to more than 1.5°C until 2050 under constant rates of greenhouse gas emissions (IPCC, 2014). The continuously rising temperatures since the 1980s affect ecosystems directly, but also via increasing vapor pressure deficits of the atmosphere (Held and Soden, 2006; Schuldt et al., 2020) leading to a higher likelihood and severity of drought conditions (Trenberth et al., 2014). Under ongoing drought, this is a self-enhancing process due to positive feedbacks of reduced evaporative cooling on surface temperatures (Breshears et al., 2013; Maness et al., 2013). The predicted increase in intensity and frequency of severe heat waves in Central Europe (Schär et al., 2004) is already reality (Christidis et al., 2015; Ionita et al., 2017). Additionally, summer precipitation rates are expected to decrease and become more irregular in many areas in Central Europe (IPCC, 2014; Fischer et al., 2014; Rowell and Jones, 2006), and the increase of precipitation deficits may even accelerate quicker than predicted (Orth et al., 2016).

Around the globe, forests are important sources of a wide range of economic and ecological services, ranging from their prominent role in primary production, CO₂ fixation and climate regulation, over pedogenesis and groundwater replenishment, to timber and food production (Bonan, 2008). Additionally, forest ecosystems are home to the biggest fraction of global biodiversity and provide a variety of socio-cultural benefits like recreational space and spiritual value (Hassan et al., 2005). Forests worldwide, however, are affected by climate change (Bonan, 2008). Possible effects include positive feedbacks (e.g. CO₂ fertilization, reduced frost impacts, longer growing seasons) as well as negative impacts (e.g. reduced productivity due to stomatal limitations, heat- and drought stress induced vulnerability to pests and pathogens and drought-induced hydraulic failure and mortality; Allen et al., 2010; Ayres and Lombardero, 2000; McDowell et al., 2011). In the past decade, though, the number of reviews and studies reporting negative impacts of climate warming on forests, increased steeply. This includes drought-induced mortality rates (e.g. Allen et al., 2010; Anderegg et al., 2013; Breshears et al., 2018; Schuldt et al., 2020; Senf et al., 2018; Senf et al., 2020) and reduced

growth and vitality (e.g. Sanginés de Cárcer et al., 2018; Yuan et al., 2019), covering a wide range of different forest types and climates. Accordingly, within all climatic extremes, drought was evaluated as the biggest global constraint on forest productivity (Choat et al., 2018; Reichstein et al., 2013).

A change in the drought characteristics over the past decades is a very plausible explanation for the former underestimation of global forest vulnerability to drought-related mortality due to global warming. This phenomenon is usually referred to as “global-change-type droughts” (Breshears et al., 2013) or “hotter droughts” (Allen et al., 2015), where water supply deficits are combined with extraordinarily high temperatures. Besides the above-mentioned additional effects of temperature on evaporative demand, higher temperatures lead to steeply increasing residual water losses in trees due to a non-linear change of cuticular permeability above 40°C (Riederer and Schreiber, 2001; Schuster et al., 2016). The role of residual water loss that cannot be mitigated by stomatal control was highlighted in recent literature and should be considered in ecosystem models (Cochard, 2019; Duursma et al., 2019).

Particularly in the context of rapidly accelerating climate change, understanding and predicting possible future forest declines in order to mitigate negative impacts on the global biosphere remain one of biggest challenges for ecologists (Boisvenue and Running, 2006; Bonan, 2008)

1.2 Drought vulnerability of primary timber species in Germany

In Central Europe, water availability is a key determinant of forest species composition and productivity (Bréda et al., 2006; Leuschner and Ellenberg, 2017) and changes in species composition under a drier climate in the future can be expected (Buras and Menzel, 2019). The latest increase in frequency of severe drought and heatwaves (Christidis et al., 2015; Schuldt et al., 2020) in combination with a sharp increase of observed tree mortality (Braun et al., 2020; Schuldt et al., 2020; Senf et al., 2020) and overall loss of forest vitality (Waldzustandserhebung Deutschland, 2019) highlight the fact, that forest transitions with a change of species composition imply broad-scale mortality events. This fundamentally affects a wide range of environmental processes and ecosystem services (Allen et al., 2015; Anderegg et al., 2013; Breshears et al., 2011). Thus, smoothing this process by anticipatory and sustainable silvicultural planning and management is of major importance.

Norway spruce (*Picea abies* [L.] H. Karst) is the most abundant tree species in Germany and its area has expanded far beyond the limits of its natural range in the 20th century (Spiecker, 2000). There is broad consensus on its sensitivity to drought and its ongoing decline due to climate change (Hanewinkel et al., 2013; Mäkinen et al., 2002; Pretzsch et al., 2013; Spiecker, 2000; Vitasse et al., 2019; Zang et al., 2014). Large-scale dieback in the past few years due to drought-related predisposition and bark beetle infestation has confirmed the concerns (Waldzustandserhebung Deutschland, 2019; Rigling et al., 2019).

Three other major timber species in Germany, European beech (*Fagus sylvatica* L.), Scots pine (*Pinus sylvestris* L.), and sessile oak (*Quercus petraea* (Matt.) Liebl.) have been regarded as relatively drought tolerant for decades (Roloff and Grundmann, 2008), but especially in case of *F. sylvatica*, this has become a matter of intense debates in the post-millennial decade (Ammer et al., 2005; Bolte, 2005; Leuschner, 2009; Rennenberg et al., 2004). Meanwhile, despite its high adaptability and plasticity (Roloff and Grundmann, 2008; Schuldt et al., 2016), reports on high climate sensitivity of radial growth (Cavin and Jump, 2017; Michelot et al., 2012; Scharnweber et al., 2011; Walentowski et al., 2017; Weber et al., 2013), long-term growth declines due to climate change (Latte et al., 2016; Scharnweber et al., 2011; Zimmermann et al., 2015), potential loss of dominance in mixed stands (Cavin et al., 2013; Mette et al., 2013), increased mortality after the drought year of 2018 (Waldzustandserhebung Deutschland, 2019; Schuldt et al., 2020), and legacy effects on crown vitality in years after drought (Bréda et al., 2006; Schuldt et al., 2020) emerged.

P. sylvestris is one of the most common species on drier sites in Germany, especially on nutrient-poor, sandy soils in the eastern federal states (Roloff et al., 2010), but is also increasingly affected by drought (Buras et al., 2018; Dobbertin et al., 2005; Rigling et al., 2013; Walentowski et al., 2007). Additionally, *P. sylvestris* is known to be a very weak competitor in mixed stands under ample nutrient availability and may therefore only be an option on sandy soils – even more in the light of increasing nutrient leaching from agriculture (Roloff and Grundmann, 2008).

Q. petraea, on the other hand, has proven its high growth resistance to drought events in many dendroecological studies (e.g. Mette et al., 2013; Scharnweber et al., 2011; Zang, 2011), is known to be a deep-rooting species with a drought-resistant fine root system (Leuschner et al., 2001; Roloff and Grundmann, 2008), and has a remarkably resistant hydraulic system in comparison to co-occurring species (based on xylem resistance to

embolism and hydraulic safety margins; Dietrich et al., 2019; Lobo et al., 2018; Schuldt et al., 2020). On the other hand, the genus *Quercus* is susceptible to infestations with pests, insects, and fungi as well as partly inexplicable vitality losses in Central Europe over the past decades (Donaubaur, 1998; Gibbs and Greig, 1997; Roloff et al., 2010). Still, *Q. petraea* is one of the major timber species in Germany that is better suited for climate change, also because of its thermophilic characteristics (Roloff and Grundmann, 2008).

Considering the above, in the sub-continental central-eastern part of Germany with mean annual precipitation sums of 500 mm and below, some of the primary timber species are already operating close to or even beyond the drought limitations of their bioclimatic envelopes (Kölling, 2007). In the context of climate change, forests in such drought-prone areas might approach the point for a substantial ecological transition in near future, which highlights the urgent need to identify timber species suited to cope with these climatic changes.

The promotion and establishment of alternative, more drought-tolerant species is broad consensus in silviculture, but the criteria for the choice of these species are heavily debated. One popular perspective is the introduction and promotion of species that are already established major timbers in other regions and known to be productive on relatively arid sites, such as Douglas fir (*Pseudotsuga menziesii* [Mirbel] Franco; Eilmann and Rigling, 2012; Isaac-Renton et al., 2014) and European black pine (*Pinus nigra* J.F. Arnold; Eilmann and Rigling, 2012). However, this approach raises concerns regarding unknown effects on native biodiversity (Felton et al., 2016) and unpredictable risks regarding future susceptibility to pests (Roques et al., 2019). For that reason, there is growing interest in concepts of admixture and promotion of native and putatively drought-tolerant species that are naturally widespread, but only minor timbers (Brang et al., 2008; Grundmann and Roloff, 2009; Kunz et al., 2018; Kunz and Bauhus, 2015).

1.3 Portraits of the studied minor timber species

The tree flora of Central Europe contains several tree species of the genera *Acer*, *Carpinus*, *Fraxinus*, *Quercus*, *Sorbus* and *Tilia*, which occur also in the more continental climate of eastern Central and Eastern Europe, indicating that they might be more drought tolerant than the major timbers. According to general assessments of the drought tolerance of native minor timbers in Germany, several species might be suitable for promotion and establishment in forests in Central Europe in a future drier climate.

Norway maple (*Acer platanoides* L.), field maple (*Acer campestre* L.), small-leaved and large-leaved lime (*Tilia cordata* Mill. and *Tilia platyphyllos* Scop.), European hornbeam (*Carpinus betulus* L.), European ash (*Fraxinus excelsior* L.), the wild service tree (*Sorbus torminalis* (L.) Crantz), and the service tree (*Sorbus domestica* L.) are expected to be relatively drought tolerant based on their distribution ranges towards continental parts of eastern Europe (Figure 1.1), their occurrence on edaphically dry sites or their ecophysiological traits (Hemery et al., 2010; Köcher et al., 2009; Leuschner et al., 2019; Leuschner and Meier, 2018; Roloff and Grundmann, 2008). *Sorbus* species, *A. campestre* and *T. platyphyllos* were already subject of recent studies comparing their drought tolerance to major timbers (Kunz et al., 2018; Walentowski et al., 2017). Thus, we focus here on *A. platanoides*, *C. betulus*, *F. excelsior*, and *T. cordata* and compare them to the well-studied and drought-tolerant major timber *Q. petraea*.

These species are widespread in Central and East Europe (Figure 1.1) with natural occurrences in various types of broadleaf mixed forest communities of the phytosociological alliances Carpinion betuli (oak-hornbeam forests) and Tilio-Acerion (mixed maple slope forests), in which European beech (*Fagus sylvatica*), the dominant species of Central Europe's natural forest vegetation, is rare or absent (Leuschner and Ellenberg, 2017). The four minor timbers are less competitive than *F. sylvatica* and more demanding in terms of soil base saturation than *F. sylvatica*, but their competitive ability increases on dry, shallow, and rocky soils (Roloff et al., 2010).

1.3.1 *Acer platanoides* (Sapindaceae)

A. platanoides grows mainly on nutrient-rich sites with medium to high base saturation and is intolerant to highly acidic soils (Caudullo and de Rigo, 2016). It often occurs widely scattered in low frequencies in mixed forests due to its low competitive potential in comparison to most other broadleaves. Only the seedlings are shade-tolerant, adult trees need increasingly more light (Roloff et al., 2010). In Central Germany, it gains competitive advantages over *F. sylvatica*, *F. excelsior* and *Acer pseudoplatanus* on shallow, calcareous soils, upper slopes, and in open stands because of its thermophilic and heliophilic characteristics (Roloff et al., 2010). Due to massive seed production and drought and shade tolerant saplings (Kunz et al., 2016; Roloff et al., 2010), *A. platanoides* has a very high natural regeneration potential which is mostly inhibited by browsing damage (Roloff et al., 2010). The wood is diffuse-porous, well-suited for woodworking and therefore often utilized for furniture production. Additionally, special fields of

application include the construction of bows and music instruments due to its elasticity and attractive grain figures (Caudullo and de Rigo, 2016; Schütt and Aas, 1992).

Several general assessments attribute *A. platanoides* a good aptitude to play a bigger role in drought-tolerant mixed broadleaf forests in the future (Hemery et al., 2010; Leuschner and Meier, 2018; Roloff and Grundmann, 2008). Its distribution range reaches relatively continental climates in the Ukraine and towards the southern Ural and it serves as ornamental tree in many cities where summer microclimate is often much drier and warmer compared to forest sites. *A. platanoides* has been compared in dendroecological studies to *Q. petraea* and *F. sylvatica* in a set of minor broadleaves by Kunz et al. (2018) in south-west Germany and by Zimmermann et al. (2015) in central Germany, attesting relatively strong growths depressions in drought years, but also a high resilience due to quick and full growth recovery afterwards. This behavior is most probably due to the strictly isohydric and drought-avoiding strategy of *A. platanoides*, conservatively sacrificing carbon assimilation for the sake of a safe and intact hydraulic system: Low xylem water potentials and xylem embolism are avoided by rigid stomatal control (Leuschner et al., 2019) and wide hydraulic safety margins (Messinger, 2017, unpublished). Summarizing the above, *A. platanoides* might be well suited to grow in a warmer and drier climate in the future in Germany and serve as a surrogate timber in regions where *F. sylvatica* is declining.

Figure 1.1: Distribution ranges of the four minor timber species (*A. platanoides*, *C. betulus*, *F. excelsior*, and *T. cordata*) and two major timbers (*Q. petraea* and *F. sylvatica*) based on the synthetic chorology database of Caudullo (2017).

1.3.2 *Carpinus betulus* (Betulaceae)

Generally, *C. betulus* is widespread and very common in most parts of Europe (except for northern and southern margins), but because of its irregular stem shape, spiral growth and mediocre qualities for woodworking (strong shrinkage and poor elasticity), economic interest in this species is low and scientific literature is scarce (Praciak, 2013; Sikkema et al., 2016). However, it occurs in admixture in many varieties of oak- and beech-dominated forests because of its exceptional shade tolerance (Leuschner and Ellenberg, 2017) and has a high ecologic value due to its ability to improve soil quality in mixed stands (enhances litter decomposition and mineralization; Dziadowiec, 2014; Roloff et al., 2010). Except for highly acidic sites, *C. betulus* tolerates a very wide range of edaphic conditions from sub-acidic to calcareous soils and from nutrient-poor sand to heavy clay (Praciak, 2013; Roloff et al., 2010). It also occurs on very shallow and rocky soils as well

as on heavily disturbed sites due to its resilience to mechanical disturbance and high vegetative regeneration potential (Sikkema et al., 2016).

Its drought tolerance has barely been evaluated and dendro-ecological studies are missing completely. Also, its southern and eastern distribution margins (slightly more continental compared to *F. sylvatica*, Figure 1.1) are not particularly insightful. Nevertheless, from the perspective of plant-water relations, *C. betulus* shows surprisingly drought tolerant properties including a high embolism resistance and wide safety margins (Schuldt et al., 2020). Additionally, Köcher et al. (2009) judged this species as fairly drought tolerant in comparison to other Central European broadleaves based on leaf water status and sap flux measurements in response to dry soils.

Hence, *C. betulus* can be expected to play an ecologically important part in mixed forests on drier sites in the context of climate change.

1.3.3 *Fraxinus excelsior* (Oleaceae)

This species occurs on a wide range of nutrient-rich, basic soil types and is most productive on moist and deep soils. It has, however, a very broad amplitude regarding water availability, as it becomes a dominant component in forests on either dry calcareous slopes or deep, nutrient-rich alluvial soils, both unfavorable conditions for otherwise dominant *F. sylvatica* (Dobrowolska et al., 2011; Leuschner and Ellenberg, 2017). This fragmentation of the realized niche to the extremes of the physiological amplitude gave birth to the differentiation in two ecotypes (so-called “water-ash” on wet and “chalk-ash” on dry sites), but this theory has been proven wrong (Roloff et al., 2010; Weiser, 1995). In juvenile stages, *F. excelsior* is very shade tolerant, but light demand increases sharply with age, resulting in high mortality among middle aged ashes in dense stands (Dobrowolska et al., 2011). The wood is ring-porous and valuable for tool production, furniture and interior construction due to its high tensile and flexural strength (Kollmann, 1941; Roloff et al., 2010).

Based on preferred habitats and indicator values (Ellenberg et al., 1991; Leuschner and Ellenberg, 2017), *F. excelsior* has often been judged as adapted to ample water supply (Roloff and Grundmann, 2008). Studies on its drought resistance are rare, Zimmermann et al. (2015) attested *F. excelsior* a high resistance to drought (comparable to *Q. petraea*) based on long-term trends and climate sensitivity of radial growth. A few other dendroecological studies were either conducted on moist study sites (Weemstra et al., 2013) or only assessed very general climate-growth relationships (Koval and Maksymenko, 2020; Roibu et al., 2020) and are not suited to evaluate the ability to grow

on arid sites with respect to its remarkable physiological plasticity. This plasticity also finds expression in a highly adaptive xylem embolism resistance in dependence of the site water availability (Lemoine et al., 2001). Additionally, *F. excelsior* is exceptionally anisohydric with a drought tolerance strategy (rather than drought avoidance; Carlier et al., 1992; Leuschner et al., 2019), keeping stomata open even at predawn water potentials near -5 MPa (Carlier et al., 1992). In combination with its distribution range across the Balkans, the Ukraine and the southern Caucasus region, *F. excelsior* is a promising candidate for a warmer and drier climate in the future.

However, *F. excelsior* is existentially threatened by the pan-European ash dieback due to the fungus *Hymenoscyphus fraxineus* (Enderle, 2019; Erfmeier et al., 2019; Pautasso et al., 2013). Dependent on the further progress of this disease and its possible mitigation due to climate change (Goberville et al., 2016; Grosdidier et al., 2018), *F. excelsior* might still be an option for future silviculture.

1.3.4 *Tilia cordata* (Malvaceae)

T. cordata has the widest natural distribution range within the set of the above-mentioned species (Figure 1.1), with common occurrences from West Europe to Central Siberia in the steppe-forest ecotone (Roloff et al., 2010; Schütt and Aas, 1992). In western parts of Europe, its silvicultural role is rather minor, but in Central Eastern Europe its abundance, silvicultural appreciation and competitive strength rises with increasing continentality (Jaegere et al., 2016). Historically, *T. cordata* has even been a semi-dominant major species in temperate primeval woodlands in Eastern Europe (Jaegere et al., 2016) because of its high shade tolerance and its mid- to late-successional character in forest dynamics (Leuschner and Ellenberg, 2017). Additionally, its growth rates are relatively high under favorable water and nutrient conditions (Jaegere et al., 2016). Its wood is diffuse-porous, semi-soft, bright and evenly colored, and has a very balanced shrinkage-behavior in axial and radial directions. Therefore, it is very well-suited for turnery and small applications and veneers in furniture production, but never used in construction (Roloff et al., 2010).

In comparison to co-occurring species in Central Europe, *T. cordata* is thermophilic (Hemery et al., 2010) but still highly frost-tolerant (Till, 1956). It is tolerant to a wide range of soil fertilities, fairly insensitive to soil acidity and grows on semi-moist to very dry and shallow sites. However, waterlogged conditions are avoided (Jaegere et al., 2016; Roloff et al., 2010).

T. cordata tolerates drought with a fairly unique strategy, not easily assessable within the isohydric-anisohydric spectrum. Literature is inconsistent on this matter (Köcher et al., 2009; Leuschner et al., 2019; Moser et al., 2016) because of a semi-isohydric stomatal control and a tight safety margin due to its vulnerable xylem (Messinger, 2017, unpublished; Schuldt et al., 2020). This “risky” strategy is only possible because of its extraordinary water capacitance on stem- (Köcher et al., 2013) and leaf-level (Leuschner et al., 2019), buffering over periods of water shortage. Thus, *T. cordata* can tolerate short to medium periods of drought easily (Hemery et al., 2010; Köcher et al., 2009; Köcher et al., 2012), but its radial growth is strongly affected by prolonged periods of drought (Kulagin and Shayakhmetov, 2007). Still, its ability to recover from drought and its long-term resilience to frequent droughts is higher in comparison to *F. sylvatica* (Latte et al., 2020).

According to Jaegere et al. (2016), almost all known aspects about its biology are indicative that *T. cordata* is a well-suited and underused timber species for admixture in Central European forests in the face of climate change, and that studies and field observations are urgently needed for further determination of its potential.

1.4 Comprehensive assessments of vulnerability to drought: A multi-method approach

Conventional and general assessments of the suitability of tree species in a warmer and drier climate are often based on climate envelopes (e.g. Kölling, 2007) or species distribution models (e.g. Falk and Hempelmann, 2013). These correlative approaches are a valuable instrument for a first estimate but lack ecophysiological explanations (Walentowski et al., 2017). Criticism further includes the over-simplistic nature of climate parameters and exclusion of extreme events, the omission of edaphic factors, and, most importantly, the missing consideration of plasticity and adaptability of the species to temporal climate variations (Bolte et al., 2008). Available assessments based on the reaction of potted plants or saplings to artificial drought conditions can hardly be extrapolated to mature stands (Cavender-Bares and Bazzaz, 2000; Cornelissen et al., 2003).

To comprehensively address the drought tolerance of the species and to enable a comparison between them, a combination of three methodological packages was chosen:

- plant hydraulic properties (xylem vulnerability to embolism, leaf turgor loss point, hydraulic safety margins, xylem efficiency),

- fine root inventories (biomass, necromass and morphology after moist and dry periods), and
- dendroecology (climate-growth relations, drought induced increment reductions and recovery)

To allow for a quantification of the species' plasticity, the assessment was accomplished in a field gradient study along a precipitation transect from putatively optimal to relatively dry conditions (mean annual precipitation range from ca. 900 to 500 mm). This allows for the deduction of precipitation limits of changes in increment, physiological parameters, and stress indicators (e.g. fine root mortality) and is a "space-for-time substitution" (Pickett, 2012) to project responses to spatially increasing drought exposure towards prospective climate change.

1.4.1 Plant hydraulics

Survival and productivity of trees under drought are intimately associated with their ability to supply water to their leaves by avoiding excessive formation of embolism in their hydraulic system (Maherali et al., 2004). Under drought, stomatal control over transpiration (and simultaneously CO₂ uptake) is an important mechanism to keep the xylem tension below a critical value and hence control the risk of embolism formation. This balancing act mediates between two interconnected physiological mechanisms (i.e. carbon starvation and hydraulic failure) that explain reduced tree productivity and increased mortality following severe drought exposure (McDowell et al., 2008; McDowell et al., 2011). Xylem vulnerability to embolism and the leaf turgor loss point (the capacity of a leaf to maintain its turgor during dehydration) are important hydraulic traits to describe the ability of a given species to withstand drought. The hydraulic safety margin is usually defined as the width of the water potential safety-buffer between stomatal closure and excessive embolism formation in the xylem (Meinzer et al., 2009). It is a measure of the conservatism of a plant's stomatal control strategy (Choat et al., 2012). Trees with smaller safety margins operate closer to the threshold of runaway embolism formation and are therefore more prone to hydraulic failure (Choat et al. 2012).

For the four minor timbers, comparative assessments of leaf-water-relations, stomatal control strategies, stem sap flow, and stem water storage are available (Köcher et al., 2009; Köcher et al., 2013; Leuschner et al., 2019). However, magnitude of the mentioned hydraulic traits and particularly their plasticity in dependence of environmental conditions have rarely or never been assessed on mature trees. Here, a set of hydraulic traits was quantified from sun-exposed branches and leaves from the upper canopy of

mature trees across the climatic gradient in order to compare the species' embolism resistance, their drought-tolerance/-avoidance strategies, and their ability to adapt to drier conditions.

1.4.2 Fine root inventories

Information on the below-ground drought responses of all four species are completely missing yet. How tree roots and the root system respond to drought is increasingly a matter of debate, but the empirical data basis is quite limited, especially for mature trees. Optimal partitioning theory predicts that trees tend to increase their root-to-shoot ratio under conditions of limited water availability to increase their absorptive capacity in relation to the transpiring surface (Brunner et al., 2015; Reich, 2002), but evidence from field studies is scarce. In contrast, literature is consistent on increased fine root mortality as a consequence of drought exposure, reflected by elevated necromass/biomass ratios. Fine root may just die due to dehydration, but active root shedding was also proposed as physiological explanation, where fine roots act as hydraulic fuses, uncoupling the rest of the hydraulic system from low water potentials in the dry soil to avoid embolism formation in more expensive plant organs (Alder et al., 1996; Jackson et al., 2000). The necromass/biomass ratio can be seen as an integral over the processes of root mortality and the production of new fine roots during the observation period, thus reflecting both, the root system's resistance to drought and its resilience after drought. The ratio has therefore been used in several studies and reviews as an inverse indicator of tree and root system vitality under exposure to drought or chemical stress (Persson and Stadenberg, 2010; Puhe, 2003; Wang et al., 2018).

Two fine root inventories were carried out across the climatic gradient, addressing biomass, necromass and morphology. The first inventory assessed the parameters under ample water supply after average spring conditions in April, and the second inventory was conducted after the exceptionally dry summer in 2018 with extended rainless periods on all study sites.

1.4.3 Dendroecology

The analysis of annual radial increment over many decades with respect to climatic drivers and the impact of exceptional drought events is a powerful tool to gain information about the climate sensitivity of trees. Arguably, temporal increment reductions are not unambiguously representing a species' vulnerability to drought (Lloret et al., 2011; McDowell et al., 2008; Walentowski et al., 2017), but also indicating an adaptive

mechanism to cope with drought (e.g. by adjusting xylem anatomy or by increasing carbon allocation to roots). However, the reduction of radial increment is, besides mortality, one of the most important economic aspects of drought impacts.

Most of the existing dendroecological studies on minor timbers either did not allow for a comparison between species or did not take the spatial or temporal plasticity of the species into account. The few studies that partially did so (Kunz et al., 2018; Walentowski et al., 2017) were addressing mainly other species and were conducted in the South German Uplands and not on Pleistocene grounds.

Here, classical dendroecological methods were applied, including climate sensitivity analyses (annual climate-growth relationships) and superposed epoch analyses of the growth response to drought years. Since climate-growth relationships are usually non-stationary (Wilmking et al., 2020), temporal dynamics with respect to recent climate warming were additionally tracked in a moving window analysis (Biondi, 1997). Drought tolerance indices (resistance and resilience) according to Lloret et al. (2011) were calculated, compared between species and regressed against climatic and edaphic gradients of water availability.

1.5 Study area and design

The study was conducted in Central Germany in the transition zone between a sub-oceanic and a sub-continental climate in the rain shadow of the Harz Mountains (Figure 1.2). The study area is situated in the planar to colline zone (110-440 m a.s.l.) between the northern parts of the Central Uplands and its foothills towards the North German Plain which is characterized by a small-scale heterogeneity in geology. The study sites are located on leptic/vertic cambisols over Triassic limestone or on Pleistocene loose sediments over Triassic sandstone.

Figure 1.2: Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from the west to the east. The nine study sites are marked with red dots. The background colors and isohyets indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm north-east of Göttingen is the Harz mountain range. For further information on the study sites, refer to the detailed tables 2.1, 3.1, and 4.1 in the following chapters.

For minor timber species, mixed stands of comparable stand structure and tree age with presence of all five species under identical edaphic conditions are uncommon. As a consequence, not all species are present at all nine study sites, but every species occurs at least at five sites along the precipitation transect. Every site consists of several mixed forests of variable species composition in a maximum distance of several hundred meter to a few kilometers to each other. All investigated stands are of mature age (range: 69–139 years), with the exception of two older oak stands (170 years). To ensure that climate and weather are the predominant factors for water availability, steep slopes (inclination $> 5^\circ$), groundwater influence, stagnant moisture and very shallow soils were avoided. To address the differences in soil types, chemical and physical soil properties were recorded for each species on each site separately, including modelled plant available water storage capacity based on soil texture classes, bulk density and soil depth.

1.5.1 Limitations

In case of *C. betulus*, dendrochronological analyses were not possible because of long sections of indistinguishable annual rings in almost all increment cores. Neither different planing, sanding or coloring techniques, nor the microscopic analysis of whole-core microsections solved this problem. Apparently, *C. betulus* shows longer periods of radial growth stagnation due to a relatively low tree height and competitive strength in mixed stands, especially in earlier stages of ontogeny. If partially suppressed, *C. betulus* allocates a bigger fraction of its carbon budget to the development of its crown, resulting

in high branching and foliation density (Roloff et al., 2010). Thus, it was excluded from the dendroecological assessment.

The assessment of some important hydraulic traits (vulnerability to embolism, hydraulic conductivity, and hydraulic safety margins) were not possible for the ring-porous species (*F. excelsior*, *Q. petraea*). The underlying reason is the distinctly different xylem anatomy. Ring-porous species feature long xylem vessels, that do not allow to use of the centrifugation method in combination with standard-sized rotors due to the so-called “open-vessel artifact” (e.g. Martin-StPaul et al., 2014). An alternative method suited for long-vesseled species (bench dehydration; Sperry and Tyree, 1988) was applied, but the comparison of results from two different methods is highly error-prone. Despite literature confirming the comparability of the two methods, the high variability and inconsistency of our bench dehydration results suggested to refrain from doing so. Therefore, the chapter on plant hydraulic properties only include the diffuse-porous species (*A. platanoides*, *C. betulus*, *T. cordata*).

1.6 General study objectives

The present study is a comprehensive assessment of the drought resistance of four minor timber species (*A. platanoides*, *C. betulus*, *F. excelsior*, and *T. cordata*) in comparison to *Q. petraea* to identify species that are suitable for silviculture in the sub-continental climate of central and eastern Germany under warmer and drier conditions. The project’s aims were

- to compare the species’ resistance to embolism, hydraulic safety margins, and hydraulic efficiency of sun crown branches,
- to quantify the plasticity of hydraulic traits within species and populations and in dependence on edaphic and climatic water availability,
- to study adaptations of the fine root system of the five species to soil water deficits,
- to compare fine root mortality in reaction to extreme summer drought,
- to identify the most important climatic drivers of radial growth and compare them between the species, across the precipitation gradient, and over the past 50 years,
- to quantify the species’ drought-year induced growth reductions (‘resistance’ index) and the ability to reach pre-drought growth levels afterwards (‘resilience’ index), and
- to test how resistance and resilience change across the gradients of edaphic and climatic water availability.

The overarching goal of the study is the deduction of a drought resistance ranking of the five species. Drought resistance will be evaluated based on a synthetic discussion of the sections on plant-water-relations, drought sensitivity of the fine root system, dendroecology, and knowledge from literature. Drought resistance is defined here as a broader term to describe a species ability to withstand water stress, either by tolerance or by avoidance mechanisms (Levitt, 1980; Basu et al., 2016).

2.1 Abstract

Plant hydraulic traits are key for understanding and predicting tree drought responses. Information about the degree of the traits' intra-specific variability may guide the selection of drought-resistant genotypes and is crucial for trait-based modelling approaches.

For the three temperate minor broadleaf tree species *Acer platanoides*, *Carpinus betulus* and *Tilia cordata*, we measured xylem embolism resistance (P_{50}), leaf turgor loss point (P_{TLP}), specific hydraulic conductivity (K_s), Huber values (HV), and hydraulic safety margins in adult trees across a precipitation gradient. We further quantified trait variability on different organizational levels (inter-specific to within-canopy variation), and analyzed its relationship to climatic and soil water availability.

Although we observed a certain intra-specific trait variability (ITV) in safety-related traits (P_{50} , P_{TLP}) with higher within-tree and between-tree than between populations variability, the magnitude was small compared to inter-specific differences, which explained 78.4% and 58.3% of the variance in P_{50} and P_{TLP} , respectively. In contrast, efficiency-related traits (K_s , HV) showed a high ITV both within populations and within the crowns of single trees. Surprisingly, the observed ITV of all traits was neither driven by climatic nor soil water availability.

In conclusion, the high degree of conservatism in safety-related traits highlights their potential for trait-based modelling approaches.

Keywords: embolism resistance, Huber value, hydraulic conductivity, hydraulic plasticity, hydraulic safety margin, leaf turgor loss point, precipitation gradient, xylem safety.

2.2 Introduction

In many regions of central Europe, important primary timber species such as European beech (*Fagus sylvatica* L.) and Norway spruce (*Picea abies* [L.] H. Karst.) are approaching their drought limit (van der Maaten-Theunissen et al., 2013; Lévesque et al., 2014; Leuschner, 2020). Since 1980, this region has experienced a continuous increase in temperature and concomitantly in atmospheric vapour pressure deficit (Schuldt et al., 2020), which culminated in a massive tree dieback of these two primary timber species in many central European forests during the exceptional 2018/2019 drought (Braun et al., 2020; Schuldt et al., 2020; Senf et al., 2020). At least in the drier regions of central Europe, there is an urgent need to identify native timber species suited for production forests that better withstand drought and heat.

The survival and therefore overall fitness of trees under drought are intimately linked to their ability to supply water to the canopy by avoiding excessive formation of embolism in their hydraulic system in order to maintain a sufficiently high carbon gain (McDowell, 2011; Sapes et al., 2019). Two interconnected physiological mechanisms that explain reduced tree productivity and increased mortality following severe drought exposure, namely carbon starvation and hydraulic failure, have widely been discussed in the past since their introduction by McDowell et al. (2008). Recent results, however, indicate that hydraulic failure is the proximate cause of drought-induced tree mortality in various biomes (Rowland et al., 2015; Anderegg et al., 2016; Adams et al., 2017; Correia et al., 2019; Hajek et al., 2020; Powers et al., 2020; Arend et al., 2021; Nolan et al., 2021).

Hydraulic traits have widely been used to characterize plants in their disposition to suffer from hydraulic failure (Choat, 2013; Skelton et al., 2015; Choat et al., 2018), and to predict the effects of increased drought exposure on the productivity and mortality of woody plants (Choat et al., 2012; Anderegg, 2015; Anderegg et al., 2016). The link between productivity and mortality under drought is mirrored by the proposed trade-off between hydraulic efficiency and safety (Tyree et al., 1994; Sperry et al., 2008). According to said trade-off, plants are not able to simultaneously maximize the conductivity of their water transport system and minimize the risk of embolism formation. Studies across species and biomes provide moderate support for this hypothesis (Maherali et al., 2004; Lens et al., 2011; Gleason et al., 2016; Schumann et al., 2019), although opposite results exist (Torres-Ruiz et al., 2017). Within species, evidence for this trade-off seems to be even weaker (Burgess et al., 2006; Schuldt et al., 2016; but see Liang et al., 2019).

Two traits commonly used to describe a plant's hydraulic safety are the xylem water potential at 50% loss of hydraulic conductance (P_{50} ; Sperry & Tyree, 1988) and the water potential at the leaf turgor loss point (P_{TLP} ; Oppenheimer, 1963). Furthermore, P_{50} is directly related to the resistance of the xylem against embolism formation, while the P_{TLP} describes the capacity of a leaf to maintain its turgor during dehydration. Hydraulic efficiency, however, has often been associated with the xylem area-specific conductivity (K_s ; Farmer, 1918) or the Huber value (HV; Huber, 1928), i.e. the sapwood-to-leaf area ratio. Both parameters are major determinants of the ratio of a tree's assimilation rate to its xylem construction costs. These four traits are crucial for understanding the hydraulic variability of tree species and their potential to cope with drought. Adaptive modifications in these traits to different levels of water availability have been demonstrated across various species and biomes. Several studies observed higher hydraulic safety (Maherali et al., 2004; Schuldt et al., 2016; Larter et al., 2017; Zhu et al., 2018; Rosas et al., 2019) and lower hydraulic efficiency in drier environments (Maherali et al., 2004; Rosas et al., 2019). Intra-specific variability of P_{50} and P_{TLP} , however, has been much less studied in the past (Anderegg & Meinzer, 2015), and the few available studies on the response of hydraulic traits to water availability in mature trees of the same species produced contradictory results. For example, while some intra-specific studies indeed observed an increase in embolism resistance with declining water availability (Schuldt et al., 2016; Stojnic et al., 2018), others observed either the opposite (Herbette et al., 2010) or no relationship across climatic gradients (Martínez-Vilalta et al., 2009; Martin-StPaul et al., 2013; González-Muñoz et al., 2018; Rosas et al., 2019). In contrast, P_{TLP} has been found to decrease rather consistently with increasing aridity across (Lenz et al., 2006; Bartlett et al., 2012b; Mitchell & O'Grady, 2015; Zhu et al., 2018) and within species (Liang et al., 2019; Rosas et al., 2019; Pritzkow et al., 2020). One reason for the difference is that P_{50} depends on wood properties that are strongly conserved, while P_{TLP} is not static and can be adjusted actively by the plant to match the current environmental conditions.

Another explanation for the often missing relationship between xylem safety and climatic variables might be that most field studies on plant hydraulics neglect the role of soil hydrology, and only use climatic drought indices like the climatic aridity index. In order to characterize the aridity of a stand, however, variation in soil texture and soil hydraulic properties should likewise be acknowledged, as both properties can strongly affect tree hydraulics (Sperry & Hacke, 2002; Hultine et al., 2006; Waite et al., 2019). Congruently, several recent studies observed a close relationship between soil hydraulic

properties (as the soil capacity for plant-available water, AWC) and drought-induced tree mortality (Peterman et al., 2013; Hember et al., 2017; Rehschuh et al., 2017; Breshears et al., 2018).

The vulnerability of the hydraulic system to drought does not solely depend on the xylem resistance to embolism, but on the interaction of several physiological processes which includes the stomatal control strategy (e.g. Mencuccini, 2003; Choat et al., 2018). Hydraulic safety margins (HSMs) relate resistance on the xylem level to stomatal control (Meinzer et al., 2009), and trees with small safety margins operate closer to the threshold of runaway embolism formation and are therefore more prone to hydraulic failure (Choat et al., 2012). HSMs are usually defined as the difference between minimum leaf water potential (P_{\min}) and a measure of xylem embolism resistance (e.g. P_{50}), representing a measure of the conservatism in a tree's hydraulic strategy (Choat et al., 2012). Recently, the point of stomatal closure (P_{gs90} , 90% reduction of stomatal conductance) or P_{TLP} have been used instead of P_{\min} (Martin-StPaul et al., 2017; Ziegler et al., 2019; Powers et al., 2020), as measurements of the latter are labour-intensive and often unreliable.

While most central European studies investigating plant hydraulic traits and their variability under altered water availability focused on the four economically most important tree genera, *Picea*, *Pinus*, *Fagus*, and *Quercus*, only little is known about minor timber species. Yet, small-leaved lime (*Tilia cordata* Mill., Malvaceae), Norway maple (*Acer platanoides* L., Sapindaceae) and European hornbeam (*Carpinus betulus* L., Betulaceae) may be more drought-resistant than European beech and Norway spruce, the most important broadleaf and coniferous timber species in Germany. Under the prospect of climate warming, the importance of minor tree species might increase if they prove to be better adapted to a future warmer and drier climate and their wood is suited for the timber industry. In the absence of physiological data, the drought tolerance assessment of minor timber trees is mainly based on analyses of the climate envelope of the distribution ranges and comparative expert assessment based on habitat preferences in natural forests (Ellenberg et al., 2001; Niinemets & Valladares, 2006; Leuschner & Meier, 2018). Hence, there is an urgent need for more precise empirical data on the drought response of these minor timber species. In particular, information on traits associated with hydraulic safety and efficiency and their variability in response to shifts in water availability is largely missing.

To close this knowledge gap, we examined the variability of the four major hydraulic traits related to hydraulic efficiency and safety at the wood and leaf level (P_{50} , P_{TLP} , HV

and K_s , respectively) in three broadleaf, diffuse-porous tree species along a precipitation gradient in central Germany, and compared the species' drought tolerance in terms of their hydraulic safety margins. For doing so, we partitioned the variance in the four studied traits into the relative contributions of different hierarchical levels of variability, and computed the fraction of variance explained by species differences, by differences between populations, by individual differences within populations, and by random within-individual variability. Subsequently, we tested the hypothesis that within each species, the differences in hydraulic traits between populations are driven by climatic and edaphic water availability. We hereby assumed that traits related to hydraulic efficiency are more closely associated to water availability than traits related to hydraulic safety.

2.3 Material and Methods

2.3.1 Study sites and tree species

The nine study sites are situated along a precipitation gradient in west–east orientation in central Germany between Göttingen and Halle/S. at planar to colline elevation (110–440 m above sea level (asl)). The climate is cool temperate with mean annual temperatures (MATs) of 7.9 to 9.9°C. Mean annual precipitation (MAP) ranges between 528 and 918 mm and mean growing season precipitation (MGSP, April–September) between 291 and 412 mm, with a general decrease from west to east (Fig. 2.1). This represents a gradient from hydrologically optimal conditions to values close to the assumed drought limit of the species (Leuschner & Ellenberg, 2017).

Figure 2.1: Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from west to east. The study sites are marked with red dots, the background colours indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm northeast of Göttingen is the Harz mountain range.

Table 2.1: Site and tree characteristics of the studied stands sorted by species and in ascending order of the local climatic water balance (CWB). MAP = mean annual precipitation (period 1991–2017); MAT = mean annual temperature; MGSP = mean growing season precipitation (April–September); CWB = climatic water balance; soil texture is defined according to the nomenclature of the FAO (Food and Agriculture Organization of the United Nations); AWC = plant-available water storage capacity of the soil; DBH = Stem diameter at breast height. Tree age, DBH, and tree height are given as means with standard deviation. Tree age of all sampled individuals was determined with dendrochronological analyses for increment cores with the exception of *C. betulus*, which was not part of the dendrochronological study; age information was here derived from forestry inventory data of the local forestry offices

The three investigated tree species (*A. platanoides*, *T. cordata*, *C. betulus*) are naturally widespread in various types of central European broadleaf mixed forest communities of the phytosociological alliances *Carpinion betuli* (oak-hornbeam forests) and *Tilio-Acerion* (mixed maple slope forests, for species distributions see Appendix A, Fig. 2.5), where the dominant species of central Europe's natural forest vegetation (*F. sylvatica* L.) is rare or absent (Leuschner & Ellenberg, 2017). The three species are more demanding in terms of soil base saturation than *F. sylvatica*, but they also occur in more continental climates in eastern Europe and thus are thought to be more drought tolerant (Roloff & Grundmann, 2008; Roloff et al., 2010). While *F. sylvatica* is the most important broadleaf timber species in central European forestry, the three investigated species are only minor timbers. Therefore, mixed stands of comparable age, soil, and structure with presences of all three species are uncommon. Consequently, not all species were present at all nine study sites, but every species occurred in five stands along the precipitation gradient. Each site was composed of several mixed forest stands of variable species composition. The target species grew at a given site in a maximum distance of several hundred metres to a few kilometres to each other under comparable edaphic and climatic conditions. To take small-scale variation within a site into account, the edaphic and climatic conditions in the different stands were recorded separately for each species. All stands were located on level terrain (maximum inclination 5°) without groundwater influence.

2.3.2 *Climatic conditions*

Precipitation, air temperature, and potential evapotranspiration (PET) data were calculated from gridded data of 1 km mesh width retrieved from the German Weather Service (Deutscher Wetterdienst (DWD), Offenbach, Germany) database. The PET data of the DWD were calculated with the Penman–Monteith equation (Penman, 1948; Monteith, 1965; Löpmeier, 1994), the climatic water balance (CWB) was computed for the whole year as the difference of precipitation and PET.

Long-term annual means of climatic variables were calculated for the period 1991–2017, because PET data are available from DWD only since 1991. We tested our models with a variety of climatic parameters including long-term (27 yr) and short-term (2–5 yr) data of precipitation and evapotranspiration of whole year-periods and growing season-periods only. Because the ratio of summer precipitation to annual precipitation is almost constant, temperature is inversely proportional to precipitation along the transect, and short-term and long-term climate data did not differ notably in the 27-yr period, we

obtained very similar results for precipitation and CWB data and decided to report results for CWB only.

2.3.3 *Edaphic conditions*

The capability of soils to store water, which is available for plant uptake, is characterized by the AWC. We employed pedo-transfer functions according to Schaap et al. (2001), using the module ‘Rosetta’ implemented in the software Retc (v.6.02; van Genuchten et al., 1991), to estimate soil hydraulic properties (the so-called van Genuchten (1980) parameters) from local data on soil texture class and bulk density. The modelled water retention curves were used to retrieve the soil water content (in vol.%) at field capacity (soil matric potential of -0.03 MPa, pF 2.5) and at the conventional permanent wilting point (-1.5 MPa, pF 4.2). AWC was then calculated as the difference between these two water contents. Soil texture classes and soil bulk density were determined in samples taken in soil pits at 0–10 cm, 10–30 cm and 30–60 cm depth. Sand fractions were obtained by sieving, silt and clay fractions by gravitational sedimentation according to the international standard ISO 11277 with an integral suspension pressure method (Durner et al., 2017), using the Pario device (Metergroup, Munich, Germany). The profile total of AWC (in millimetres) of a given stand was obtained by adding the AWC values of the three measured layers for the 0–60 cm profile, and extrapolating AWC to 120 cm depth by assuming constant soil texture below 60 cm depth. The data of three pits per stand were averaged. In case of shallower soils, we used the measured average bedrock depth for AWC extrapolation.

2.3.4 *Tree selection and sampling*

Five mature trees of comparable size per species and site were selected. All trees belonged to the upper canopy (dominant or co-dominant individuals). Tree height (H) was comparable across the gradient except for *T. cordata*, where H decreased notably towards the drier sites (Table 2.1). In June and July 2017/2018, branches were collected from the uppermost sun-exposed canopy with tree-climbing equipment. Sampling took place in a rotating scheme so that sites and species were spread evenly across the sampled season and the studied years. Seasonal or year effects on the traits of interest were not detected. To decide for an appropriate sample length, we performed preliminary measurements with the air-injection method that suggested the maximum vessel length of all studied species was well below 20 cm. Per tree, six branches of 100 cm length were air-cut, re-cut to 50 cm under water, immediately transferred to plastic tubes filled with

de-ionized water, and stored at 4°C. Within five days, three of these branches were used to construct xylem vulnerability curves, and the remaining three used for hydraulic conductivity measurements and quantification of the total leaf area distal to the reference measuring point (basipetal end of the sample, 50–100 cm from the apex). Additionally, three distal twigs per tree with *c.* 5–10 mature and fully intact leaves were harvested from the uppermost canopy to determine turgor loss point. Twigs were recut under water and transported to the laboratory with the cut surface submerged in water bottles to enable rehydration over-night at 10°C and 100% air humidity. For all four measured variables (P_{50} , P_{TLP} , K_s , HV), each 75 samples per species were investigated (three branches \times five trees \times five sites), yielding 225 in total.

2.3.5 Hydraulic efficiency

For calculating HV, i.e. the sapwood-to-leaf area ratio, all leaves distal to the reference measuring point of a branch were scanned (Expression 11000XL; Epson Deutschland GmbH, Meerbusch, Germany) and analysed with WinFolia 2014 software (Régent Instruments, Quebec City, QC, Canada). In order to estimate the cross-sectional xylem area (A_{xylem} in mm²) without pith and bark at the reference measuring point, a linear regression was carried out between total cross-sectional area (A_{cross}) and A_{xylem} (cf. Hajek et al., 2014; Schuldt et al., 2016). Per species, 75 digitalized semi-thin transverse sections, taken at 1–3 cm proximal from the reference measuring point, were used. The obtained equations are as follows (Eqs. 1–3):

$$\text{Acer: } A_{xylem} = -5.84755 + 0.70525 \cdot A_{cross} \quad (R^2 = 0.98) \quad (1)$$

$$\text{Carpinus: } A_{xylem} = -2.02419 + 0.76517 \cdot A_{cross} \quad (R^2 = 0.98) \quad (2)$$

$$\text{Tilia: } A_{xylem} = -4.86760 + 0.56120 \cdot A_{cross} \quad (R^2 = 0.90) \quad (3)$$

For measuring hydraulic conductivity (K_h ; in kg m MPa⁻¹ s⁻¹), branches (mean reference point diameter \pm SE: 10.12 \pm 0.08 mm; mean length \pm SE: 298.83 \pm 0.46 mm; $n = 225$) were recut under water with a razor blade, lateral branches cut off and glued with quick-drying superglue working on wet surfaces in combination with an activator (Loctite 431 and 7452; Henkel, Düsseldorf, Germany). The value of K_h was measured along a 6 kPa-pressure gradient with the Xyl'em apparatus (Bronkhorst, Montigny les Cormeilles, France) after flushing the segments three times at 120 kPa with filtered, degassed, and demineralized water (10 mM potassium chloride and 1 mM calcium chloride). The value of K_s (in kg m⁻¹ MPa⁻¹ s⁻¹) was calculated by dividing K_h by A_{xylem} .

2.3.6 Hydraulic safety

Vulnerability curves were constructed with the flow-centrifuge method (Cochard et al., 2005) using a custom-made honeycomb rotor attached to a commercially available centrifuge (Sorvall RC-5C; Thermo Fisher Scientific, Waltham, MA, USA). Nonflushed branches (mean diameter at basipetal end \pm SE: 9.14 ± 0.07 mm; $n = 225$) were recut to 27.5 cm with a razor blade and exposed to increasingly negative water potentials starting at -0.8 MPa. Xylem water potential was lowered stepwise until the percentage loss of conductivity (PLC) reached at least 90% (Appendix A, Fig. 2.6). Nonlinear mixed-effects models (R package `nlme`; Pinheiro et al., 2020) were fitted for each species to estimate the xylem pressure at 50% loss of conductivity (P_{50}) and the slope of the curve at the inflexion point (s) according to the sigmoidal function given by Pammenter & van der Willigen (1998):

$$PLC = 100 / \left(1 + \exp\left(\frac{s}{25}(\Psi - P_{50})\right) \right) \quad (4)$$

where Ψ is the water potential and PLC the percentage loss of conductivity. Due to repeated measurements on the same sample and three investigated samples per tree, a hierarchical structure of random effects had to be considered in the statistical analysis. We allowed both s and P_{50} to vary with a site-specific fixed effect and random effects for trees and samples nested in tree. Further analyses were based on conditional predictions on the branch level. The values for P_{12} and P_{88} (xylem pressure at 12% and 88% loss of conductivity) were calculated from branch-level P_{50} predictions by rearranging Eq. 4 (where x is the desired percentile loss of conductivity):

$$P_x = \frac{\ln\left(\frac{100-x}{x}\right) \cdot 25}{s} + P_{50} \quad (5)$$

Leaf P_{TLP} (in MPa) was determined within 48 hours after sampling by the osmometric method (Bartlett et al., 2012a). The leaf osmotic potential (Ψ_0) of freeze-thawed (liquid nitrogen) leaf discs from fully expanded, sun-exposed, and rehydrated leaves was measured in a vapour pressure osmometer (VAPRO 5600, Wescor, Logan, UT, USA) following the protocol of Bartlett et al. (2012a) and used to predict P_{TLP} as:

$$P_{TLP} = 0.832 \Psi_0 - 0.631 \quad (6)$$

The HSM was subsequently calculated on the tree level as the difference between mean P_{TLP} and mean P_{50} .

2.3.7 Statistical analyses

The coefficient of quartile variation ($CQV=(Q3 - Q1)/(Q1+Q3)$) was used to assess trait variability, as it provides a more robust measure of dispersion than the coefficient of variation, when data are partly nonnormally distributed or log-transformed (Canchola et al., 2017; Altunkaynak & Gamgam, 2019; Rosas et al., 2019). To decompose the variability of each trait for different levels of organization (species, populations (sites), individuals, within-tree (branches)), log-linear mixed-effects models were fitted for each trait separately using the R package `lme4` (Bates et al., 2015). Each of the models contained fixed effects for species, and random tree effects as well as species-wise random site effects (i.e. random effects for each combination of site and species). The total variance in the traits was then decomposed into variance components for the fixed (between-species) and random effects (between-population and between-tree) as well as the residual (within-tree) standard deviation analogous to the definition of conditional and marginal R^2 (cf. Nakagawa & Schielzeth, 2013). The same models were used to investigate pair-wise differences between species across all sites using Tukey-adjusted P -values with degrees of freedom based on Satterthwaite's approximation (R package `emmeans`; Lenth, 2020).

To assess the effect of water availability on intraspecific trait variation, sets of linear mixed-effects models were fit for each trait (P_{50} , P_{TLP} , K_s , HV) and species. Climatic (CWB) and edaphic (AWC) water availability were included as fixed effects (both centred and scaled to simplify the comparison of regression coefficients). As the low number of five sites per species precluded adding random site effects, in these models we could only introduce tree-wise random intercepts, which thus are assumed to account both for between-site and within-site intra-specific variability. The explained variance was calculated according to Nakagawa & Schielzeth (2013). This set of models was not fitted for the HSMs, as this variable could only be calculated on the tree level. Likewise, trait interrelations could not be assessed on the branch level because traits were not measured on the same observational units (different branches, leaves, etc.). Therefore, simple linear regressions across species based on means per site and species are reported in order to illustrate tendencies in trait interrelations. We are aware that the small number of species is not sufficient to draw generalizable conclusions for a larger species number.

For all dependent variables, model residuals were checked for normality and natural log-transformed whenever required to meet the assumption of normality. All analyses were carried out with the statistical software R (v.3.6.3; R Core Team, Vienna, Austria).

2.4 Results

2.4.1 Magnitude of traits and variability on different levels of organization

According to their average P_{50} -values, the xylem embolism resistance of the three species could be ranked in the sequence *A. platanoides* > *C. betulus* > *T. cordata* (Table 2.2). Both *A. platanoides* and *C. betulus* showed a fairly resistant xylem with the vast majority of P_{50} -values in the range of -5 to -4 MPa, but *C. betulus* was markedly less resistant at the driest site with a median P_{50} of -3.8 MPa (Fig. 2.2a). By contrast, the estimated P_{50} of *T. cordata* was generally much less negative (mean of -3.06 MPa; Table 2.2). This species ranking was, however, not mirrored in the P_{TLP} -values. The highest P_{TLP} was found in *A. platanoides* and the lowest in *C. betulus* (Table 2.2; Fig. 2.2c). Consequently, the three species showed pronounced differences in HSMs with *A. platanoides* having the largest safety margin (2.59 MPa; Table 2.2), *C. betulus* showing intermediate values (1.6 MPa), and *T. cordata* operating with a narrow margin of 0.84 MPa.

The species rankings in terms of P_{12} and P_{88} were the same as in case of P_{50} , but the vulnerability curves of *C. betulus* showed less steep slopes (Appendix A, Fig. 2.6) and thus relatively low P_{88} values that were very close to the values of *A. platanoides* (Table 2.2; Fig. 2.2b).

The values of K_S and HV barely differed between *A. platanoides* and *C. betulus*, but HV was significantly higher in *T. cordata* and K_S was at least tendentially higher and more variable in *T. cordata* (Table 2.2; Fig. 2.3).

Table 2.2: Means \pm SE of measured traits per species pooled over all study sites. Different letters denote significantly different means based on Tukey-adjusted p-values from linear mixed effects models with post-hoc tests for pairwise species differences with degrees of freedom based on Satterthwaite's approximation. $P_{50/12/88}$ = xylem water potential at 50/12/88 % loss of conductivity; P_{TLP} = leaf water potential at turgor loss point; HSM = hydraulic safety margin; Huber value (HV) = A_{Xylem}/A_{Leaves} -ratio of branches; K_S = xylem area specific hydraulic conductivity of branches.

Species	P_{50} (MPa)	P_{12} (MPa)	P_{88} (MPa)	P_{TLP} (MPa)	HSM (Mpa)	HV (A_{xylem}/A_{leaf})	K_S ($\text{Kg m}^{-1} \text{s}^{-1} \text{Mpa}^{-1}$)

Figure 2.2: Hydraulic safety-related traits: (A) Xylem water potential at 50 % loss of conductivity (P_{50}), (B) xylem water potential at 12/88 % loss of conductivity ($P_{12/88}$), (C) leaf water potential at turgor loss point (P_{TLP}), and (D) hydraulic safety margins of the three tree species at all study sites. Sites are sorted in ascending order according to the climatic water balance. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to max. 1.5 times the interquartile range. Different letters denote significantly different means between sites within a species based on Tukey-adjusted p-values with degrees of freedom based on Satterthwaite's approximation from linear mixed effects models with post-hoc tests for pairwise differences.

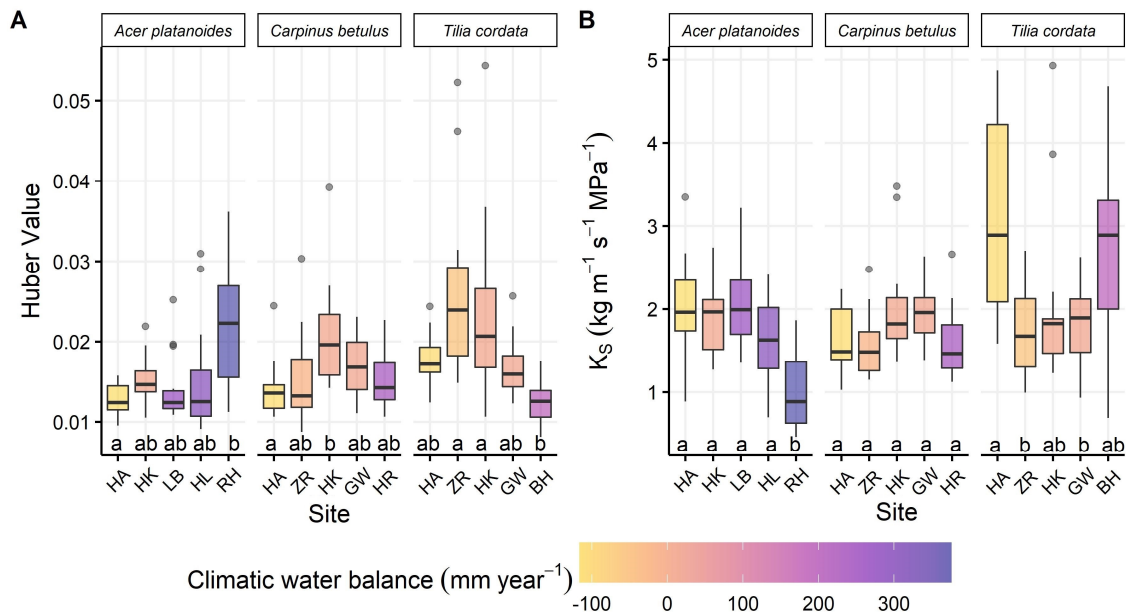

Figure 2.3: Hydraulic efficiency-related traits: (A) $A_{\text{Xylem}}/A_{\text{Leaves}}$ -ratio of branches (Huber value), and (B) xylem area-specific hydraulic conductivity of branches (K_S) of the three tree species at all study sites. Sites are sorted in ascending order according to the climatic water balance. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to max. 1.5 times the interquartile range. Different letters denote significantly different means between sites within a species based on Tukey-adjusted p-values with degrees of freedom based on Satterthwaite’s approximation from linear mixed effects models with post-hoc tests for pairwise differences.

Generally, K_S and HV were the most variable traits, whereas P_{TLP} showed the lowest variation (Fig. 2.4a). For the two hydraulic safety-related traits (P_{50} and P_{TLP}), the by far largest fraction of variance was explained by species differences. The intra-specific trait variability (ITV) between and within populations was small compared to the ITV in efficiency-related traits, especially in case of P_{50} (22% or 42% of total trait variance for P_{50} and P_{TLP} , respectively; Fig. 2.4b). For P_{50} , we estimated a between-population standard deviation of 0.20 MPa and between- and within-tree standard deviations of 0.23 MPa and 0.16 MPa, respectively (Fig. 2.4b; Appendix A, Table 2.4), while P_{TLP} varied by ± 0.14 MPa between populations, by ± 0.14 MPa between trees within populations and by ± 0.10 MPa within trees (Fig. 2.4b; Appendix A, Table 2.4). Hereby, the range of site averages of P_{50} spanned 0.84 MPa, 0.52 MPa and 0.31 MPa in case of *C. betulus*, *A. platanoides* and *T. cordata*, respectively (Fig. 2.2a). The range in site averages of P_{TLP} was comparable (*T. cordata*: 0.50 MPa, *C. betulus*: 0.36 MPa, *A. platanoides*: 0.26 MPa; Fig. 2.2c).

In contrast to hydraulic safety, average efficiency-related traits (K_S and HV) nearly did not differ between species, but varied substantially between populations as well as between and within individuals (Fig. 2.4b). Particularly the residual variability within

individuals was high (44% of total variance in case of HV and 50% of total variance in case of K_s).

For all four traits, the variability within populations (intra- and inter-individual) was larger than the variability between populations (Fig. 2.4b).

Figure 2.4: (A) Coefficient of quartile variation of the studied traits across all species and measurements; (B) variance decomposition between different levels of organization (between species, between populations, and between individuals; see Appendix A, Table 2.4 for full model output). Given are the xylem water potential at 50% loss of conductivity (P_{50}), the leaf water potential at turgor loss point (P_{TLP}), A_{xylem}/A_{leaf} – ratio of branches (Huber value, HV) and xylem area-specific hydraulic conductivity (K_s). ‘Residual’ denotes the unexplained variance of the models (i.e. variability between branches + estimation and measurement uncertainty).

2.4.2 Trait dependence on environmental and stand structural parameters

For most studied traits, significant differences between the study sites were observed for at least one species (Figs 2.2, 2.3). However, water availability (as expressed by the combined effect of CWB and AWC) explained only a small fraction of variance in the analysed traits (marginal R^2 0.04–0.19 in nearly all cases; Table 2.3). The only exception was *T. cordata*, where 37% of the variance in HV was explained by water availability. Conditional R^2 were much larger (0.28–0.88, Table 2.3), indicating that most of the variance in the data resulted from unexplained differences between sites and individual trees.

In general, the observed associations between the studied traits and climatic and soil water availability were weak, the only exceptions being a positive effect of AWC on HV

in *T. cordata* (higher xylem area-to-leaf area ratio on sites with higher soil water storage capacity), a negative effect of AWC on P_{TLP} in *A. platanoides* (lower turgor loss point on sites with better soil water storage capacity; Table 2.3; Appendix A, Fig. 2.7), and a reduction in K_S with AWC in *T. cordata* and with CWB in *A. platanoides*. Water availability had no significant influence on P_{50} , except for a marginally positive effect of AWC on P_{50} in *A. platanoides* ($P < 0.1$; Table 2.3). The value of P_{TLP} of *C. betulus* and *T. cordata* was not influenced by AWC, although the leaves of *C. betulus* showed a tendency of a turgor loss point reduction with increasing climatic aridity (positive effects of CWB on P_{TLP} at $P < 0.1$; Table 2.3; Fig. 2.2c). Although not part of the regression models, HSMs did not change systematically along the climatic gradient within species, as evident from Fig. 2.2d.

Further relationships between site variables and interrelations between traits are presented in the correlation matrix in Fig. 2.8 (Appendix A).

Table 2.3: Results of the linear mixed effects models examining the relationships between environmental variables and functional traits. P_{50} = xylem water potential at 50% loss of conductivity; P_{TLP} = leaf water potential at turgor loss point; HSM = hydraulic safety margin; Huber value (HV) = $A_{\text{xylem}}/A_{\text{leaf}}$ – ratio of branches; K_S = xylem area specific hydraulic conductivity of branches. Given are the scaled estimates for CWB (climatic water balance) and AWC (plant-available water storage capacity of the soil), as well as the standard deviation for the tree-wise random intercept (Tree SD), the residual standard deviation (Res. SD), and marginal and conditional R^2 of the models (Marg. R^2 and Cond. R^2). Bold estimates represent significant effects (*, $P < 0.05$; **, $P < 0.01$), (a) denotes marginally significant effects ($P < 0.1$). The full output of the models is given in Appendix A, Table 2.5.

2.5 Discussion

2.5.1 Variability of efficiency- and safety-related traits on different levels of organization

In our field study on mature trees, the HV, i.e. the sapwood-to-leaf-area ratio, and K_S showed the highest, and the P_{TLP} the lowest variability across the three diffuse-porous species. This is in line with recent findings by Rosas et al. (2019). The high variability of the efficiency-related hydraulic traits K_S and HV was driven by large intra- and inter-individual differences. Most likely, this can be attributed to small-scale variability in microclimatic conditions within the canopy of single trees and corresponding morphological and anatomical adjustments (e.g. Lemoine et al., 2002; Sellin & Kupper, 2004; Schuldt et al., 2011; Sellin et al., 2011). In agreement hereon, both branch age and branch growth rate were found to vary considerably within the crown, and both are closely related to hydraulic efficiency (Schuldt et al., 2016). In dependence on the position in the canopy and associated differences in flow-path length, light exposure and evaporative demand, the xylem architecture is adjusted in order to meet the water demand of the supported leaf area. Still, the covered range in both efficiency-related variables was relatively low compared to other studies (cf. Rosas et al., 2019). We focused on co-occurring diffuse-porous angiosperms only, and did not include conifers or ring-porous angiosperms. This might explain why the efficiency-related traits were more or less comparable across species despite pronounced differences in xylem safety. All three species have co-evolved and are widespread in central and eastern Europe in various types of broadleaved mixed forest communities in which European beech (*F. sylvatica*), the dominant species of central Europe's natural forest vegetation, is rare or absent (Leuschner & Ellenberg, 2017).

The low variability in P_{TLP} compared to other hydraulic traits has likewise been observed in other studies (Mencuccini et al., 2015; Bartlett et al., 2016; Farrell et al., 2017; Zhu et al., 2018). When excluding plants with sclerophyllous leaves or from perhumid ecosystems, the range of P_{TLP} -variation based on differences in osmolality seems to be restricted to 2 MPa (Bartlett et al., 2012b). In our study, most of the variability in P_{TLP} could be attributed to species differences, although there still was a considerable amount of ITV between populations and individuals.

In contrast to the two efficiency-related traits, the xylem pressure at P_{50} differed distinctly between species. Although ITV in xylem safety was not completely negligible

as we observed intra-specific ranges of 0.3 to 0.8 MPa across sites, 78% of the total variance in P_{50} could be attributed to species differences. The highest ITV was observed between trees at given sites, which explained 14% of the total variance in P_{50} . This pattern of higher variability within than between populations has been confirmed for P_{50} (Herbette et al., 2010; Wortemann et al., 2011; Hajek et al., 2016; Schuldt et al., 2016) and a wide range of other anatomical, foliar and hydraulic traits (Hajek et al., 2016; Rosas et al., 2019).

The low ITV in P_{50} reinforces the assessment of xylem embolism resistance as an evolutionarily canalized trait (cf. Flatt, 2005; Lamy et al., 2014; Rosas et al., 2019; Sanchez-Martinez et al., 2020). Accordingly, neither environment nor genotype seems to have strong control over the phenotypic expression of P_{50} . For trait-based models of tree mortality (cf. Adams et al., 2013; Choat et al., 2018), this is an important finding as these models implicitly rely on trait conservation within species and do not account for ITV.

2.5.2 *Effects of water availability and tree height on hydraulic traits*

Given the relatively small intra-specific variation in hydraulic safety-related traits, we expected to trace this ITV back to local climatic or edaphic conditions that define the water availability of the stands. However, none of the two measures of water availability had a consistent influence on P_{50} , P_{TLP} , or HSMs. For P_{50} , a majority of intra-specific studies on a wide range of tree species failed to identify environmental variables that drive ITV (Van der Willigen & Pammenter, 1998; Cornwell et al., 2007; Martínez-Vilalta et al., 2009; Herbette et al., 2010; Wortemann et al., 2011; Martin-StPaul et al., 2013; González-Muñoz et al., 2018; Li et al., 2019; Rosas et al., 2019; but see Schuldt et al., 2016; Stojnic et al., 2018). It is therefore reasonable to conclude that the limited environmental control over P_{50} is relatively complex, as assumed by Wortemann et al. (2011). In our study, only less than 10% of total variability occurred between populations, indicating that the effects of different drivers may often be difficult to disentangle in field studies on mature trees. For example, most of the aforementioned studies disregarded that various site-specific factors might, in addition to atmospheric climatic aridity, affect embolism resistance. To our knowledge, only Rosas et al. (2019) also included a wide range of stand, soil, and climatic factors as potential drivers of P_{50} , but the authors were likewise not able to identify the sources of the ITV in P_{50} in adult field-grown trees.

In contrast to P_{50} , reports on an intra-specific decline in P_{TLP} with increasing aridity are rather consistent (e.g. Liang et al., 2019; Rosas et al., 2019; Pritzkow et al., 2020). In our study, *C. betulus* indeed showed a marginally significant negative relationship between

P_{TLP} and aridity. Leaf traits might thus be under a stronger environmental control than wood traits, and one of the main acclimative responses of the broadleaf tree species of our sample to local climatic gradients might be osmotic adjustment (cf. Hartmann et al., 2021).

We did not find the expected increase in HV on drier sites, even though a high variability of HV across climatic gradients has been reported both within (Martínez-Vilalta et al., 2009; Rosas et al., 2019; Pritzkow et al., 2020) and across species (Gleason et al., 2013; Mencuccini et al., 2019). However, intra-specific variability in HV in response to climatic aridity has mainly been observed in different ecosystems or in conifers that showed limited variability in xylem traits (Martínez-Vilalta et al., 2009; Lamy et al., 2014).

While intra-specific adaptation of hydraulic efficiency in terms of xylem anatomical adjustments has been demonstrated (e.g. Schreiber et al., 2015; Liang et al., 2019), studies quantifying actual conductivities often failed to report such adaptive modifications (Martínez-Vilalta et al., 2009; Schuldt et al., 2016; Rosas et al., 2019). This is in line with our findings that K_s was not under environmental control, despite its very high ITV. One explanation for the missing relationship might be that empirically measured conductivity, in contrast to theoretical values, additionally includes the flow resistance of inter-vessel pits and conduit irregularities along the flow path, which are estimated to account for 50% of the total xylem resistance (Sperry et al., 2005).

We found a general inter-specific safety-efficiency trade-off as observed by others (Maherali et al., 2004; Gleason et al., 2016; Schumann et al., 2019). Across the three species of our sample, P_{50} and K_s were correlated ($P < 0.05$, $R^2 = 0.23$; Appendix A, Fig. 2.9), but this observed safety-efficiency relationship did not hold within any of the species. We are aware that this finding may not be transferable to more general between-species pattern due to the small number of species in our sample.

2.5.3 Hydraulic safety in comparison to major timbers

In our study, *A. platanoides* and *C. betulus* showed both an embolism resistant xylem (P_{50} : -4.62 MPa and -4.25 MPa, respectively) and large HSMs (2.59 MPa and 1.6 MPa, respectively). In contrast to these two species that have been of minor silvicultural interest so far, the major broadleaf timber species in the study region, *F. sylvatica*, is less drought-resistant in terms of hydraulic safety (P_{50} : -3.8 MPa to -3.5 MPa; HSM: 0.2 MPa to 1.5 MPa; P_{50} and P_{min} data obtained from Schuldt et al., 2016; Dietrich et al., 2018; Schuldt et al., 2020). These two species even turned out to be a match—in terms of hydraulic

safety—for another major timber species of the region, namely sessile oak (*Quercus petraea*), which is known to be more drought-resistant than European beech (P_{50} : -5.0 MPa to -4.6 MPa, HSM: 1.8 MPa to 2.3 MPa; based on P_{50} and P_{\min} data from Dietrich et al., 2018; Lobo et al., 2018). Especially *F. sylvatica* is currently widely affected by drought-induced defoliation and tree mortality following the extreme 2018/2019 drought (Braun et al., 2020; Schuldt et al., 2020). According to dendroecological analyses, this species is more drought-sensitive than *A. platanooides* even in the core area of its distribution range (Zimmermann et al., 2015; Leuschner, 2020). Thus, *A. platanooides* and, from a plant hydraulic perspective, also *C. betulus* seem to be better suited than *F. sylvatica* for a future drier climate.

However, HSMs alone are not sufficient to capture drought tolerance on the whole-tree level, because stem and leaf water capacitance act as additional buffers against desiccation (Choat et al., 2018). *Tilia cordata* has a relatively high stem water storage due to its low wood density (Köcher et al., 2013) and a high leaf water capacitance linked to a highly elastic leaf tissue (Leuschner et al., 2019), which might partly compensate for the species' relatively high xylem vulnerability and small HSM. Consequently, more holistic and integrated studies on whole-tree drought responses are needed to fully understand tolerance strategies and compare different species.

2.5.4 Conclusions

The three investigated minor timber species showed a considerable amount of intra-specific variability in efficiency-related traits, which were highly variable between and within individuals. In contrast, ITV was low in xylem safety-related traits despite pronounced differences between species. This implies that xylem safety-related traits at the wood (P_{50}) and leaf (P_{TLF}) levels are more strongly conserved traits, which—given their high mechanistic importance for plant drought responses—underlines their value for trait-based modelling approaches in dynamic vegetation and land surface models.

Environmental control over hydraulic traits in mature stands seems to involve complex interactions with abiotic drivers. In our study, it was not possible to clearly disentangle their influence from other factors, even though both climate and soil water capacity were taken into account. Most likely, local properties of the stand and soil, including small-scale variability in moisture availability, belowground and aboveground competition with direct neighbours, as well as a high within-crown variability in branch hydraulic properties hamper the identification of the environmental drivers of xylem safety and efficiency for given species.

Despite these uncertainties, our study provides valuable information on hydraulic traits and their variability for three promising minor timber species that may help to assess their suitability for broader inclusion in silvicultural concepts in central Europe in a future warmer and drier climate. In the light of large-scale vitality losses and dieback in some of the primary timber species in central Europe, minor timber species such as *A. platanoides* or *T. cordata* emerge as well-suited potential components of future more drought-tolerant production forests.

Figure 2.5: Distribution ranges of the three minor timber species (*Acer platanoides*, *Carpinus betulus*, and *Tilia cordata*) based on the synthetic chorology database of Caudullo et al. (2017).

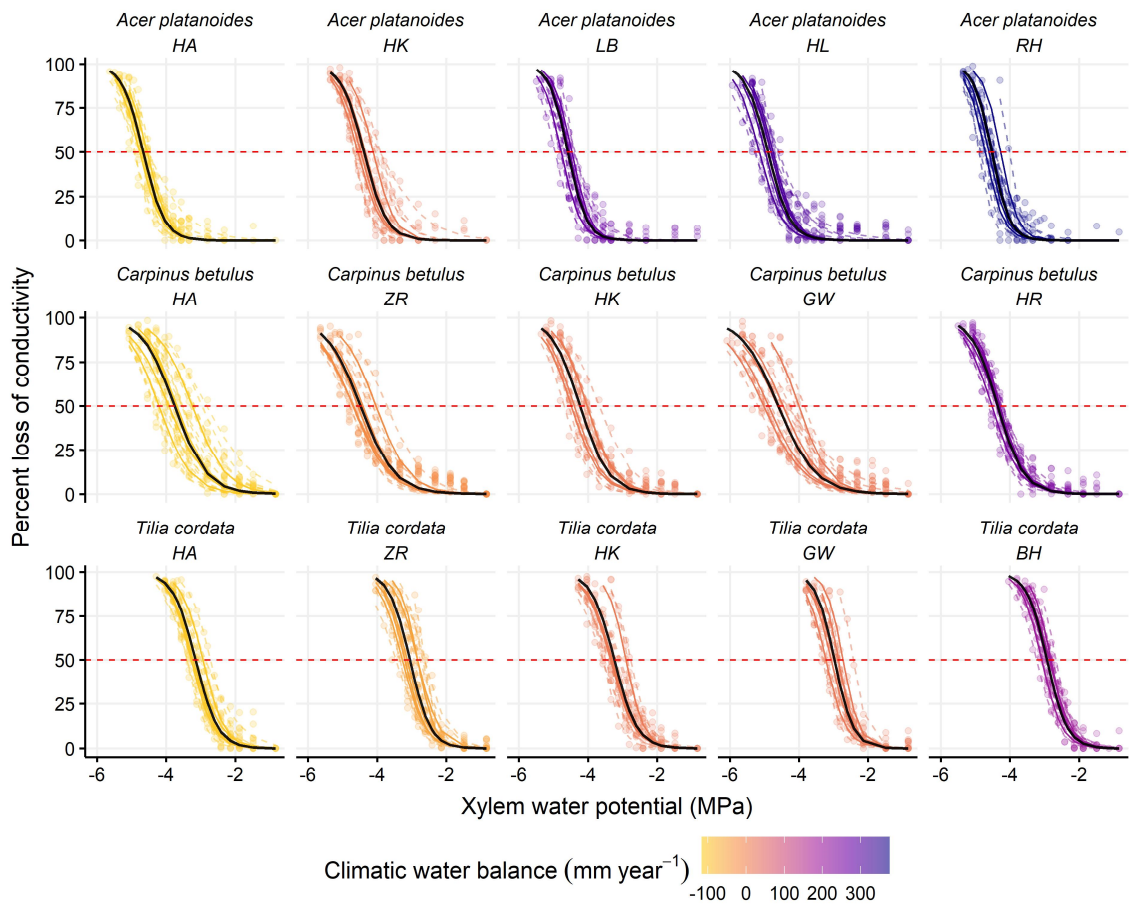

Figure 2.6: Xylem vulnerability curves illustrating percent loss of conductivity vs. xylem water potential. Plotted lines represent conditional predictions for single branches (colored, dotted), single trees (colored), and sites (black) based on species-wise non-linear mixed-effects models (pointsymmetrically, sigmoidal).

Figure 2.7: (A) Xylem water potential at 50 % loss of conductivity (P_{50}), (B) leaf water potential at turgor loss point (P_{TLP}), (C) A_{Xylem}/A_{Leaves} -ratio of branches (Huber value), and (D) xylem area-specific hydraulic conductivity of branches (K_S) of the three tree species on all study sites. Sites are given in ascending order of plant-available water capacity of the soil. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to 1.5 times the interquartile range.

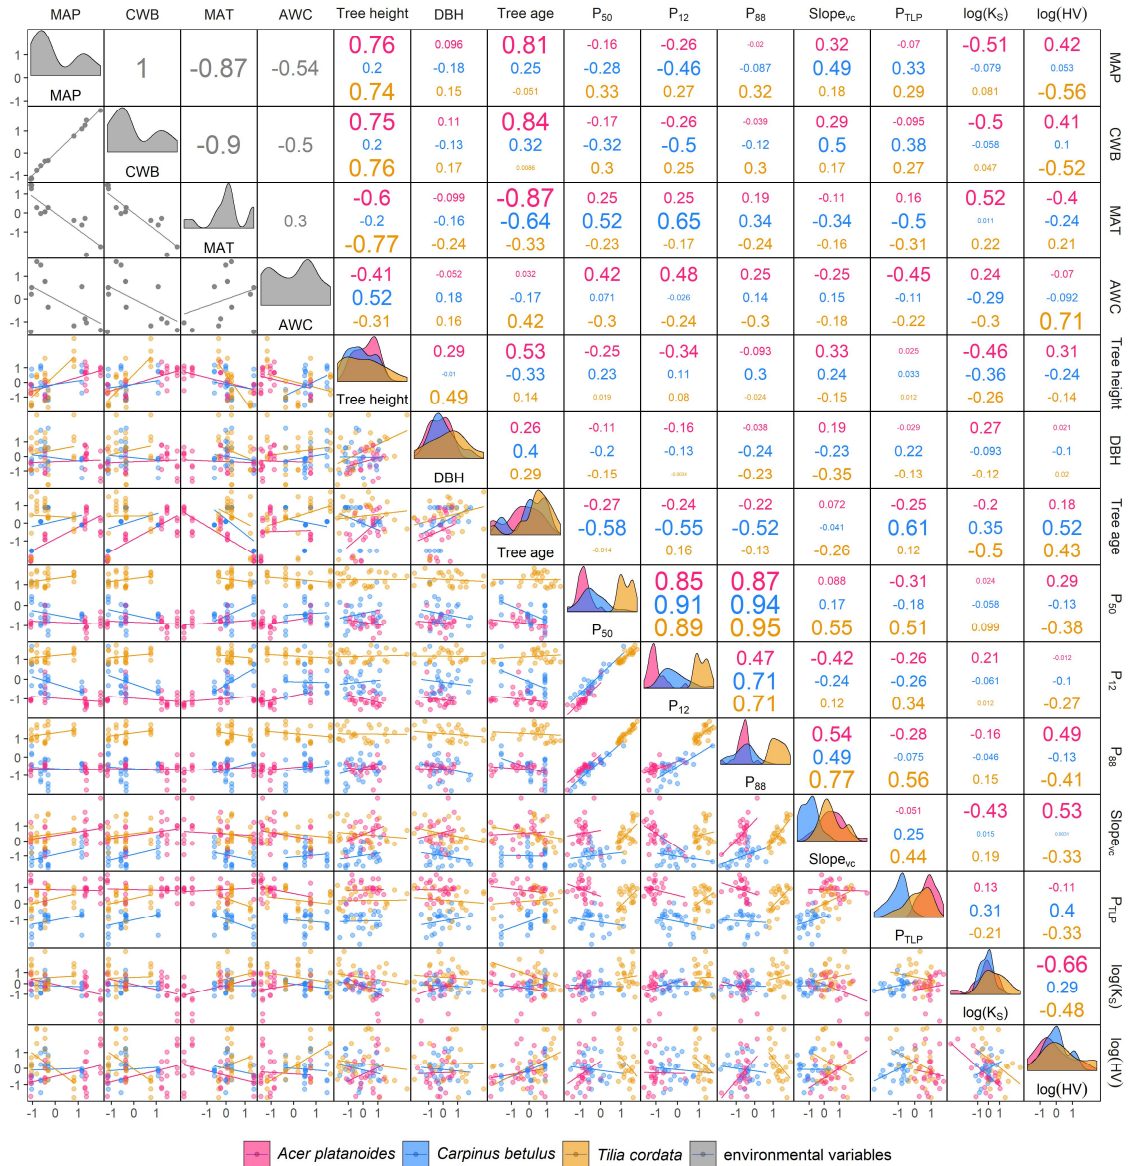

Figure 2.8: Pearson correlation matrix of environmental and tree-specific predictors and functional traits. Given are Pearson correlation coefficients per species in the top right triangle and the corresponding data in the lower left triangle. MAP = mean annual precipitation (period 1991–2017); CWB = climatic water balance; MAT = mean annual temperature; AWC = plant-available water storage capacity of the soil; DBH = Stem diameter at breast height; P₅₀/P₁₂/P₈₈ = xylem water potential at 50/12/88 % loss of conductivity; Slope_{vc} = slope of the vulnerability curve at the inflexion point; P_{TLP} = leaf water potential at turgor loss point; K_s = xylem area specific hydraulic conductivity of branches; HV = Huber value (A_{Xylem}/A_{Leaves}-ratio of branches). K_s and HV are natural log-transformed, traits measured on branch/leaf-level are means per tree. All variables are scaled by their standard deviation and centered around zero.

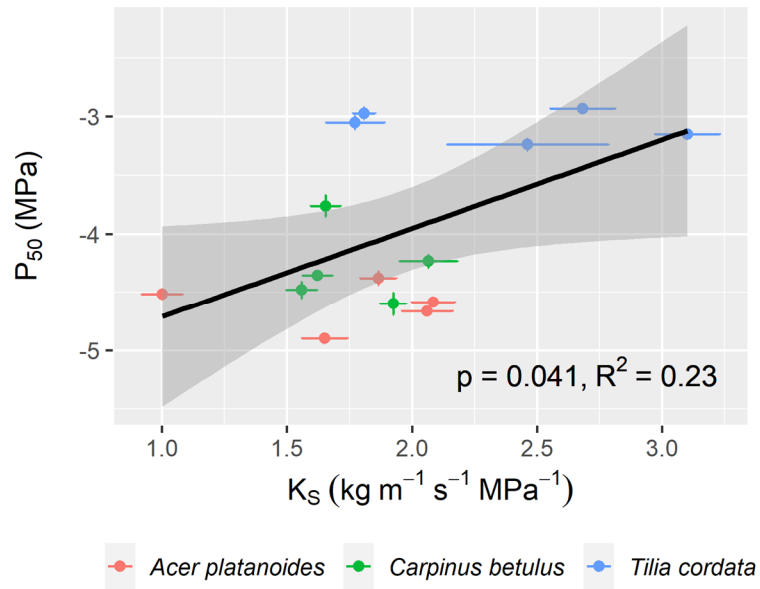

Figure 2.9: Tendency of a hydraulic safety-efficiency trade-off across species between K_S (xylem area-specific hydraulic conductivity) and P_{50} (xylem water potential at 50 % loss of conductivity). Shown are mean values per site and species with standard errors and p-value and R^2 of a linear regression across all species and sites.

Table 2.4: Full output table of the linear mixed effects models for the variance decomposition (Fig. 4b). Given are the fixed effect estimates for the intercept (i.e. the *Carpinus* average), the differences of *Acer* and *Tilia* to *Carpinus*, with their standard errors, estimated degrees of freedom (edf) based on Satterthwaite's approximation and *P*-values, as well as the estimates of the three variance components (tree level, population level and residual SD).

Variable	Term	Estimate	Std.error	edf	<i>p</i> -value
P ₅₀	<i>Carpinus</i> (Intercept)	-4.284	0.103	12.0	< 0.001
	Δ <i>Acer</i>	-0.325	0.146	12.1	0.046
	Δ <i>Tilia</i>	1.216	0.146	12.0	< 0.001
	Tree SD	0.232			
	Population SD	0.203			
	Residual SD	0.158			
P _{TLP}	<i>Carpinus</i> (Intercept)	-2.655	0.070	12.0	< 0.001
	Δ <i>Acer</i>	0.634	0.099	12.0	< 0.001
	Δ <i>Tilia</i>	0.423	0.099	12.0	0.001
	Tree SD	0.144			
	Population SD	0.141			
	Residual SD	0.096			
HV	<i>Carpinus</i> (Intercept)	-4.143	0.094	11.9	< 0.001
	Δ <i>Acer</i>	-0.058	0.132	11.9	0.669
	Δ <i>Tilia</i>	0.116	0.133	12.0	0.397
	Tree SD	0.172			
	Population SD	0.185			
	Residual SD	0.235			
K _S	<i>Carpinus</i> (Intercept)	0.532	0.108	12.0	< 0.001
	Δ <i>Acer</i>	-0.065	0.153	12.0	0.679
	Δ <i>Tilia</i>	0.212	0.153	12.1	0.191
	Tree SD	0.150			
	Population SD	0.219			
	Residual SD	0.290			

Table 2.5 (next page): Full output table of the linear mixed effects models examining the relationships between environmental variables and functional traits (corresponds to Table 2.3). Given are the scaled estimates for CWB (climatic water balance) and AWC (plant-available water storage capacity of the soil), the standard errors of the estimates (SE), the estimated degrees of freedom (DF) based on Satterthwaite's approximation, *P*-values, and lower and upper border of likelihood-profile-based confidence intervals (CI low and CI high).

3.1 Abstract

While much research has addressed the aboveground response of trees to climate warming and related water shortage, not much is known about the drought sensitivity of the fine root system, in particular of mature trees. This study investigates the response of topsoil (0–10 cm) fine root biomass (FRB), necromass (FRN), and fine root morphology of five temperate broadleaf tree species (*Acer platanoides* L., *Carpinus betulus* L., *Fraxinus excelsior* L., *Quercus petraea* (Matt.) Liebl., *Tilia cordata* Mill.) to a reduction in water availability, combining a precipitation gradient study (nine study sites; mean annual precipitation (MAP): 920–530 mm year⁻¹) with the comparison of a moist period (average spring conditions) and an exceptionally dry period in the summer of the subsequent year. The extent of the root necromass/biomass (N/B) ratio increase was used as a measure of the species' belowground sensitivity to water deficits. We hypothesized that the N/B ratio increases with long-term (precipitation gradient) and short-term reductions (moist vs. dry period) of water availability, while FRB changes only a little. In four of the five species (exception: *A. platanoides*), FRB did not change with a reduction in MAP, whereas FRN and N/B ratio increased toward the dry sites under ample water supply (exception: *Q. petraea*). *Q. petraea* was also the only species not to reduce root tip frequency after summer drought. Different slopes of the N/B ratio-MAP relation similarly point at a lower belowground drought sensitivity of *Q. petraea* than of the other species. After summer drought, all species lost the MAP dependence of the N/B ratio. Thus, fine root mortality increased more at the moister than the drier sites, suggesting a generally lower belowground drought sensitivity of the drier stands. We conclude that the five species differ in their belowground drought response. *Q. petraea* follows the most conservative soil exploration strategy with a generally smaller FRB and more drought-tolerant fine roots, as it maintains relatively constant FRB, FRN, and morphology across spatial and temporal dimensions of soil water deficits.

Keywords: *Acer platanoides*; *Carpinus betulus*; fine root biomass; fine root necromass; *Fraxinus excelsior*; necromass/biomass ratio; *Quercus petraea*; root morphology; *Tilia cordata*; water availability

3.2 Introduction

Tree fine roots (roots < 2 mm in diameter) play a crucial role in forest ecosystem functioning, even though they represent only a few percent of tree biomass (Jackson et al., 1997; Leuschner and Ellenberg, 2017; Nadelhoffer and Raich, 1992). Fine roots serve as the interface between soil and tree and thus control water and nutrient uptake, they closely interact with mycorrhizal fungi and rhizosphere microbiota, and represent a major source of soil organic carbon (C) (Eissenstat and Yanai, 2002; Rasse et al., 2005). Due to their rapid turnover, it has been estimated that up to a third of the global annual net primary production refers to fine root growth (Jackson et al., 1997). The size, morphology, and turnover rate of the fine root system of trees is dependent on many biotic and abiotic factors. Water availability is a key determinant among the soil factors besides nutrient availability, soil acidity, and temperature (Brunner et al., 2015; Leuschner et al., 2004; Leuschner and Hertel, 2003).

With climate change, forests are exposed to warmer summers and a higher evaporative demand, and, in various regions, reduced and more irregular summer precipitation (IPCC, 2014; Schär et al., 2004), likely exposing trees to increased drought and heat stress. Recent reviews of climate change-related decreases in tree vitality and increasing mortality in many forest regions of the earth have predominantly focused on aboveground tree parts (Allen et al., 2010; Anderegg et al., 2013; Ryan, 2011; Senf et al., 2018), ignoring root responses. This is primarily caused by the fact that the fine root system of mature forests is difficult to observe, and methods are labour-intensive and often quite imprecise (Brunner et al., 2015).

How tree roots and the root system respond to drought is increasingly a matter of debate, but the empirical data basis is quite limited, especially for mature trees. Optimal partitioning theory (OPT) predicts that trees tend to increase their root-to-shoot ratio (R/S) under conditions of limited water availability to increase their absorptive capacity in relation to the transpiring surface (Bloom et al., 1985; Brunner et al., 2015; Reich, 2002). Evidence in support of OPT has been obtained by comparing the R/S of different plant functional types from different biomes (Kozlowski and Pallardy, 2002; Mokany et al., 2006), by analysing the R/S of trees or forests along precipitation gradients (Coomes and Grubb, 2000; Hertel et al., 2008), and by manipulating soil moisture in experiments with tree saplings (Thomas and Gausling, 2000; Tomlinson and Anderson, 1998; van Hees, 1997). Most studies with increases in R/S found a reduction in aboveground biomass (leaf mass or shoot mass), while fine root biomass (FRB) changed only a little, suggesting that

shoot growth may respond more sensitively to drought than root growth (Kuster et al., 2013). Yet, it is not well understood how the fine root system of trees responds to a decrease in soil water availability, and existing findings are partly contradictory (Brunner et al., 2015; Hertel et al., 2013; Meier and Leuschner, 2008a). Many sapling studies found a decrease in FRB with decreasing soil moisture (Aspelmeier and Leuschner, 2006; Bongarten and Teskey, 1987; Meier and Leuschner, 2008b; Zang et al., 2014), but these responses can hardly be extrapolated to mature trees, and limited rooting space may sometimes have influenced the results. For mature stands, Leuschner and Hertel (2003) found in a meta-analysis of studies from temperate broad-leaved forests no clear trend in FRB in dependence on precipitation. The results of multi-site field studies with a single tree species are inconsistent: Some authors reported a higher FRB at drier sites (Bakker et al., 2006; Hertel et al., 2008; Hertel et al., 2013; Parker and van Lear, 1996), others a higher biomass at moister sites (Chenlemuge et al., 2013; Leuschner et al., 2004; Meier and Leuschner, 2008a; Santantonio and Hermann, 1985). The controversial results are partly explained by differences in species, in the steepness of the precipitation gradient, or in the severity and timing of drought events at the study sites. Moreover, different combinations of growth-related reductions in overall productivity, of shifts in aboveground/belowground carbohydrate partitioning, and of altered root lifespan may lead to opposing root/shoot ratio responses (McCormack and Guo, 2014).

More consistent are the reports about a fine root necromass (FRN) increase or elevated necromass/biomass (N/B) ratios as a consequence of drought exposure (Brunner et al., 2015; Wang et al., 2018), indicating increased fine root mortality. In accordance, (Hertel and Leuschner, 2002) found a large FRN increase in a mature beech forest after a summer drought, while FRB remained constant over the study period. It appears that certain tree species are capable of compensating elevated drought-induced fine root losses through increased production of new fine roots, thereby avoiding reductions in standing FRB. It is not known which species are capable of this response and under which conditions it occurs.

Root mortality reduces the lifespan of fine roots and, when dying roots are replaced by new ones, a reduction in mean fine root age in the root population is the consequence (Eissenstat et al., 2000; McCormack and Guo, 2014). One possible physiological explanation of a shortened fine root lifespan in dry soil is active root shedding, in which fine roots act as ‘hydraulic fuses’ in the tree’s xylem system, uncoupling the rest of the hydraulic system from low water potentials in the dry soil to avoid embolism formation

in more expensive or irreplaceable plant organs (Alder et al., 1996; Jackson et al., 2000; Rewald, 2008). This could happen when fine roots are indeed more sensitive to cavitation in the xylem than the stem and branches in the canopy. An alternative explanation assumes that younger fine roots, that replace the shed ones, are physiologically more active and therefore can support the tree by extracting more water, which increases fitness (Brunner et al., 2015; Eissenstat et al., 2000). Such a response would also be in agreement with OPT, which predicts a higher investment in the root system. In any case, root mortality will increase the N/B ratio, which must be seen as an integral over the processes of root mortality and the production of new fine roots during the observation period, thus reflecting both the root system's resistance to drought and its resilience after drought. The ratio has therefore been used in several studies and reviews as an indicator of tree and root system vitality under exposure to drought and chemical stress (Leuschner et al., 2004; Persson and Stadenberg, 2010; Puhe, 2003; Wang et al., 2018).

Field studies on the drought response of tree fine root systems usually adopt one of two approaches, either investigating temporal (natural or experimental) variation in soil moisture (Gaul et al., 2008; Leuschner et al., 2001a; Mainiero and Kazda, 2006; Makkonen and Helmisaari, 1998; Teskey and Hinckley, 1981; Tierney et al., 2003), or examining spatial differences in water availability, often along precipitation or soil moisture gradients (Bakker et al., 2006; Hertel et al., 2013; Hertel and Leuschner, 2002; Leuschner et al., 2004; López et al., 1998; Meier and Leuschner, 2008a; Persson and Stadenberg, 2010; Santantonio and Hermann, 1985). In central Europe, such studies focused on the economically most important coniferous and broad-leaved tree genera, i.e., *Picea*, *Pinus*, *Fagus*, and *Quercus*.

Only little is known about the fine root system of other common tree species that are minor timber species or of no use in current forestry. Small-leaved lime (*Tilia cordata* Mill.), Norway maple (*Acer platanoides* L.), European hornbeam (*Carpinus betulus* L.), and European ash (*Fraxinus excelsior* L.) may be more drought resistant than European beech and Norway spruce according to their distribution ranges and knowledge of aboveground physiological traits (Hemery et al., 2010; Leuschner and Ellenberg, 2017; Leuschner and Meier, 2018). While these species can be of interest for forestry in a warmer and drier climate in the future, their belowground drought response is unknown. Recent root research in temperate mixed forests with lime, maple, hornbeam, oak, and ash species has focused on species interactions and diversity effects, but drought responses have not been examined (Jacob et al., 2014; Kubisch et al., 2015; Meinen et

al., 2009). A better understanding of the belowground drought response of these minor timber species is fundamental for predicting the species' performance in a drier climate.

This study investigates the response of the fine root biomass and necromass, and fine root morphology of four secondary tree species (*T. cordata*, *A. platanoides*, *C. betulus*, and *F. excelsior*) to a reduction in water availability, combining a precipitation gradient study with the comparison of a moist and a dry season. The well-studied and relatively drought-resistant sessile oak (*Quercus petraea* (Matt.) Liebl.) was included in the study for comparison. The sample thus comprised three ECM (ectomycorrhizal; *T. cordata*, *C. betulus*, *Q. petraea*) and two AM tree species (arbuscular mycorrhizal; *A. platanoides*, *F. excelsior*), and two ring-porous (*Q. petraea*, *F. excelsior*) and three diffuse-porous species (*T. cordata*, *C. betulus*, *A. platanoides*), thereby covering a broad range of tree functional types of the European temperate tree flora. Fine root inventories were carried out in the topsoil of nine study sites along a precipitation gradient (mean annual precipitation (MAP): 918–528 mm year⁻¹), comparing data from a moist (spring 2017) and a subsequent dry period (summer 2018). The precipitation gradient covers most of the MAP range encountered by the species at their natural occurrences in northern central Europe.

We expected that the five species differ in their root system response to water deficits and that the sensitivity of belowground and aboveground organs are linked to each other in these species. The extent of the N/B ratio increase was used as a measure of the species' belowground sensitivity to water deficits. Based on the existing knowledge about the drought response of tree fine root systems (Brunner et al., 2015; Hertel et al., 2013; Meier and Leuschner, 2008a), we hypothesized that, in all species, (i), the fine root N/B ratio increases with decreasing mean annual precipitation due to higher root mortality and thus an increase in necromass, while biomass changes only little, (ii) a severe summer drought increases necromass and the N/B ratio, and (iii) the increase in the N/B ratio upon drought is more pronounced at the moister sites, where trees are assumed to be more sensitive to water shortage.

3.3 Materials and Methods

3.3.1 Forest Stands and Tree Species

Nine study sites were chosen along a transect in central Germany between Göttingen and Halle/S., which represents a steep precipitation gradient in west-east orientation. All sites are in the planar to colline zone (110–440 m a.s.l.) and have a cool-temperate climate

with annual mean temperatures of 7.9 to 9.9 °C. Mean annual precipitation (MAP) ranges between 918 and 528 mm and mean growing season precipitation (MGSP, April–September) between 291 and 412 mm, with a general decrease from west to east (Figure 3.1).

Figure 3.1: Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from the west to the east. The nine study sites are marked with red dots. The colors indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm NE of Göttingen is the Harz mountain range.

Four of the five investigated tree species (*A. platanoides*, *T. cordata*, *C. betulus*, and *F. excelsior*) are widespread in Central Europe with natural occurrences in various types of broadleaf mixed forest communities of the phytosociological alliances *Carpinion betuli* (oak-hornbeam forests) and *Tilio-Acerion* (mixed maple slope forests), in which European beech (*Fagus sylvatica* L.), the dominant species of Central Europe's natural forest vegetation, is rare or absent (Leuschner and Ellenberg, 2017). The four species are more demanding in terms of soil base saturation than beech and *Q. petraea*, the fifth species of this study, but they also occur in eastern Europe under a more continental climate and thus are thought to be relatively drought tolerant. While *Q. petraea* is one of the most important timber species of Central European forestry, the four other species are only secondary timber species in the study region. Therefore, mixed stands of comparable stand structure and tree age with presence of all five species are uncommon. As a consequence, not all species are present at all nine study sites, but every species occurs at least at five sites along the precipitation transect. Every site consisted of several mixed forests of variable species composition in a maximum distance of several hundred m to a few km to each other. The target species grew in these mixed stands of two to six species

under comparable edaphic and climatic conditions. All stands were located on level terrain with an inclination of less than 5° without groundwater influence.

The target trees in the stands were all of mature age (range: 69–139 years), with the exception of two older oak stands (170 years). The exact age of all individuals was determined from the investigation of increment cores and dendrochronological analysis, except for *C. betulus*, which was not included in the tree ring study, as the increment cores consist of long sections of indistinguishable annual rings. Age information for this species was taken from forest inventory data supplied by the local forestry offices. The investigated trees were selected for comparable height and DBH at the different sites (Table 3.1). From the moister western to the drier eastern sites, average tree height in the stands slightly decreased from 28.2 to 25.8 m (means of all species), while average DBH increased from 44.5 to 47.1 cm. This indicates that aboveground biomass changes only little along the transect. Only in the case of *T. cordata*, tree height decreased notably towards the drier sites. In case of *F. excelsior*, we selected only trees that were not visibly affected by ash dieback, a recently spreading lethal infection caused by the fungus *Hymenoscyphus fraxineus*.

Table 3.1: Site and tree characteristics of the nine study sites with the each 2–5 species occurring in the stands, sorted in ascending order of mean annual precipitation (MAP).

No soil chemistry data is available for the site Knutbühren. DBH = Stem diameter at breast height; MAP = mean annual precipitation (period 1991–2017); MGSP = mean growing season precipitation (April–September); MAT = mean annual temperature; soil texture is defined according to the nomenclature of the FAO (Food and Agriculture Organization of the United Nations).

^[1] Mean tree age for all species except *C. betulus* was determined from increment cores of all sampled trees and dendrochronological analysis. *C. betulus* stand age was taken from forest inventory data from the accountable forestry offices.

3.3.2 *Climatic Conditions*

Precipitation, air temperature, and potential evapotranspiration (PET) data were taken from the DWD (Deutscher Wetterdienst, Offenbach, Germany) database and the required local data were calculated from extrapolated 1 km-gridded data. The gridding method of the DWD employs the reduction to a reference elevation level, the calculation of inverse squared-distance weights (horizontal interpolation), and finally the transformation to the actual elevation of the grid point using regression over elevation (Kaspar et al., 2013; Müller-Westermeier, 1995). This gridding method is relatively simple, but comparison and verification against other GIS-based interpolation methods (Maier and Müller-Westermeier, 2010) have confirmed its accuracy, which is partly a consequence of the relatively high weather station density in Germany. The largest distance between a study site and the closest weather station was ca. 7.1 km.

PET was extrapolated from data derived from the agrometeorological model AMBAV (“Agrarmeteorologisches Modell zur Berechnung der aktuellen Verdunstung”, Löpmeier, 1994) that is based on the Penman-Monteith equation. Without doubt, these agrometeorological PET data do not characterize potential forest evapotranspiration exactly, but the values are used in the study only for characterizing the weather conditions prior to the two fine root inventory campaigns.

The mean de Martonne Index (DMI) for the respective three-month periods prior to each sampling date was calculated by dividing precipitation sums by the mean temperature + 10 (Martonne, 1926).

Long-term mean annual climate data were calculated for the period 1991–2017, because PET data generated with the AMBAV model are only available from DWD stations since 1991. Fine root data were modelled in dependence on a variety of parameters characterizing site water availability, notably mean annual precipitation (MAP), mean growing season precipitation (MGSP; April–September), and the climatic water balance (precipitation—PET, whole year and growing season). Because the ratio of summer precipitation to annual precipitation is constant and temperature is inversely proportional to precipitation along the transect, we obtained similar results for all tested variables in the correlation analyses and thus used in the analyses MAP as a proxy for climatic aridity along the transect. The actual precipitation in the 12 months prior to sampling was tested as well and resulted in the same patterns of correlation, as it was mostly proportional to MAP along the transect (see Appendix B, Table 3.6 and Figure 3.5).

3.3.3 *Edaphic Conditions*

Various soil chemical and physical properties were analysed for the topsoil (0–10 cm of mineral soil) of three soil pits per site, notably soil texture, organic matter content, soil pH (in H₂O and in KCl), and organic C, organic N, and resin-extractable P content. Organic carbon and nitrogen concentrations were determined by gas chromatography (C/N elemental analysis) and the resin-extractable P concentration was determined with ICP-OES (inductively coupled plasma optical emission spectrometry) analysis, after P extraction with water using an anion-exchange resin and subsequent re-exchange of P with NaCl and NaOH solutions. The soil organic matter content was additionally determined through the dry ignition method at 600 °C, the soil texture by sieving (sand fractions) and sedimentation (silt fractions) according to the international standard ISO 11277.

3.3.4 *Fine Root Inventories: Sampling Periods*

To examine the effect of seasonal drought on fine root mortality, two inventories with determination of fine root biomass and necromass were carried out at all sites in spring 2017 and summer 2018. The first inventory in April 2017 was conducted after a moderately moist spring period in order to examine fine root mass under ample soil moisture conditions along the precipitation gradient without the influence of unusual drought periods. On the other hand, no soil frost was influencing this inventory, as the winter was mild with no harsh frost periods. A second inventory was conducted in September 2018 after an exceptionally dry summer with an extended rainless period to investigate the effect of pronounced soil drought on the fine root system. The summer of 2018 with its extraordinary heatwave was on average 2.0–2.3 °C warmer and had 55–74% lower rainfall amounts than the average (1991–2017) in the study region. All study sites were exposed to very low rainfall between May and September prior to the inventory, with mostly <30 mm of precipitation per month (Table 3.2). We decided to report the average weather in the 3 months prior to each sampling date and related it to the long-term means of the respective seasons. A period length of three months was chosen, because loamy soils in the study region are known to desiccate only with some delay after precipitation ceased in a dry period, and the peak of fine root mortality thus typically happens after an additional time lag of 1–2 months, according to a root study in central northern Germany (Hertel and Leuschner, 2002).

Table 3.2: PET, precipitation, and temperature in the three months prior to the sampling dates in 2017 and 2018. Given are the totals of potential evapotranspiration (PET) and precipitation (P), the deviation of P from the long-term mean (1991–2017) in percent, and the absolute deviation of the average temperature of the three-month period from the long-term mean (1991–2017) in that period in °C.

Site	2017				2018			
	PET (mm)	P (mm)	P deviation (%)	T deviation (°C)	PET (mm)	P (mm)	P deviation (%)	T deviation (°C)

3.3.5 Fine Root Inventories: Fine Root Biomass and Necromass

Five mature, similarly-sized and vital trees were chosen per site and species, and two topsoil samples per tree extracted in 1.5 m distance from the stem base in eastern and western direction using a soil corer of 3.5 cm in diameter. These two samples were later combined to one, as we did not intend to study FRB variation within the same tree. For reasons of comparability, the second sampling campaign was conducted at coring locations in close vicinity of the previous campaign, but in a distance of 40 cm to exclude possible interference from the soil disturbance of the earlier coring.

Because the study focus was on the comparison of five species at many sites with a large number of samples, we had to restrict the sampling to the uppermost 10 cm of mineral soil (A-horizon), where drought effects are assumed to be largest. At all sites, the A-horizon contained by far the highest density of fine roots which decreased exponentially with soil depth. Organic layers on top of the soil were generally thin, consisted mainly of undecomposed litter and rarely contained fine roots.

The soil samples were transferred to plastic bags and stored at 4 °C in the laboratory until processing within 3 months. Prior to the root extraction procedure, the samples were soaked in tap water and carefully cleaned from attached soil residues under gently running water over a sieve of 0.25 mm mesh size. Only fine root fragments (< 2 mm in diameter, > 10 mm in length) of the target species were considered for analysis. In most samples, shrub and herb roots were rare or missing and the percentage of roots of non-target species was very small, because all sampling locations were situated in small monospecific forest patches of 5–10 individuals of the target species. The sorting of fine roots by species was done by morphological criteria (colour and surface structure of the root periderm,

branching patterns of the rootlets, morphology of ectomycorrhizae in the ECM species), established in our lab during earlier work in mixed broadleaf forests in Central Germany (Jacob et al., 2014; Kubisch et al., 2015; Meinen et al., 2009). Living (biomass) and dead roots (necromass) were distinguished under the stereomicroscope by inspecting colour, root elasticity, and cohesion of the cortex, periderm, and stele (Hertel and Leuschner, 2002; Persson, 1978). The fine root biomass and necromass of every sample was dried at 70 °C for 48 h and weighed and expressed as g L⁻¹ soil volume.

We did not take any dead root particles <10 mm length into account, although this finest fraction of decaying root particles is known to represent a considerable portion of total FRN (Bauhus and Bartsch, 1996; Leuschner et al., 2004). One reason is the sheer impossibility to assign these particles to different tree species in samples containing more than one tree species. In addition, a main study aim was the analysis of the effect of the 2018 summer drought on the N/B ratio of fine root mass. Yet, it is likely that the bulk of partly decomposed FRN fragments in the samples originate from earlier die-off events, and that the <10 mm fraction is the one most influenced by the activity of decomposers in the soil. This suggested focusing on the larger, still intact necromass fragments (>10 mm length), which more likely were formed in summer 2018.

3.3.6 *Fine Root Inventories: Fine Root Morphology*

Four to five intact rootlets were picked from the living biomass fraction and further analysed for their mean root diameter, specific root surface area (SRA, in cm² g⁻¹), specific root length (SRL, in m g⁻¹), root tissue density (in g cm⁻³), and the number of root tips per mass using a water bath scanner and the WinRhizo (Régent Instruments Inc., Quebec, QC, Canada) visual analysis system. All morphological parameters were calculated on a dry biomass (70 °C for 48 h) basis.

3.3.7 *Statistical Analyses*

All calculations and tests were conducted with version 3.6.1 of R (R Core Team 2019). All fine root biomass, necromass, and morphological data showed a strong right-skewed distribution and were neither within the species, nor among plots and different species normally distributed. In some cases, the necromass values were almost bi-modally distributed, as root necromass distribution within the soil was highly patchy. We therefore used non-parametric tests to detect differences between years in fine root bio- and necromass. Since it is a priori unclear, whether two soil samples taken at short distance (40 cm) in two subsequent years are paired or independent, we decided to conduct two

non-parametric tests: the Wilcoxon signed-rank test and the Wilcoxon-Mann-Whitney U test. Since both tests resulted in exactly the same pattern of significant differences, we here only report the results of the signed-rank test, because pair-wise comparison seems to better fit to the repeat-sampling strategy of this study.

In order to explore the relationships between various site-specific soil characteristics, tree size attributes, climate variables and fine root data, principal components analyses (PCA) were conducted separately for site- and species-level data for the 2017 and 2018 sampling campaigns (R Packages “FactoExtra” and “FactoMineR”, Kassambara and Mundt, 2017; Lê et al., 2008). The PCA included the variables mean annual precipitation (MAP), mean annual temperature (MAT), de Martonne aridity index (DMI) of the 3 months prior to sampling, soil pH, C/N ratio, resin-exchangeable P concentration, organic matter content, silt content and soil bulk density (0–10 cm depth), mean tree height, diameter at breast height (DBH), FRB, FRN, N/B ratio, specific root area (SRA), and specific root length (SRL). To account for the right-skewed distribution of fine root data, we log-transformed, centred, and scaled all biomass, necromass, and morphological data prior to the PCA analysis.

Further, linear mixed effects models were fitted for the 2017 and 2018 data sets separately for all predictors and dependent variables (R package *lme4*, Bates et al., 2015). The models included one of the predictors (MAP, MGSP, MAT, soil pH, soil C/N ratio, silt proportion, soil organic matter content, tree age, height, and DBH) and its interaction with the factor “species” as fixed effects, while the factor “site” was introduced as random effect. The random effect was introduced, because fine root data on tree level were nested within species per site. The dependent variables in the models were the log-scaled fine root mass and morphology data. Here, we only report the results of the models with MAP as predictor, as the other variables led either to very similar results (e.g., MGSP) or showed no significant effects and very small effect sizes. These minor inter-relationships among biotic, edaphic, and climatic variables in the data set are already demonstrated by the PCAs.

All models were checked for constant variance of the residuals across fitted values and between levels of the fixed effects, as well as for acceptable normality of the distribution of the residuals using Q-Q-plots. Only the model with fine root necromass as dependent variable showed slightly distorted residuals in part of the data set due to several very low necromass values, which did not apply to the model with necromass/biomass ratio. Conclusions from the N/B ratio model are thus more robust than those from the

necromass-only model. All estimates are based on the restricted maximum likelihood (REML) criterion and p -values were calculated with the `lmerTest` package based on Satterthwaites degrees of freedom method (Kuznetsova et al., 2017).

Reported marginal “pseudo- R^2 ” values were calculated per species according to Nakagawa and Schielzeth (2013) and represent a measure for explained variance of the fixed effects in mixed-effects models:

$$R_{marg}^2 = 1 - \frac{\text{variance}(res_{marg})}{\text{variance}(\log(variable))} \quad (1)$$

where res_{marg} are the residuals of the marginal predictions of the model.

3.4 Results

3.4.1 Fine Root Biomass, Necromass, and Morphology in the 2017 and 2018 Inventories

Across the nine sites, FRB density in the mineral topsoil (0–10 cm) was lowest in stands of *Q. petraea* and *T. cordata* (mostly in the range 0.2–0.8 g L⁻¹), intermediate in *A. platanoides* (0.3–2.0 g L⁻¹), and highest in *C. betulus* (0.8–2.0 g L⁻¹) and especially *F. excelsior* (1.5–4.0 g L⁻¹; Figure 3.2a). The corresponding FRB pools in the 0–10 cm layer were 20–80, 30–200, 80–200, and 150–400 g m⁻². Thus, across all sites, *F. excelsior* had about fivefold larger FRB densities in the topsoil than *Q. petraea*. The FRN pools (only fragments > 10 mm) were 10 to 100 times smaller than the biomass pools (Figure 3.2b), resulting in N/B ratios mostly in the range of 0.1 to 0.01 (Figure 3.2c).

Figure 3.2: Fine root biomass (a), necromass (b), and necromass/biomass (N/B) ratio (c) of the five tree species in the topsoil (0–10 cm) in April 2017 and September 2018. Box-whisker plots with median and interquartile ranges (Q_1 – Q_3); whiskers extend to 1.5 times the interquartile range. Indicated significant differences between the inventories for each species are based on a non-parametric signed-rank-test; ***: $p \leq 0.001$, *: $p < 0.05$. Note the log-scaled y-axes in (b) and (c).

Comparing the FRB recorded in the moist spring of 2017 to the biomass of the dry summer of 2018 revealed in none of the five species a significant difference, whereas necromass was significantly greater after the 2018 drought in three species (*A. platanoides*, *F. excelsior*, and *Q. petraea*) but unchanged in the other two (Figure 3.2a,b). The N/B ratio was higher after the 2018 drought in *A. platanoides* and *F. excelsior*, but not in the other three species (Figure 3.2c).

Figure 3.3: Specific root surface area (SRA) and root tips per fine root biomass of the five tree species in the topsoil (0–10 cm) in April 2017 and September 2018. Box-whisker plots for all species and both inventories with median and interquartile ranges (Q₁–Q₃); whiskers extend to 1.5 times the interquartile range. Indicated significant differences between the inventories for each species are based on a non-parametric signed-rank-test; ***: $p \leq 0.001$, **: $p \leq 0.01$, *: $p < 0.05$. Note the log-scaled y-axes.

While FRN was not different between the two inventories in *C. betulus* and *T. cordata*, SRA was significantly smaller in these species after the 2018 drought than in 2017 (Figure 3.3a). A similar morphological response was observed also in *A. platanoides*, while the SRA of the other two species did not respond to the drought. All species except *Q. petraea* showed significantly reduced root tip numbers per FRB after the 2018 drought (Figure 3.3b).

3.4.2 Changes in Fine Root Mass and Root Traits along the Precipitation Gradient

Under conditions of ample soil moisture in the spring of 2017, FRB density at the nine sites revealed a positive relationship with MAP in case of *Q. petraea*, a negative relation in *A. platanoides*, and no significant relations in the other three species (Figure 3.4, Table 3.3). FRN density increased with a decrease in MAP in all species except *Q. petraea*, and so did the N/B ratio. After the summer drought in 2018, in contrast, we found no dependence of FRB, FRN and N/B ratio on MAP (Table 3.3) due to a marked increase in FRN at the moister end of the precipitation gradient (Figure 3.4). FRB changed relatively little between 2017 and 2018 in four species, but showed a marked increase at the moist end of the gradient in *A. platanoides* (Figure 3.4).

Figure 3.4: Fine root biomass (a), necromass (b), and necromass/biomass ratio (c) in the topsoil (0–10 cm) of the five species in relation to mean annual precipitation (MAP) in the 2017 and 2018 inventories. Data points are tree-level values, lines represent conditional predictions of the linear mixed effects model (the predictions of the fixed effect “MAP” for each species plus an intercept for each level of the random factor “site”). Note the log-scaled y-axis. The corresponding p and pseudo- R^2 values are summarized in Table 3.3. Graphs for the morphology variables are given in Figure 3.6 in the Appendix B.

Table 3.3: Results of linear mixed effects models for fine root traits in dependence of mean annual precipitation (MAP). Given are estimates of the fixed effect (fine root trait ~ species:MAP), marginal pseudo- R^2 for the fixed effect (calculated according to Nakagawa and Schielzeth (2013)) and p -values. p -values below 0.05 are given in bold. All fine root traits were log-transformed in advance except for root diameters.

Of the root morphological traits, SRA and the number of root tips per biomass increased with decreasing MAP in the 2017 inventory in *Q. petraea*, and in 2018 in *C. betulus*, pointing at a larger absorptive capacity of the finest roots at drier sites (Table 3.3 and Figure 3.6 in the Appendix B). Accordingly, mean fine root diameter in the <2 mm category increased towards the moister sites. A similar pattern was also observed in the other species in both years, but the relationships were mostly not significant (exception: root diameter in *F. excelsior* in 2018) and the explained variance was low; especially *T. cordata* did not show significant morphological plasticity along the gradient (Table 3.3).

3.4.3 Interdependencies between Climatic and Edaphic Factors and Fine Root Variables along the Precipitation Gradient

The principal components analysis for the inventory in spring 2017 revealed a relatively continuous distribution of the study sites along the first three axes that explained 63.4% of the total variance of the dataset (Table 3.4, a graphical representation of the PCA results is provided in the Appendix B in Figure 3.7). The first axis (27.5% explained variance) coincided mainly with the climatic factors MAP and MAT and the weather prior to sampling (DMI). FRN and the N/B ratio were strongly correlated with the first axis as well, whereas root biomass itself and morphological attributes (SRA and SRL) coincided with the second axis (21.2% explained variance) and soil physical and chemical properties (C/N, silt content, bulk density, organic matter content). FRB was generally positively associated with high organic matter content in the upper mineral soil and negatively influenced by high bulk density, which itself coincided with high silt content. The third axis (14.8% explained variance) reflects the positive association between tree height and soil pH and P availability, but did not correlate with climate or fine root variables.

Table 3.4: Results of the principal components analysis for the spring inventory in 2017. Given are the loadings of the selected variables along the four axes with the highest explained variance in the dataset. Bold numbers mark the variables with the highest loading (>0.4) on the respective axis. The values in brackets give the cumulative fraction of variance explained by the variable. MAP = mean annual precipitation, MAT = mean annual temperature, DMI = de Martonne aridity index of the three months prior to sampling.

After the 2018 summer drought, the environmental and root-related variables in the data set were in general less tightly correlated to each other according to the PCA (Table 3.5, a graphical representation of the PCA results is provided in the Appendix B in Figure 3.8). The first axis (22.7% explained variance) coincided again mostly with climatic factors but did not explain root bio- or necromass variation. Instead, root morphological parameters had a reasonable loading on this axis (-0.67 , -0.56). The second axis (21.1% explained variance) reflected influences of soil properties (C/N ratio, organic matter content, bulk density, soil texture) on FRB: The same positive effect of organic matter content and negative effect of bulk density as in 2017 was visible in this data set. Fine root bio- and necromass were strongly inter-related after the summer drought along the first two PCA axes in 2018, which relates to the relatively constant N/B ratio across plots and species in this inventory.

Table 3.5: Results of the principal components analysis for the drought inventory in 2018. Given are the loadings of the selected variables along the four axes with the highest explained variance in the dataset. Bold numbers mark the variables with the highest loading (>0.4) on the respective axis. The values in brackets give the cumulative fraction of variance explained by the variable. MAP = mean annual precipitation, MAT = mean annual temperature, DMI = de Martonne aridity index of the three months prior to sampling.

Stand and tree age was only weakly correlated with the studied fine root traits and we decided not to include it in the final PCAs to avoid mixing tree age/stand age data from different sources because dendrochronological determination of tree age was not possible for *C. betulus*.

3.5 Discussion

3.5.1 Fine Root Biomass and Belowground C Allocation in Dependence on Long-Term Water Reduction

Our study at nine sites along the steep precipitation gradient in the rain shadow of the Harz mountains (MAP: 920–530 mm year⁻¹) found only weak support for optimal partitioning theory, when applied to the FRB stocks in the topsoil. FRB in the moist sampling period 2017 did not change in a consistent manner with decreasing mean annual precipitation. *A. platanoides* was the only species with a significant increase in FRB from the moister to the drier sites in 2017, which could point at increased belowground C allocation to increase water uptake, while *Q. petraea* showed a decrease and the other three species no relation of FRB to MAP. The outcome was not different when other precipitation variables (e.g., MGSP, current-year precipitation or climatic water balance) were used instead of the long-term mean. Other studies along precipitation gradients obtained mixed results, either no consistent change in FRB and relative C allocation to roots (Joslin et al., 2000; Meier et al., 2018), a decrease (Leuschner et al., 2004; Meier and Leuschner, 2008a), or an increase with decreasing water availability (Hertel et al., 2013; Parker and van Lear, 1996), suggesting a large influence of species and soil moisture conditions on the drought response of carbon allocation. Clearly, our fine root inventory covers only the topsoil and we hence may have missed preferential biomass partitioning to other parts of the root system. Trees growing at drier sites could allocate more carbon to root growth in deeper soil layers to access the moister subsoil and escape surface drying (Konôpka and Lukac, 2013; Persson et al., 1995). However, a meta-analysis of root biomass data by Schenk and Jackson (2002) and a detailed study of the subsoil root system of *Fagus sylvatica* along a precipitation gradient by Meier et al. (2018) showed the opposite response to long-term precipitation reduction, i.e., shallower rooting of trees under water limitation. An alternative explanation for the weak support for OPT in our study could be the only moderate length of the studied precipitation gradient (MAP difference: 390 mm year⁻¹), which apparently had only a minor effect on total tree productivity. Carbon allocations shifts in support of OPT were mostly found in studies across biomes or in experiments with very different treatments. Poorter et al. (2012) concluded from a meta-analysis that marked increases in allocation to the root system occur only, when drought reduces biomass by 50 percent or more, which is not the case here.

The PCAs with root-related and environmental variables support the conclusion that the average soil moisture regime as indicated by the MAP gradient has only a minor influence on the FRB stocks at our study sites. In both root inventories, the association of FRB with edaphic and climatic variables suggests that topsoil FRB generally increases with organic matter content, but decreases with increasing nitrogen content, silt content and soil bulk density, while the effect of climatic factors (MAP, MAT) and also soil pH and P content is weak. This is in accordance with the observation that fine root density in temperate forest soils is usually highest in the carbon-rich Ah horizon and the organic layer with low bulk density (Kirfel et al., 2019; Leuschner et al., 2004).

Inherited tree species differences in FRB seem also to be more influential on FRB patterns than moisture conditions. In our study, *F. excelsior* had up to five times higher FRB densities in the topsoil than *Q. petraea* and *T. cordata*, with intermediate values in *C. betulus* and *A. platanoides*. While part of this variation may be due to differences in DBH and small-scale variations in stem density between species in mixed stands, comparison with earlier fine root studies in mixed forests suggests that the high FRB of *F. excelsior* and the low values of *Q. petraea* may be species-specific. This is indicated by a meta-analysis of fine root studies from temperate forests (Leuschner and Hertel, 2003) and root inventories in mixed forests (Jacob et al., 2014; Leuschner et al., 2001b). An additional explanation for low FRB values of *Q. petraea* might be a different depth distribution of fine roots, as other authors state that Central European oak species are generally deeper rooted than beech and other broadleaf tree species (Rosengren et al., 2006), but precise data on depth-distributions are lacking for our sites. The contrasting FRB patterns of *A. platanoides* and *Q. petraea* along the precipitation gradient further indicate that co-occurring tree species may differ not only in standing FRB but also in root mortality and the response of their carbon allocation modes to long-term reduction in water availability.

As predicted (hypothesis 1), all five species showed increasing amounts of FRN and an increasing N/B ratio in the topsoil with a decrease in MAP, while FRB remained unchanged (with the exception of *A. platanoides*). One possible explanation of this pattern is that fine root mortality increases with a permanent reduction in water availability, as has been observed in many field studies (e.g., Meier and Leuschner, 2008a) and concluded from literature reviews (e.g., Eissenstat et al., 2013; McCormack and Guo, 2014), which in turn may trigger increased carbon allocation to root growth in compensation of the FRB loss. This was observed, for example, in Norway spruce roots

under mild drought stress (soil matrix potentials of -0.06 MPa, Gaul et al., 2008). Such a response will reduce mean fine root age and likely increase the water and nutrient uptake capacity of the tree and thus its fitness under water shortage (Brunner et al., 2015; Eissenstat and Yanai, 2002). Another possible explanation is fine root shedding with the assumed function to uncouple the rest of the hydraulic system from very low water potentials in dry soil to avoid embolism formation in more valuable organs (hydraulic fuse theory, Alder et al., 1996; Jackson et al., 2000). It could take place during more severe drought events and does not imply the immediate replacement by new fine roots. In support of this idea, McCormack and Guo (2014) predicted on the basis of a conceptual model exponential increases in root mortality at the highest drought stress intensities. This is in accordance with the results of a rainfall exclusion experiment with *Picea abies* trees, in which, under mild drought, root mortality increased, while fine root production was also stimulated. Under more severe drought, root mortality was high and no replacement occurred (Gaul et al., 2008).

Our data suggest that the five species differ in specific root mortality rates upon soil desiccation, as the N/B ratio showed a more than tenfold increase with the MAP reduction along the transect in *T. cordata*, intermediate N/B slopes in *C. betulus*, *A. platanoides*, and *F. excelsior*, and the lowest increase in *Q. petraea*. We interpret these patterns as a hint that *Q. petraea* is better able than the other species to produce fine roots capable of tolerating long-term reductions in soil moisture without suffering increased root mortality. Physiological and genetic studies have to show whether this is due to a principally different physiological constitution of the fine roots of this ring-porous species, or is caused by the specific acclimation or adaptation of different oak populations along the precipitation gradient. An alternative explanation for increasing FRN amounts and N/B ratios with a MAP reduction is that the drier and somewhat warmer climate toward the east of the transect reduces root decomposition rate and thus leads to the accumulation of FRN, independent of changes in root mortality rate. In the absence of decomposition data, this possibility cannot be ruled out, but it is not very likely. The gradients in MAT (7.9–9.9 °C), soil pH (4.2–6.5) and C/N ratio (10.7–18.9) along the transect were only moderate and the latter factors did not covary significantly, either with MAP or FRN. Moreover, site differences in decomposition rate should mainly affect the finest root necromass particles, which were not investigated here. We assume that the analyzed larger, less fragmented necromass fractions (>10 mm length) reflect more

directly the root mortality processes, where decomposition likely has started only very recently.

3.5.2 *Effects of the 2018 Summer Drought on Fine Root Biomass and Belowground C Allocation*

It is noteworthy that none of the species showed a decrease in mean FRB across the transect after the severe 2018 summer drought (in *C. betulus*, a non-significant tendency for a decrease existed). The 2018 drought with summer precipitation amounts 55–73 % lower than the long-term average was extreme and resulted in the local dieback of more sensitive tree species (*Picea abies*, *Fagus sylvatica*) in the region. This indicates that all five species must be relatively tolerant of soil desiccation compared to other major timber species, and that precipitation is playing only a secondary role for the standing FRB of these species. It is possible that our FRB figures are influenced by temperature and other seasonal influences unrelated to summer drought, as fine root production and biomass stocks typically peak between April and July in central European broadleaf tree species, as is visible from studies in beech (Ladefoged, 1939; Meier and Leuschner, 2008a) and beech-oak mixed forests (Hertel and Leuschner, 2002). Thus, we cannot exclude with certainty that the biomass figures observed in September 2018 represent reduced values which are influenced by the typical seasonal FRB decrease that should have taken place later in summer. However, we did not observe a FRB reduction. Moreover, if the reduction had occurred, it should have been similar along the transect. In addition, the *A. platanoides* data from the moist transect end indicate the opposite, a FRB increase from the 2017 to the 2018 inventory.

Higher FRN amounts in three of the species (*A. platanoides*, *F. excelsior*, and *Q. petraea*) in 2018 (in comparison to 2017) indicate that drought has increased root mortality. Interestingly, the severe drought drove all N/B ratios to converge on a higher level, or, in other words, all species lost the MAP dependence of necromass and N/B ratio after the drought. This suggests that the mortality increase was greater at the moister than the drier sites in all species except for *Q. petraea*, which largely supports hypothesis 3. We explain this pattern with a generally higher drought sensitivity of the root systems at $\text{MAP} > \text{ca. } 700 \text{ mm year}^{-1}$, which caused higher root mortality and leveled all FRN differences that exist along the transect in normal years. In *T. cordata* and *C. betulus*, FRN and N/B ratio were also higher at the moister sites in 2018 than 2017, but this response was compensated by lower FRN amounts at the drier sites. Thus, our second hypothesis is only partly supported.

In a meta-analysis about stand- and soil-related drivers of fine root N/B ratio across biomes, Wang et al. (2018) found elevated N/B ratios at reduced precipitation only in forests dominated by ECM tree species, but not in AM forests. This suggests an influence of mycorrhizal type on the drought response of the root system. Liese et al. (2019) confirmed these findings in a mesocosm experiment for several temperate tree species (including *Acer*, *Fraxinus*, *Carpinus*, *Tilia*, and *Quercus* taxa), demonstrating a much greater drought-induced root lifespan reduction in ECM than AM species (40–56% vs. 0.5–13%). Our data from three ECM (*C. betulus*, *T. cordata*, and *Q. petraea*) and two AM species (*A. platanoides* and *F. excelsior*) do not support this conclusion, as *Q. petraea* was the species with the smallest N/B response to a MAP reduction at the drier end of the gradient. The response to the 2018 summer drought even revealed the opposite response pattern to that found by Wang et al. (2018) and Liese et al. (2019), with a significant increase in the N/B ratios in the AM species *A. platanoides* and *F. excelsior*, while all ECM species did not respond. One possible explanation for the discrepancy between the results of the Wang et al. (2018) and Liese et al. (2019) studies and our investigation is that largely different spatial scales (comparison of biomes with different climates; sapling experiment; regional gradient study) are considered.

3.5.3 Root Morphological Change in Response to Reduced Water Availability

Trees can adapt to shortages in water or nutrients by increasing the absorptive capacity of the root system in two different ways: by enhancing root production and maintaining larger absorbing surface areas (extensive strategy), or by modifying root morphology and physiology in order to increase uptake efficiency per root mass (intensive strategy, Lõhmus et al., 2006; Ostonen et al., 2007). In contrast to the other four species, *Q. petraea* showed characteristics of an intensive adaptation strategy by increasing SRA and the number of root tips per root mass towards the drier sites according to the 2017 inventory, while FRB remained constant. *Q. petraea* differed further from the other species by showing no root tip shedding and no SRA reduction after the 2018 drought. *A. platanoides* showed the opposite response with a FRB increase towards the drier sites, while root morphology was not altered. The other three species maintained a constant FRB along the gradient, but the marked FRN increase toward the drier sites points at elevated root turnover and compensatory stimulation of fine root production under desiccation, which can be viewed as attributes of an extensive strategy.

After the 2018 drought, all species except *Q. petraea* showed a marked dieback of root tips and more distal thin rootlets. This resulted in the observed SRA reduction, which was

particularly strong in *T. cordata*. The losses in the putatively most active finest rootlets had not been replaced until September 2018, when sampling was conducted. We interpret this response in 2018 as an indicator of belowground vulnerability to extreme drought, which must have reduced the vitality and absorptive capacity of the fine root system of *F. excelsior*, *A. platanoides*, *C. betulus*, and *T. cordata*.

3.5.4 Species Differences in the Belowground Drought Response

The fine root system of *Q. petraea* seems to be more resistant to both permanent moisture reduction and severe drought events than that of *T. cordata*, *C. betulus*, *F. excelsior*, and *A. platanoides* due to the following features: (1) Although fine root necromass increased after the 2018 summer drought, the N/B ratio changed only a little and it was roughly constant across the precipitation gradient. (2) Fine root morphology and the number of root tips were not affected by the drought, indicating either low sensitivity or rapid recovery in oak roots. This fits to findings from the dendrochronological analysis of climate sensitivity (e.g., Kunz et al., 2018) and more general comparative assessments of drought resistance of the species based on climate envelopes (Leuschner and Ellenberg, 2017; Walentowski et al., 2017). On the other hand, *Q. petraea* maintained the lowest fine root density in the topsoil and more generally seems to produce a relatively small fine root system. Due to still-unknown morphological and/or physiological properties, oak can also maintain its fine roots in dry periods instead of shedding and partly replacing them. This rather “conservative” strategy with lower maintenance costs and a more or less constant root biomass during wet and dry periods was also observed in other Central European oak forests by Leuschner et al. (2001b), who compared *Q. petraea* to *F. sylvatica* and concluded that this strategy comes with the drawback of inferior interspecific competitive ability.

The other four species have in common that they all show indications of a somewhat greater belowground vulnerability to severe soil drought, but they pursue different strategies. *T. cordata* seems to be the most vulnerable species due to large drought-induced reductions in SRA and tip frequency, which is in line with assessments based on leaf and stem level data (Köcher et al., 2009; Leuschner et al., 2019). *F. excelsior* is unique due to its high fine root density, which may secure water uptake in drought periods and increase the species’ competitive ability in mixed stands and on very shallow and dry soils.

Our results suggest that co-occurring tree species differ in the drought sensitivity of their fine root systems, which could play an important role with respect to the species’

fitness and drought survival. Yet, much less is known about the belowground growth and stress tolerance strategies of trees than about aboveground responses.

This case study suffers from a number of shortcomings that are introduced with the study design and the methods used, which may bias some of the conclusions. First, the study design is not fully symmetric, as not all tree species occur at all sites, which weakens the power of statistical analysis. Second, our FRN analysis covers only the larger fragments, as the finest particles could not be identified to the species level. Consideration of the complete root necromass pool might have led to somewhat different results. Finally, edaphic inhomogeneity introduces some noise in the climatic signal retrieved from the precipitation gradient, which may weaken some of the conclusions. Fortunately, climate and soil properties did not covary systematically. While the retrieved patterns seem plausible, they need verification by additional gradient studies in other regions and with additional species.

We conclude that the comparative analysis of fine root biomass, necromass, and fine root morphology along precipitation gradients, and in moist and dry periods, has the potential to provide valuable information on the belowground drought sensitivity of tree species, thereby complementing results from canopy- and leaf-level studies.

4.1 Abstract

Climate warming and a rise in evaporative demand expose forests to increasing stress, challenging silvicultural planning in many temperate forest regions. As some major timber species are drought susceptible, the choice of native broadleaf minor timbers with assumed higher drought tolerance is a promising alternative option. However, their growth performance and vitality in a warmer and drier climate are not well known. We studied tree-ring chronologies of the Central European minor timbers *Acer platanoides* L., *Fraxinus excelsior* L., and *Tilia cordata* Mill. in comparison to the widely planted *Quercus petraea* Matt. Liebl in different mixed stands along a precipitation gradient in Central Germany and analyzed the sensitivity of radial growth to climatic drivers and severe drought events with the aim to compare the species' drought tolerance. While growth responded in all four species positively to summer (or spring) precipitation and negatively to higher summer temperature and climatic aridity, climate sensitivity of growth decreased in the period 1967-2016, proving non-stationarity. Superposed epoch analysis revealed larger growth reduction during severe drought in the diffuse-porous species (*A. platanoides*, *T. cordata*) than the ring-porous species (*Q. petraea*, *F. excelsior*), but resilience was high in all species. Moreover, none of the species showed negative growth trends with recent climate warming, and drought sensitivity was not higher at drier sites, suggesting a considerable acclimation and adaptation potential to increasing drought stress. As all four species proved to be fairly drought tolerant, they deserve broader consideration in silvicultural concepts targeted at adapting production forests to climate warming.

4.2 Introduction

Accelerated climate warming since the 1980s (IPCC, 2014) and the predicted future increase in the frequency and severity of summer heat-waves (Schär et al., 2004) challenge silvicultural concepts in Central Europe. In this region, some of the main timber species seem to be relatively susceptible to drought and possibly also heat, notably Norway spruce (*Picea abies* (L.) H. Karst.; Spiecker, 2000), European beech (*Fagus sylvatica* L.; Bréda et al., 2006; Leuschner, 2020) and Scots pine (*Pinus sylvestris* L.; Rigling et al., 2013). This became obvious during the extreme drought and heat years 2003, 2018, and 2019 that caused widespread vitality loss and mortality increase in *P. abies*, *F. sylvatica*, and locally also *P. sylvestris*, as well as in other coniferous and broadleaf tree species (Schuldt et al., 2020; Walthert et al., 2021). *F. sylvatica* and *P. abies* suffered distinct growth declines over the past decades especially in regions of Central Europe with mean annual precipitation sums of less than ca. 700 mm and on shallow soils (Leuschner, 2020; Mäkinen et al., 2002; Scharnweber et al., 2011; Zimmermann et al., 2015).

As a response, forest ecologists and foresters have proposed to reduce stem density in drought-affected stands, to replace monocultures by mixtures, and to introduce more drought-resistant native and non-native temperate timber species (Pretzsch et al., 2013; Pretzsch et al., 2017). A favored strategy in many regions of Central Europe is to plant productive conifers in mixture with native broadleaf trees assuming that mixtures are more stable against environmental hazards, notably droughts (Steckel et al., 2020; Vannoppen et al., 2019) and pests (Brockerhoff et al., 2017; Jactel et al., 2005). However, drought exposure depends on the water consumption of the stand, and mixtures with productive species can exhaust soil water reserves to a larger extent than monocultures (Gebauer et al., 2012; Grossiord et al., 2014), which might expose one or more species of the mixture to increased drought stress. This was shown, for example, for European beech when planted in mixture with Norway spruce or Douglas fir (*Pseudotsuga menziesii* [Mirbel] Franco; Pretzsch et al., 2020; Thurm et al., 2016). Thus, doubts remain as to whether species mixing alone will be an effective measure to achieve a higher tolerance of temperate production forests to future drought and heat waves. It appears that the choice of suitable drought-tolerant tree species is more decisive for meeting the challenges of climate warming than the silvicultural options of species mixing and stand thinning alone. This requires information about the drought tolerance of the prospective timber species, which is available in Central Europe only for a few widely planted species

such *F. sylvatica*, *P. abies*, and *P. sylvestris*, but is mostly lacking for putatively more drought-tolerant alternative native tree species.

In drought-prone regions in Central Europe, the promotion and establishment of alternative, more drought-tolerant species is broad consensus in silviculture, but the criteria for the choice of species are heavily debated. A widely preferred option is the introduction of non-native conifers with proven or assumed higher drought tolerance, such as *Pseudotsuga menziesii* and *Pinus nigra* J.F. Arnold (Eilmann and Rigling, 2012; Isaac-Renton et al., 2014). However, this approach raises concerns regarding the species' invasive potential and associated negative effects on native biodiversity (Felton et al., 2016), unpredictable risks regarding future susceptibility to pests (Roques et al., 2019), and soil acidification by conifers (Cremer and Prietzel, 2017; Hobbie et al., 2006). For that reason, concepts to admix and promote native, putatively drought-tolerant species that are currently only secondary timbers in Central Europe, are gaining growing interest (Brang et al., 2008; Grundmann and Roloff, 2009; Kunz et al., 2018; Vitali et al., 2017). The tree flora of Central Europe contains several tree species of the genera *Acer*, *Carpinus*, *Fraxinus*, *Quercus*, *Sorbus* and *Tilia*, which occur also in the more continental climate of eastern Central and Eastern Europe, indicating that they might be more drought tolerant than the major timbers. Scattered information from ecophysiological studies on juvenile or mature trees additionally suggest that *Acer platanoides* L. (Norway maple), *Fraxinus excelsior* L. (European ash), and *Tilia cordata* Mill. (Small-leaved lime) may be promising candidate species with a putatively higher drought tolerance (Hemery et al., 2010; Jaegere et al., 2016; Köcher et al., 2009; Kunz et al., 2016; Leuschner et al., 2019; Leuschner and Meier, 2018; Scherrer et al., 2011; Schumann et al., 2019).

The bulk of dendroecological studies in Central Europe have dealt with the economically most important tree genera (*Picea*, *Pinus*, *Fagus*, and *Quercus*), while the minor timber species have only rarely been studied. The dendroecology of *A. platanoides* has been compared to that of sessile oak (*Quercus petraea* Matt. Liebl) and *F. sylvatica* by Zimmermann et al. (2015) in Central Germany and by Kunz et al. (2018) in south-west Germany with partly diverging conclusions. In terms of radial growth patterns, *T. cordata* turned out to be more drought tolerant than *F. sylvatica* in Belgium (Latte et al., 2020), but the results from this moist and oceanic climate may only partly be transferable to more continental climates. Most of the published dendroecological studies on *F. excelsior* were either conducted under climates very different to that of Central Europe, or the study focus did not allow for a comparative assessment of the species' drought

tolerance (Jalilvand, 2008; Koval and Maksymenko, 2020; Roibu et al., 2020; Weemstra et al., 2013). According to the study of Zimmermann et al. (2015) in mixed stands, *F. excelsior* is similarly drought tolerant as *Q. petraea*, and both species are more tolerant than *F. sylvatica*.

To fill the knowledge gap with respect to the drought tolerance of minor broadleaf timber species in Europe's temperate forests, we studied the growth patterns and climate response of *A. platanoides*, *F. excelsior* and *T. cordata* in comparison to *Q. petraea*, a major timber species in Central Europe that is dendroecologically well studied (Härdtle et al., 2013; Mette et al., 2013; Mayer et al., 2020; Scharnweber et al., 2011; Zang, 2011) and known to be drought-tolerant. The study was conducted in mixed forests along a precipitation gradient from sub-oceanic to sub-continental climate (ca. 900 to 500 mm annual precipitation) in Central Germany, i.e. from hydrologically optimal conditions close to the assumed drought limit of the species. The species sample consists of two ring-porous (*Q. petraea*, *F. excelsior*) and two diffuse-porous species (*A. platanoides*, *T. cordata*), representing two tree functional types with a likely different climate sensitivity of growth (Elliott et al., 2015). In 3 to 7 stands per species, we investigated temporal changes in climate-growth relationships with a moving window approach (Biondi, 1997) for the last 50 years, testing the common assumption of stationarity in the climate dependence of growth (Wilmking et al., 2020). For selected climatically defined droughts, we conducted superposed epoch analyses (SEA) to quantify growth depressions and lag effects, and calculated growth resistance and resilience indices (Lloret et al., 2011).

Based on earlier dendroecological studies in diffuse- and ring-porous species in temperate forests (Cavin et al., 2013; Muffler et al., 2020; Zimmermann et al., 2015), we formulated the following four hypotheses that guided our research: (i) Summer drought and heat are the main climatic determinants of radial growth in all four species. (ii) The sensitivity of radial growth to low summer precipitation and summer heat decreases toward the drier sites due to local adaptation. (iii) Radial growth is more resistant to summer drought events in the ring-porous than the diffuse-porous species, while growth resilience is similar. With complementary data from earlier studies on the drought sensitivity of the hydraulic system and the fine root system (Fuchs et al., 2020, Fuchs et al., submitted), and information on crown defoliation of the same species in a severe drought, we aimed at developing a comparative assessment of the suitability of *A.*

platanoides, *F. excelsior* and *T. cordata* for Central European silviculture in a future drier and warmer climate.

4.3 Material and methods

4.3.1 Study sites and tree species

Eight study sites were selected along a precipitation gradient in the planar to colline belt (110-440 m a.s.l.) of Central Germany. The climate is cool temperate with mean annual temperatures (MAT) ranging from 7.5 to 9.6°C and mean annual precipitation (MAP) from 502 to 894 mm, with cooler and moister climate found in the west and warmer and drier climate in the east (Figure 4.1, Table 4.1).

The four investigated tree species (*Acer platanoides*, *Fraxinus excelsior*, *Quercus petraea*, and *Tilia cordata*) are widespread in Central European broadleaf mixed forests, when *Fagus sylvatica*, the dominant species of Central Europe's natural forest vegetation, is absent. They occur mostly in communities assigned to the phytosociological alliances Carpinion betuli (oak-hornbeam forests) and Tilio-Acerion (mixed maple slope forests, Leuschner and Ellenberg, 2017). All four species are thought to be more drought tolerant than *F. sylvatica* (Leuschner, 2020), which is reflected in their occurrence in the more continental east of Europe. While *Q. petraea* is a primary timber species with high economic importance in most Central European countries on drier and more acidic soils, the other three species are only rare secondary timbers.

Figure 4.1: Map of the study region between the cities of Göttingen and Halle/S. in Central Germany with the precipitation gradient from west to east. The study sites are marked with red dots, the background colors indicate the long-term mean growing season precipitation (MGSP, April – September, 1967 - 2016) in mm. The area with MGSP >500 mm north-east of Göttingen is the Harz mountain range.

Table 4.1: Stand structural, soil physical and chemical and climatic characteristics of the stands selected to study the four species. Note that the species in many cases occurred in different stands at given sites, and thus different site characteristics are reported. Mean DBH (diameter at breast height), height and age of the studied trees in the stand are given with standard deviations. Soil properties include mean pH, C:N-ratio, Carbon content (C %), and soil texture of the top 60 cm of the profile, and the profile total (0-120 cm) of the soil capacity for plant-available water (AWC). Long-term annual means (1967-2016) of precipitation (MAP), growing season precipitation (MGSP, April - September), temperature (MAT), and growing season temperature (MGST) are also given. The table is sorted by species and in ascending order of growing season precipitation.

Spe- cies	Site	DBH (cm)	Height (m)	Age (years)	pH	C (%)	C:N	Soil texture	AWC (mm)	MAP (mm)	MGSP (mm)	MAT (°C)	MGST (°C)

Due to their widespread but infrequent occurrence in Central Europe, not all of the four species are present at each site. *F. excelcior* and *Q. petraea* occurred at seven sites along the transect, and *A. platanoides* and *T. cordata* at only five sites. Unfortunately, we had to exclude two stands in case of *T. cordata* due to a large numbers of missing rings, and poor cross-dating results that did not match the criteria for trustworthy chronologies. All eight sites consisted of several neighboring mixed and species-rich hardwood forest stands of variable species composition, and the target species grew in a maximum distance of several hundred meters to a few kilometers within those sites. The local edaphic and climatic conditions were investigated separately for those species that did not grow in close proximity to each other in the mixed stands (Table 4.1).

Primary criteria for stand selection were the presence of at least 12 (co-)dominant individuals of a given species in the upper canopy, no groundwater influence, and the absence of steep slopes and stony or very shallow soils. We aimed at selecting mature trees of about 90-120 years in age growing on silty to loamy soil of at least 40 cm of soil depth, but these conditions could not always be met regarding stand age and soil texture (cf. Table 4.1). To account for differences in soil texture, we included plant-available soil water capacity (AWC) as an additional factor besides climatic variables in the analysis of tree growth responses.

4.3.2 Climate

We used monthly precipitation and temperature data provided by the German Meteorological Service (DWD, Deutscher Wetterdienst, Offenbach, Germany) as gridded datasets with 1 km-mesh width, which provides precise local climatic data (Kaspar et al., 2013; Maier and Müller-Westermeier, 2010). The largest distance between any of our study sites and a weather station was 7.1 km. All long-term means were calculated for the investigation period 1967-2016.

The non-dimensional, multi-scalar standardized precipitation-evapotranspiration index (SPEI) was calculated with the R package *SPEI* using monthly precipitation sums and potential evapotranspiration data based on the approach of Thornthwaite (1948). To conduct correlation analyses with monthly climate data, we calculated the SPEI for a three months-window, assuming that drought conditions in the current month mainly depend on precipitation and evapotranspiration patterns in the recent and the two preceding months. In order to identify drought years in a climatological sense, we used the SPEI score of the month August calculated with a six months-window (SPEI_{summer}) to consider the drought conditions of the main vegetation period in combination with the spring and

early summer conditions as the period with highest physiological relevance. By definition, a drought year was characterized by a $\text{SPEI}_{\text{summer}} < -0.84$, a threshold also used by Sohn et al. (2016) in a study in a cold-temperate climate and the SPEI Global Drought Monitor (<http://sac.csic.es/spei/map/maps.html>).

Mean growing season precipitation (April – September; MGSP) does not show a clear trend during the study period from 1967 to 2016, while mean growing season temperature (MGST) increased by roughly 1°C (Figure 4.2). The warming was associated with a decrease in the standardized precipitation evapotranspiration index (SPEI; Vicente-Serrano et al., 2010) from $+0.6$ to -0.4 from 1967 to 2016.

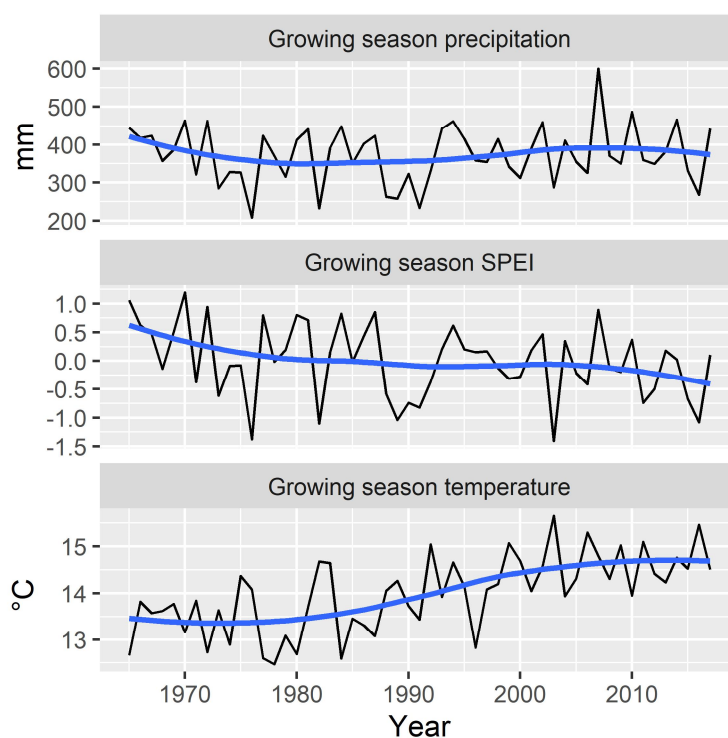

Figure 4.2: Temporal variation and long-term trend (25 year moving average) of growing season precipitation, temperature and SPEI (standardized precipitation-evapotranspiration index) in the period 1965-2016 in the study region (averaged over all study sites).

4.3.3 Edaphic conditions

Per site, soil samples were collected at three soil depths (0-10 cm, 10-30 cm, 30-60 cm), analyzed for soil chemical and physical parameters and subsequently averaged. We determined soil texture, bulk density, stone content (gravel >2 mm), and soil depth (using a Pürckhauer soil corer). Soil chemical variables quantified were soil pH (measured in H_2O), soil carbon and soil nitrogen content (measured with gas chromatography). Values reported in Table 4.1 are weighted means of the upper 60 cm of the soil. To estimate soil hydrologic characteristics (van Genuchten parameters; van Genuchten, 1980) from bulk

density and soil texture data, we employed the pedo-transfer functions proposed by Schaap et al. (2001) using the module “ROSETTA light” implemented in the software RETC (version 6.02, van Genuchten et al., 1991). Based on the van Genuchten parameters, we modelled water retention curves and estimated the soil water content at field capacity (soil matric potential of -300 hPa) and at the permanent wilting point (-1.5 MPa). Subsequently, the soil capacity for plant-available water (AWC) was calculated as the difference between these two water contents. The profile total of AWC (in mm) of a given stand was obtained by adding the AWC values of the three measured layers for the 0-60 cm profile, and extrapolating AWC to 120 cm depth or to bedrock depth by assuming uniform soil texture below 60 cm depth.

4.3.4 Sampling and processing of wood cores, and quality assessment of chronologies

At each study site, 12-18 dominant or co-dominant tree individuals from the upper canopy layer of each present species were cored in spring 2017. One core per tree (322 cores in total) was taken at breast height in the direction, where the influence of tension wood and other anomalies was assumed to be smallest. The cores were planed with a core microtome (WSL, Zürich, Switzerland; Gärtner and Nievergelt, 2010), colored with safranin and chalked. Tree-ring widths (TRW) were measured with a Lintab digital positioning table (Lintab 5, Rinntech, Heidelberg, Germany) using the software TSAP-Win v. 4.67c (Rinntech, Heidelberg, Germany).

Cross-dating and synchronization of the tree-ring series were performed both visually and by means of statistical analysis in TSAP-Win, employing the interval-sign test (“Gleichläufigkeit”, Eckstein and Bauch, 1969) and calculating t -values (Baillie and Pilcher, 1973). Several ring series could not be synchronized, leaving 249 cross-dated tree-ring series for further analysis (9-13 per site and species).

We applied conservative and rigorous detrending techniques, since our stands differed in age and management intensity, and we focused on single-year climate-growth interactions and short-term reactions to drought events. Flexible cubic smoothing splines with 50% frequency cut-off at 25 years were used to detrend and standardize the raw ring-widths series and we removed first-order autocorrelation by autoregressive modelling to eliminate age- and management-related trends and to accentuate year-to-year variability (Cook and Peters, 1981; Speer, 2010). Following Thurm et al. (2016), we additionally used basal area increment (BAI) time series and detrended them in the same manner as the ring-width series. All analyses were then carried out with detrended ring-width and

BAI data, revealing very similar results for both procedures. We therefore report only the results of the detrended ring-width index series.

Chronologies were built for all sites and species with Tukey's bi-weight robust mean (Cook and Kairiukstis, 1990) and truncated to the period of 1967-2016 to exclude younger tree life stages. The quality and strength of the common signal of the chronologies was assessed by means of the inter-series correlation (R_{bar}) and the expressed population signal (EPS) of the 50-year time series (Table 4.2). EPS was >0.85 in 20 of the 22 chronologies (0.84 and 0.80 in the other two). R_{bar} was further calculated for the chronologies in a 20-year moving window to search for temporal changes in growth synchronicity.

To assess long-term trends (only for Figure 4.9, Appendix C), ring-width series were age-detrended using the regional curve standardization (RCS) method (Biondi and Qeadan, 2008; Briffa et al., 1992). The regional age trend of all investigated species was estimated by aligning all tree-ring series per species based on the cambial age and the estimated average growth curve was used to detrend single series. Subsequently, RCS-chronologies were built using Tukey's bi-weight robust mean (Figure 4.9, Appendix C). All detrending procedures and the statistical analyses of chronologies were performed with the software R (version 4.0, R Core Team, Vienna) using the package "dendrochronology program library in R", `dplR` (Bunn, 2008).

4.3.5 *Climate sensitivity analysis*

Climate-growth relationships were analyzed with the R package `treeclim` (Zang and Biondi, 2015) by exploring the correlation between various current-year and previous-year climate parameters and annual ring width indices in the residual chronologies. With 1000-fold bootstrapping against random climate-growth pairs of the respective chronologies, the 95%-confidence intervals of the correlation coefficients were calculated and used to decide whether a coefficient was significantly different from zero or significantly different from another coefficient (when comparing the correlation coefficients of different chronology sections).

Several approaches were applied to investigate temporal and spatial variation of the climate sensitivity of growth: (1) Principal climate-growth relationships of the four species and different sites were calculated for the whole study period of 50 years between monthly precipitation, temperature and SPEI values of the previous or current season and annual radial increment to compare species and sites in terms of the general drought and

heat sensitivity of growth, and to identify the climatic parameters with largest influence. (2) After having identified the six most influential aggregated climatic parameters (previous-summer precipitation, current-spring precipitation, current-summer precipitation, previous-summer temperature, winter temperature, current-summer temperature), we calculated correlation coefficients for these parameters using a moving window approach (window size: 20 years, window offset: 1 year) to search for temporal change over the 50 years in the sensitivity of growth to these climatic drivers. (3) Due to the finding that the influence on growth of several factors changed markedly between the first (1967-1991) and the second half of the investigation period (1992-2016), we repeated the correlation analyses separately for the first and second 25 years of the period and tested for significant differences in the correlation coefficients of the two periods. We further searched for spatial variation in the trends of growth sensitivity to climatic aridity ($SPEI_{summer}$) along the precipitation gradient using linear models that relate the correlation coefficients of this relation to mean growing season precipitation (MGSP) and AWC at the respective site (cf. Weigel et al., 2018; and Muffler et al., 2020).

4.3.6 Drought response: pointer years, superposed epoch analysis, resistance and resilience indices

For exploring whether synchronous negative growth departures increase in frequency over time or with site aridity, negative pointer years were analyzed based on Cropper-values (Cropper, 1979) with normalization in a 5-year moving window (cf. Neuwirth et al. 2007). Thresholds for weak, strong, and extreme negative pointer years were 0.8, 1.2, and 1.5 standard deviations of growth decline, respectively, for at least 60% of the population (Figure 4.13, Appendix C).

To avoid bias due to the pre-selection of pointer years according to growth performance (Schwarz et al., 2020), we based the definition of a climatic drought year on the $SPEI_{summer}$ threshold of < -0.84 only, independent of the degree of growth depression. This resulted in the identification of 9-13 drought years at the different sites.

The selected drought years were used for superposed epoch analysis (SEA) of growth depressions and for calculation of the indices of growth resistance and resilience (as defined by Lloret et al., 2011). An epoch of 11 years (five years before and after the drought year) was chosen as recommended by Kunz et al. (2018). SEA calculates the mean departure in growth performance of each year in the epoch from the mean of all analyzed epochs per chronology (Lough and Fritts, 1987). Bootstrapping (5000-times) against randomly drawn epochs from the respective chronology was used for defining

95% confidence intervals of the departure. SEAs were performed with the R package `dplR` (Bunn, 2008).

The indices of growth resistance and resilience were calculated for each tree and each drought year using detrended ring-width index data. Resistance was defined as the drought/pre-drought and resilience as the post-drought/pre-drought ratio of growth, averaging over the five pre-drought and five post-drought years (Lloret et al., 2011). The index values were averaged across the different drought years for a given tree and tree-wise mean values were used for further analyses. To test for significant differences in indices between the species, linear mixed effects models (R package `lme4`, Bates et al., 2015) were fitted, where “species” was introduced as fixed effect and the “site×species” interaction as a random intercept in order to take the hierarchical variance structure of the dataset into account and correct for random site effects per species. Significant differences between species were identified using Tukey-adjusted p-values with degrees of freedom based on Satterthwaite’s approximation. To test whether the indices varied across sites, we fitted sets of linear mixed effects models for every species with MGSP and AWC as fixed effects and “site” as a random intercept to account for the hierarchical variance structure of the dataset. Various other climatic and soil physical or chemical parameters were tested, but none had a significant effect on growth resistance and resilience in any of the species. *P*-values were calculated with the R package `lmerTest` (Kuznetsova et al., 2017) with degrees of freedom based on Satterthwaite’s approximation and *R*² values calculated according to Nakagawa and Schielzeth (2013).

4.4 Results

4.4.1 General characteristics of the chronologies and long-term trends in radial growth

Mean annual tree-ring width (TRW) varied between 1.2 and 2.7 mm in *Q. petraea*, *A. platanoides* and *T. cordata* and between 1.7 and 3.0 mm in *F. excelsior* (Table 4.2) without a clear trend from the moister western to the drier eastern sites. Mean basal area increment (BAI) across all sites in the 50-year period was higher in the ring-porous species (23.5 and 23.2 cm² year⁻¹) than in the diffuse-porous species (16.8 and 16.8 cm² year⁻¹). Mean sensitivity of radial growth was nearly twice as high in the two diffuse-porous species (0.39-0.49) as compared to the two ring-porous species (0.20-0.27; Table 4.2). Despite marked increases in temperature and climatic aridity since the 1980s, none of the four species showed growth trends over time that were consistent across the sites,

neither in the 50-year study period since 1967 nor in the more distant past, and neither in the age-detrended index nor in the raw data (Figure 4.9 and 4.10, Appendix C).

The inter-series correlation (Rbar) of the detrended chronologies, i.e. the growth synchronicity within a population, was higher for *A. platanooides* and *Q. petraea* than for *F. excelsior* and *T. cordata* (Table 4.2). In most cases, growth synchronicity either increased or decreased during the study period, but a clear pattern among species and sites with different precipitation levels did not appear (Figure 4.16, Appendix C).

Table 4.2: Statistics of ring-width series (raw data) and index-based chronologies (all truncated to the period 1967-2016) of the four species at the different sites. MRW = mean ring width of all series \pm SD, AC (1) = first order autocorrelation \pm SD, MBAI = mean basal area increment of all series \pm SD, Rbar = inter-series correlation, MS = mean sensitivity, EPS = expressed population signal. The different sites of a species are sorted in ascending order of mean growing season precipitation.

4.4.2 Climate sensitivity of growth

The SPEI index, which combines precipitation and temperature effects, showed a significant positive influence on growth through a more humid weather (positive SPEI) in the current and previous year's summer months (May-August) in all four species and

at nearly all sites (Figure 4.3). While *T. cordata* and *F. excelsior* were supported equally by a higher summer SPEI in the current and previous summers, *A. platanoides* and *Q. petraea* responded more strongly to the current than the previous season. All four species showed a positive effect of higher precipitation on radial growth, which was most pronounced for current June rainfall in all species and visible at most sites. In the ring-porous species *Q. petraea* and *F. excelsior*, growth was further stimulated by the precipitation of current spring (February, March or April), while the influence of previous summer precipitation was generally not significant (Figure 4.11, Appendix C). Less clear was the influence of temperature, with all species showing a negative effect of higher temperature in single months of current and previous year's summer (Figure 4.12, Appendix C). On the other hand, *Q. petraea* responded positively to mild winter and spring temperatures at several sites, while *F. excelsior* reduced growth after warm Septembers in the previous year (Figure 4.12, Appendix C). Comparing the eight sites along the precipitation gradient revealed no trends in the growth dependence on climatic factors that could be explained by the decrease in MGSP. *Q. petraea* showed a weaker SPEI influence at the intermediate sites HK and GW than at the moister and drier sites (Figure 4.3).

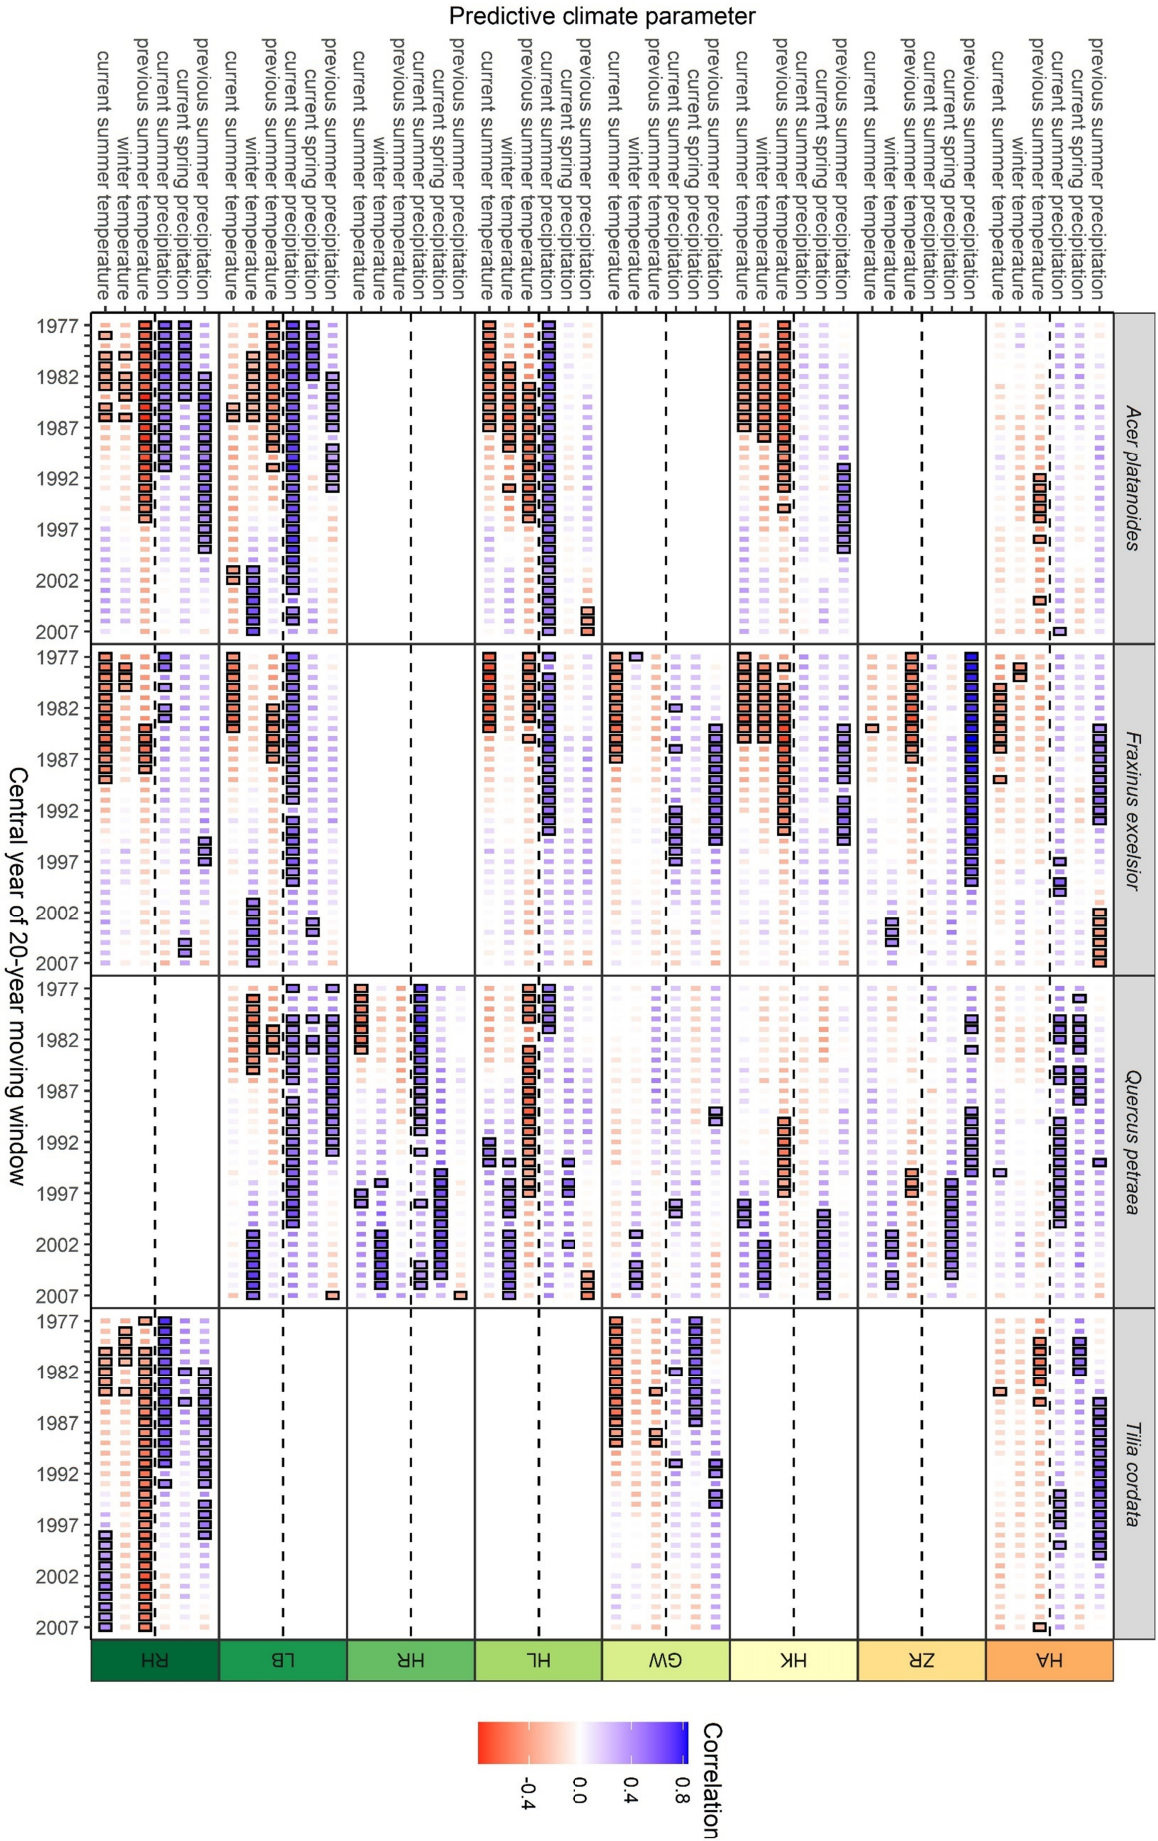

Figure 4.3: Correlation between radial growth (ring width index values) and the SPEI (standardized precipitation-evapotranspiration index) for months in the previous and current year for the four species at eight sites. The SPEI is calculated on a timescale of 3 months, because the drought conditions in the current month mainly depend on precipitation and evapotranspiration patterns in the current and the two preceding months. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars: $p > 0.05$). The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation. For site abbreviations see Figure 4.1.

The moving-window analysis of climate-growth relations in the 1967-2016 period proved for all four species non-stationarity. For most of the aggregate climate variables (averaging or summing over seasons instead of months), clear differences in the direction and strength of the correlation became evident between the first and the second half of the study period. In the majority of cases, a general trend towards declining growth sensitivity to both temperature and precipitation-related variables in the last 25-year period appeared (Figure 4.4). Especially for *A. platanoides* and *F. excelsior*, the positive effect of precipitation and negative effect of temperature declined markedly in importance at almost all sites over time. The correlation coefficient for the effect of temperature (previous summer, winter and current summer) became more positive over the 50 years in almost all species-site combinations, suggesting a diminishing negative effect and/or

increasing stimulating effect of elevated temperatures. In case of *Q. petraea*, higher winter temperatures became at nearly all sites a growth-stimulating factor over the past two decades, which was not the case in the first 30 years. In contrast to the other three species, *Q. petraea* did not show the general decline in its positive responsiveness to precipitation. Yet, the positive effect of spring precipitation on growth became significant at most sites only after 1995 (Figure 4.4).

Testing for differences between the climate-growth correlation coefficients of a species for the first (1967-1991) and the second half of the investigation period (1992-2016) confirmed in many cases significant changes primarily for the influence of winter and current summer temperatures (Figure 4.5). All significant changes in temperature correlation coefficients were positive, i.e. negative influences of temperature on growth weakened or turned into a positive effect. In contrast, observed changes in the correlation coefficients with previous and current summer precipitation were mostly negative, but changes were significant in only a few cases. This suggests that the positive influence of summer precipitation on radial growth tendentially decreased over time in the majority of species.

Figure 4.4 (next page): Moving window analysis of climate-growth relationships in the four species at eight sites for the period 1967-2016. Shown are the central years of the respective 20-year periods, testing for the correlation between six aggregate climate variables and annual ring width indices. Given is the size and sign of the correlation coefficient for the six relationships (red: negative relation, blue: positive relation, black frame: $p < 0.05$). Summer stands for June-August, Winter for December-February, spring for March and April. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Predictive climate parameter		Site								Species

Figure 4.5: Change in the climate-growth correlation coefficients between the 1967–1991 and the 1992–2016 period. The “+”/“-“ signs indicate positive/negative changes in the correlation coefficients, respectively. Bold red signs represent significant changes ($p < 0.05$), grey shading stands for missing data. Note: A positive change in the correlation coefficient can mean the switch from no to a positive correlation, or a switch from a negative to no correlation, a negative change means a shift in the opposite direction; see Figure 4.4 for a more detailed picture of temporal changes in the correlation coefficients.

Regressing the SPEI_{summer}-growth correlation coefficients against site specific MGSP for the first and second half of the investigation period separately revealed strong spatial trends for all species except *Q. petraea* in the first half of the investigation period (Figure 4.6). Sensitivity to SPEI_{summer} increased significantly towards the moister sites for *A. platanoides* and *F. excelsior* (R^2 of 0.89 and 0.55, respectively) and the same trend was visible for *T. cordata*, which unfortunately could not be tested due to the low number of sites in this species. These trends, together with the underlying positive influence of the SPEI on growth, disappeared in the second half of the investigation period (Figure 4.6). Regressing SPEI_{summer}-growth correlation coefficients against AWC (plant-available water capacity of the soil) revealed no trends at all (data not shown).

Figure 4.6: Relationship between annual ring width indices and summer SPEI (= standardized precipitation-evapotranspiration index of the month August, calculated for a 6-months window) for the four species in dependence on mean growing season precipitation (MGSP) of the stand for the 25-year periods 1967-1991 and 1992-2016. Significant correlation coefficients are marked by red 95%-confidence interval bars. Each dot represents one site per species; MGSP refers to the corresponding 25-year periods. The blue regression lines with 95% confidence interval display significant relationships between correlation coefficient and MGSP, non-significant regression lines are not shown.

4.4.3 Growth response to drought years

Negative pointer years did not show a trend over time in the 50-year study period in any of the species, nor a clear pattern in dependence on MGSP (Figure 4.13, Appendix C).

Superposed epoch analysis (SEA) conducted for 9-13 climatically defined drought events revealed reduced growth in drought years for most site-species combinations, but this pattern was significant at $p < 0.05$ only in 5 of the 22 site-species combinations (Figure 4.7). The negative growth deviations were stronger and more often significant in the diffuse-porous than in the ring-porous species. *F. excelsior* did not show a single significant growth reduction in any of the drought years, but revealed a lagged negative growth departure one to three years after the drought at several sites. *T. cordata* showed the strongest and most consistent lag effect after drought years with an always significantly reduced increment in the first year after drought and at two of the three sites

in the second year after drought as well (Figure 4.7). In three of the species, MGSP had no influence on the pattern of post-drought growth response. Only *A. platanoides* showed tendentially stronger and more often significant growth reductions towards the moist end of the precipitation gradient (Figure 4.7).

Figure 4.7: Results of superposed epoch analyses on the response of radial growth of the four species at the eight sites to drought events with a $\text{SPEI}_{\text{summer}} < -0.84$. Shown is the deviation of mean ring width in an 11-year period with the drought years in the center from the mean ring widths in all analyzed 11-year epochs of the chronology. Significant departures ($p < 0.05$) are shown in dark grey with red frame. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

With respect to the two tested drought tolerance indices, *A. platanoides* showed the lowest drought resistance, i.e. the strongest growth depression in drought years with a median increment reduction of 21%, followed by *T. cordata*, *F. excelsior*, and *Q. petraea* with 19%, 11%, and 8%, respectively (Figure 4.8). The differences between the species were only significant between *A. platanoides* and the ring-porous species. Growth

resilience, i.e. the ratio of post-drought to pre-drought increment, was similar among the four species without significant differences and values close to 1 (Figure 4.8). This indicates that all species regained their pre-drought increment level within less than five years and were able to compensate possible lags in growth recovery in the first years after drought that were visible in the SEA (Figure 4.7) by overshooting in the 3rd to 5th year after drought.

Figure 4.8: Resistance and resilience of radial growth of the four species to selected droughts in an 11-year window with the drought year in the centre of the period. All drought events with a SPEI < -0.84 (based on the SPEI of the month August with consideration of a six-months window) in the study period were considered. The indices were calculated using detrended ring width indices pooling for every species over all sites and all identified drought years. Resistance is the growth depression in a drought year compared to the 5 years prior to drought, resilience the ratio of mean radial growth in the five post-drought years relative to the growth in the five years prior to drought. Different small letters indicate significant differences between species based on Tukey-adjusted p-values from linear mixed effects models with degrees of freedom based on Satterthwaite's approximation. Number of trees was $n = 57$ for *A. platanoides*, $n = 83$ for *F. excelsior*, $n = 80$ for *Q. petraea*, and $n = 29$ for *T. cordata*; the number of studied drought events varied between 9 and 13, depending on sites.

We are aware that many studies use raw ring widths or raw BAI to calculate tolerance indices (70% according to Schwarz et al. 2020). However, using detrended data seems to be the safe choice when dealing with all the heterogeneity and irregular management

effects that come with minor timber species and species-rich stands. Nevertheless, the same patterns of the indices were found, when resistance and resilience were calculated with raw BAI data (Figure 4.15, Appendix C).

No relationship was observed between measures of site-specific water availability (MGSP or AWC) and growth resistance or resilience (Table 4.3). The marginal R^2 s of all models were very low (0.02-0.12), indicating low explanatory power of the predictors; a considerable portion of the variance was explained by random site-effects (site SD), but most of the variance occurred between individuals (residual SD).

Table 4.3: Results of linear mixed effects models exploring the relationship between various environmental variables and the tolerance indices growth resistance and resilience. Given are the scaled estimates for the effect of MGSP (mean growing season precipitation) and AWC (soil capacity for plant-available water), as well as the standard deviation for the random effect “Site” (Site SD), the residual standard deviation (Res. SD), and marginal and conditional R^2 values of the models. None of the fixed effects was significant at $p < 0.05$. As data were available for *T. cordata* only at three sites, this species is omitted here.

Species	Term	Resistance	Resilience
Acer platanoides, n = 57	MGSP estimate	-0.042	0.204

4.5 Discussion

4.5.1 Higher drought tolerance of the ring-porous species

We found a nearly twice as high mean sensitivity of radial growth for the diffuse-porous species (*A. platanoides*, *T. cordata*) as compared to the ring-porous species (*F. excelsior*, *Q. petraea*). This was linked to the ring-porous species' lower growth sensitivity to severe drought events, as revealed in the superposed epoch analysis (SEA),

supporting our third hypothesis. A relatively low growth sensitivity to drought of temperate ring-porous tree species is a well-recognized phenomenon (Kunz et al., 2018; Meyer et al., 2020; Scharnweber et al., 2011; Zimmermann et al., 2015). While the high drought tolerance of *Q. petraea* has been reported in many dendrochronological studies (Cavin et al., 2013; Elliott et al., 2015; Kunz et al., 2018; Zang, 2011; Zimmermann et al., 2015), much less is known about the drought response of *F. excelsior*. Our results confirm the judgement of Zimmermann et al. (2015) that the drought tolerance of growth of *F. excelsior* is comparable to that of *Q. petraea*.

A plausible explanation of the higher drought sensitivity of growth of diffuse-porous species is provided by the different seasonality of cambial activity and the contrasting hydraulic importance of early-wood formation in ring- and diffuse-porous species. Earlywood formation in ring-porous species usually occurs before and during bud burst (Barbaroux and Bréda, 2002), and the hydraulic capacity of ring-porous species is highly dependent on these newly formed early-wood vessels. In fact, the bulk of the hydraulic conductance in the stem xylem is provided by the current-year ring, while older vessels typically suffer from drought- or frost-induced embolism formation (Cochard and Tyree, 1990; Michelot et al., 2012b).

Temporal avoidance of drought effects on cambial activity may be a main cause of the reduced inter-annual variation in tree-ring widths (TRW) in ring-porous species. In agreement with this interpretation, we did not find a single missing ring in any of the ring-porous cores. Drought stress during spring has been identified as the single most important climatic factor controlling radial increment in oak (Tardif and Conciatori, 2006). This is supported by the growth response to the 1976 drought with water deficits already in spring, when negative growth departures were similarly strong in *Q. petraea* and *F. excelsior* as in *A. platanoides* and *T. cordata* (Figure 4.14, Appendix C). However, when the drought occurs later in the season, as usually does in Central Germany, ring-porous species may show smaller growth reductions than diffuse-porous species.

4.5.2 Climatic drivers of radial growth

The SPEI index as a proxy of the climatic water balance had in all species a larger influence on radial growth than precipitation or temperature alone, which suggests that water availability acts together with the atmospheric evaporative demand in the control of foliar, stem and root water status and thus cambial growth activity. Many dendrochronological studies in Central European lowland forests have shown that the growth of beech, oak and other broadleaf trees is primarily limited by moisture

availability (Knutzen et al., 2017; Latte et al., 2016; Scharnweber et al., 2011). A reduced TRW in dry summers might be caused by processes that impair the growth potential of the stem cambium, among others reduced carbon gain due to partial stomatal closure, turgor loss in cambial cells due to a reduction in the tree's hydraulic capacity, and reduced allocation of carbohydrates to radial growth due to enhanced investment in roots (Allen et al., 2010; Bréda et al., 2006; Müller-Haubold et al., 2013). However, smaller annual rings can also mirror an acclimation response of the tree to increase drought hardiness through the production of thicker pit membranes and narrower and/or a smaller number of conduits that accompany smaller tree rings (Fonti et al., 2013). This reduces hydraulic efficiency, but increases hydraulic safety (Hacke and Sperry, 2001). Reduced radial growth could then increase fitness in the longer term, and the growth reduction may represent a strength rather than a weakness in the face of drought (Bréda et al., 2006; Gessler et al., 2020, Lloret et al., 2011). In the absence of long-term mortality records of the stands, it remains questionable whether the ring-porous species of our sample with their lower responsiveness to summer droughts are more successful than the diffuse-porous species.

The consistent influence of previous-year's summer SPEI on the growth of *F. excelsior* and *T. cordata* indicates that radial growth relies strongly on stored carbohydrates of the past summer in these species (Kozłowski and Pallardy, 1997). In accordance, earlier studies on *F. excelsior* also observed that the previous years' summer climate explains most of the current-year growth (Jalilvand, 2008; Koval and Maksymenko, 2020; Roibu et al., 2020). Important carry-over effects on radial growth have also been found in other temperate broadleaf species such as *F. sylvatica* (Di Filippo et al., 2007; Dittmar et al., 2003; Lebourgeois et al., 2005; Müller-Haubold et al., 2015). In our study, *A. platanoides* showed a significant and consistent influence of the previous summer only for the negative temperature effect, but a much weaker influence of previous year's precipitation. For the radial growth of *Q. petraea*, in contrast, previous summer's weather was relatively unimportant, matching the generally lower susceptibility of oak growth to variation in precipitation and temperature (Friedrichs et al., 2009b; Mérian et al., 2011; Michelot et al., 2012a; Meyer et al., 2020). One possible explanation of species differences in the importance of carry-over effects on radial growth is the extent of carbohydrate allocation to the fine root system. *Q. petraea* seems to maintain a smaller fine root system than the other species and its fine roots are less drought-sensitive than in the other species (Fuchs

et al., 2020). Temporal shifts in the carbohydrate allocation to the root system might therefore be less important in oak than in the other species.

4.5.3 *Climate sensitivity of growth and drought acclimation*

Our data demonstrate non-stationarity in the relationship between climate factors and TRW during the last 50 years for all species with a major change in the correlation patterns occurring in the 1980s/90s. All four species showed distinct and similar temporal trends of the climate sensitivity of growth, notably a loss of temperature and summer precipitation sensitivity from the 1970s and 1980s towards the 1990s and 2000s. This unexpected trend was particularly strong in *A. platanooides* and *F. excelsior* and less clear in *Q. petraea*. While age- and size-related processes often affect the climate-growth relationships of trees (Carrer and Urbinati, 2004; Rozas, 2005; Trouillier et al., 2019), this influence can be excluded as the predominant driver in our study, as the sensitivity decline was observed across all age classes and in stands of different height and stem diameter. For the same reason, an increase in competition intensity, which has been shown to cause a gradual loss of climate sensitivity (Piutti and Cescatti, 1997; Rozas, 2001), can be excluded as a driver as well. The stands have been subject to repeated selective cutting in the past, yet at different intervals and intensities. Since the climate-growth response was similar, but the management regime different in the stands, low-intensity timber extraction cannot be the underlying cause either. Thus, the ongoing temperature increase and decrease in the SPEI in the growing season must be the principal driver of the declining climate sensitivity of growth.

Our finding relates to the ‘divergence problem’ (D'Arrigo et al., 2008) and the ‘loss of track’ phenomenon (Wilmking et al., 2020) that have been reported mostly in forests at colder sites, where radial growth failed to capture the climate warming trend of the past decades and concomitantly lost its temperature sensitivity. However, most of the observations refer to tree line or high-latitude forests, where the temperature influence on growth is positive (D'Arrigo et al., 2008). In lowland forests, in contrast, summer temperature is usually negatively correlated with growth. Here, edaphic and atmospheric drought and heat exposure are usually the main climatic drivers of growth (Knutzen et al., 2017; Scharnweber et al., 2011). Increases in temperature and climatic aridity should increase the drought sensitivity of tree growth in such environments, which has been observed for various species including *Q. petraea* (Friedrichs et al., 2009b; Kolář et al., 2017; Roibu et al., 2020). In contrast, other authors reported decreases in growth sensitivity to summer temperature or summer SPEI during the last decades (Mérián et al.,

2011; Dobrovolný et al., 2016) and during the warm decade in the 1940s for *Q. petraea* (Friedrichs et al., 2009a), which is in line with our results.

One possible explanation for such a phenomenon may be offered by the analysis of theoretical environment-growth response curves (Wilmking et al., 2020). Applying this concept to our observations suggests that episodically increased drought intensities in an already drought-limited environment should reduce the drought sensitivity of the species, because water shortage is limiting growth in every year. However, this concept does not provide a plausible explanation for the climate sensitivity decrease in our study, because a general growth reduction over time was absent.

We observed in none of the species a clear decrease in mean radial growth rate towards the drier end of the transect, which might indicate acclimation or adaptation of the local populations to reduced water availability either genetically or within the frame of phenotypic plasticity. This is supported by the decreasing sensitivity to summer SPEI towards the dry end of the climatic gradient in all species except *Q. petraea*, which was found for the period 1967-1991 (but not in the 1992-2016 period; Figure 4.6). Corresponding patterns of apparent adaptation to drier habitats were reported for *F. sylvatica* in pan-European studies (Cavin and Jump, 2017; Muffler et al., 2020), but lacked in *Q. petraea* in our study. Whatever the cause, constant growth rates in a period of increasing climatic aridity, in association with reduced climatic sensitivity of growth, must be interpreted as a sign of a considerable drought tolerance of all four tree species. In conclusion, the decreasing drought sensitivity towards drier conditions in the three minor timber species, both on a spatial and a temporal scale, indicates adaptation and acclimation processes to drier conditions.

4.5.4 Growth resistance and resilience to severe drought events

The results of the SEA study on the species' growth response to climatically defined droughts revealed species differences. The growth depression in the drought year was generally greater in the two diffuse-porous species (smaller resistance), suggesting that diffuse-porous species may be more flexible in their carbon allocation by reducing radial growth more strongly in drought years. This could be a result of higher investment in fine root production, which seems to be rather low in ring-porous *Q. petraea* (Fuchs et al., 2020; Hertel and Leuschner, 2002). Yet, all species showed high growth resilience in the five post-drought years with partial overshoot in some cases. This suggests that the four species may pursue different growth and allocation strategies in response to severe droughts, while fitness maintenance after drought is similar. This is indicated by the 50-

year TRW chronologies (Figure 4.9 and 4.10, Appendix C), which show for none of the species a lasting growth depression after the severe 1976 drought.

To which extent radial growth reductions after drought and mortality are interlinked in the four species is largely unknown. However, many temperate tree species exhibit decades of reduced growth before they die (Cailleret et al., 2017). This suggests that the studied populations of the four species are unlikely to suffer increased drought-induced dieback in the near future, as none of the TRW chronologies showed marked declines. The survey of crown conditions conducted on all study sites in late summer 2019 after two consecutive drought years with the most extreme heatwaves in Central Europe since the beginning of climate records supports this assumption, as no severe defoliation or partial canopy dieback was observed (Figure 4.17, Appendix C).

Growth resistance and resilience did not vary systematically with the local climate and soil water capacity of the sites. The high residual variance of the models indicates that most of the variation found in the resistance and resilience indices occurs between individuals and not sites. This is plausible, as small-scale heterogeneity in stand microclimatic and soil physical properties at the position of the tree individuals is large in mixed stands with bigger distance between the sampled individuals.

Climate and soil are not the only factors influencing the growth response to drought, tree age may also be important. We tested for tree age effects on growth resistance and resilience but did not find any effect (but see Kunz et al., 2018). We attribute this to the fact that most trees of our study were of mature age (90-130 years).

4.5.5 *Other sources of growth reductions*

Negative pointer years may not only be caused by exceptional droughts, but can result from other abiotic and biotic factors as well. The two most important biotic factors are mast years (Pearse et al., 2016) and infestations with insects, fungi or other pests (Schweingruber, 1996). Within our species sample, *Q. petraea* is by far most affected by these biotic stress factors with a large number of periodically upcoming pests and insect infestations (Gibbs and Greig, 1997; Roloff et al., 2010). Oak is also a distinct mast-fruited species with a large seed mass amplitude between years and related high carbon costs (Nussbaumer et al., 2018). *F. excelsior* is a mast-fruited species as well (Tapper, 1996), whereas fluctuations in seed production of *A. platanoides* and *T. cordata* are rather low (Roloff et al., 2010; Wesołowski et al., 2015). The species-specific mast-fruited behavior offers a possible explanation of the high frequency of negative pointer years in *Q. petraea*

that mostly did not coincide with drought years, in contrast to the small number of negative pointer years in *T. cordata*.

Mast years in *F. excelsior* are, in a similar manner as in *F. sylvatica*, typically cued by a warm and sunny previous summer with a long foliation period (Piovesan and Adams, 2001; Tapper, 1996; Vacchiano et al., 2017). In contrast, mast-fruiting in *Q. petraea* is triggered by a warm spring of the current year (Bogdziewicz et al., 2019). These species differences between *F. excelsior* and *Q. petraea* can explain the different lag effects of warm and dry previous years on radial growth (Figure 4.3), because low SPEI values over the previous vegetation period may have induced masting years with reduced TRW in *F. excelsior* but not in *Q. petraea*. The consistent negative growth reaction of *F. excelsior* to a higher previous year's September temperature, which is associated with a longer foliation period, supports this explanation.

Due to large differences in pest-induced vitality fluctuation and in inter-annual variability of masting intensity and related carbon costs among the four species, we rate pointer year frequency as a weak tool for drought-sensitivity assessments in species comparisons. Conventional pointer year definitions (e.g after Cropper, 1979) depend on growth synchronicity in the stand, with higher growth synchronicity increasing the probability of pointer year identification. Yet, low synchronicity is not necessarily an indicator of high drought tolerance. In our study, pointer year frequency was not consistently related to the frequency and severity of drought events during the past 50 years. The strongest and regionally most consistent negative pointer year in *Q. petraea* was 1996, a cold and moist year, in which negative growth deviations of *Q. petraea* were most likely caused by a relatively short vegetation period due to cold spring temperatures. Further, the species with the lowest growth synchronicity (*T. cordata*) exhibited the lowest frequency of pointer years, but showed stronger growth reductions in drought years than *Q. petraea* and *F. excelsior*. Considering the influence of these drought-unrelated factors suggests that the calculation of growth resistance and resilience to droughts may in part be biased and the drought tolerance of highly pest-susceptible and mast-fruiting species such as *Q. petraea* and partly *F. excelsior* might be overestimated.

4.5.6 Conclusions

Assessing the drought tolerance of tree species through the analysis of radial growth resistance to drought events and its responsiveness to climatic factors can provide valuable information on abiotic drivers of tree vitality. However, a concise drought tolerance assessment requires additional information on background and drought-induced

mortality in unmanaged stands, which is difficult to obtain in the managed forests of Central Europe. A causal analysis of drought-induced mortality events that includes physiological measurements would help to identify lethal stress levels and critical elements in the species' drought response strategy, as it remains questionable whether growth reductions are always an expression of vitality loss, or are part of a plastic drought response that leads to morphological, anatomical and physiological acclimation.

All three minor timber species showed decreasing summer drought sensitivities towards the dry end of the gradient in the 1970s and 1980s and a general loss in climate sensitivity over time, which may point at considerable potential to acclimate to a warmer and drier climate. *Q. petraea* exhibits only minor inter-annual variation in TRW and thus a low growth sensitivity to climate and the highest resistance to drought years of all studied species. However, the apparent climate-insensitivity of growth in *Q. petraea* is partly caused by the large number of other growth-reducing events, notably pests and mast-fruited, which may weaken the climatic signal and lead to overestimation of the species' drought tolerance. The dendrochronological data for *F. excelsior* suggest that the species is almost as drought tolerant as *Q. petraea* and thus equally suited for a warmer and drier climate. However, the species is severely threatened by the pan-European ash dieback caused by the fungus *Hymenoscyphus fraxineus*. *A. platanooides* and *T. cordata* showed distinct growth reductions in drought years and a high growth sensitivity to the SPEI, but both were highly resilient and fully regained their pre-drought growth levels, which is reflected in only low defoliation and no recorded dieback on the study sites after the exceptional 2018/19 drought. We conclude that all four studied broadleaf species are in terms of their radial growth performance relatively drought tolerant. This qualifies the three minor timbers for further assessment of their suitability for the establishment of drought-tolerant forests in Central Europe.

Acknowledgements: We gratefully acknowledge the financial support granted by the Bundesministerium für Ernährung und Landwirtschaft (Germany), Bundesministerium für Umwelt, Naturschutz und nukleare Sicherheit (Germany) and the Fachagentur Nachwachsende Rohstoffe e. V. (Germany) within the frame of the “Waldklimafonds” (project DIVforCLIM). Additionally, we thank the local forestry authorities of Lower Saxony and Saxony-Anhalt and the DBU-Naturerbe GmbH for permissions to conduct the study, and the Nordwestdeutsche Forstliche Versuchsanstalt for kindly providing forest inventory data for the identification of suitable study sites. Special thanks go to Annegret Kellner, Jutta Czernitzki, Irmgard Gerstmann and Leonhard Klinck for their skillful support in the lab and field work.

4.6 Appendix C

Figure 4.9: Ring width index chronologies for the four species at the eight sites, age-detrended with regional curve standardization (RCS). The blue line is a 25-year smoothing spline. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Figure 4.10: Ring-width chronologies for the four species at the eight sites using the raw data from 9-13 tree individuals per stand which were averaged using Tukey's bi-weight robust mean. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Figure 4.11: Correlation between radial growth (ring width index values) and the precipitation totals of months in the previous and current year for the four species at eight sites. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars: $p > 0.05$) based on 1000x bootstrapping against randomly chosen precipitation-growth pairs. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Figure 4.12: Correlation between radial growth (ring width index values) and mean temperature of the months in the previous and current year for the four species at eight sites. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars: $p > 0.05$) based on 1000x bootstrapping against randomly chosen temperature-growth pairs. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

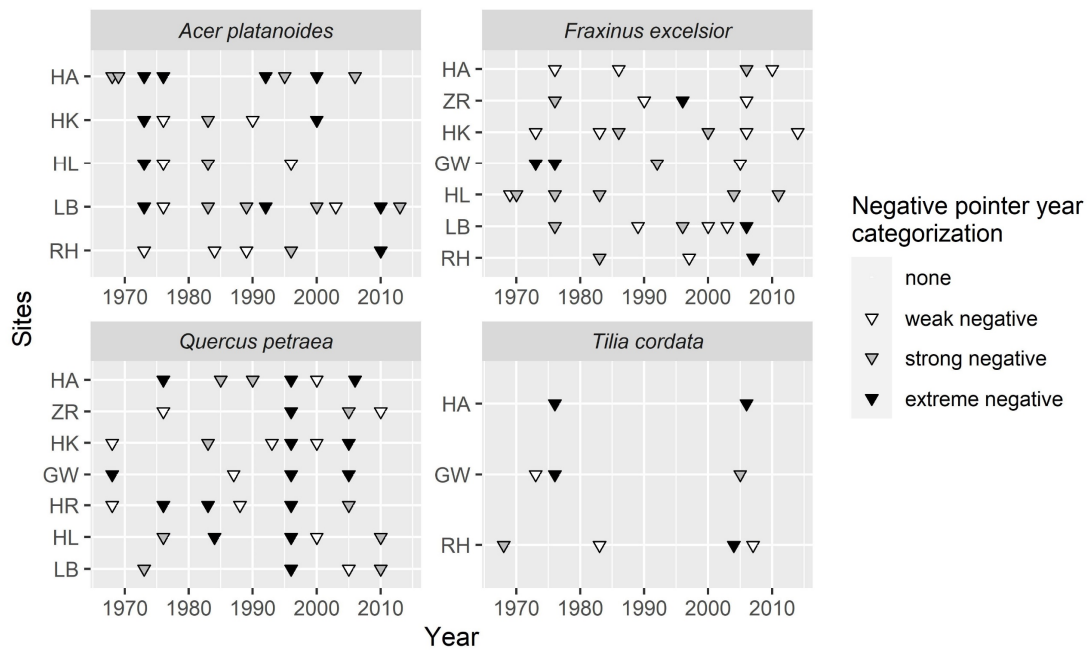

Figure 4.13: Negative pointer years of the four species on the eight sites in the period 1967-2016 according to Cropper-values following the approach of Neuwirth et al. (2007) with normalization in a 5-year moving window. Thresholds for weak, strong, and extreme negative pointer years were 0.8, 1.2, and 1.5 standard deviations of growth decline, respectively, for at least 60% of the population. Site are arranged according to mean growing season precipitation from drier to moister.

Figure 4.14: Percentual reduction in BAI in the drought year 1976 relative to the average BAI of the five preceding years for the four species at the eight sites. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Figure 4.15: Resistance and resilience of basal increment of the four species to selected droughts in an 11-year window with the drought year in the centre of the period. All drought events with a SPEI < -0.84 (based on the SPEI of the month August with consideration of a six-months window) in the study period were considered. The indices were calculated using raw BAI data pooling for every species over all sites and all identified drought years. Resistance is the growth depression in a drought year compared to the 5 years prior to drought, resilience the ratio of mean radial growth in the five post-drought years relative to the growth in the five years prior to drought. Different small letters indicate significant differences between species based on Tukey-adjusted p-values from linear mixed effects models with degrees of freedom based on Satterthwaite's approximation. Number of trees was $n = 57$ for *A. platanoides*, $n = 83$ for *F. excelsior*, $n = 80$ for *Q. petraea*, and $n = 29$ for *T. cordata*; the number of studied drought events varied between 9 and 13, depending on sites.

Figure 4.16: Within-population growth synchronicity of the four species at the eight sites in the period 1967-2016. Given is the interseries correlation (R_{bar}) as derived from a moving 20-year window analysis of ring width index series. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high).

Figure 4.17: Frequency of crown damage classes in late summer of 2019 (September) in the stands of the four species at eight sites after the extreme 2018/19 drought as derived from the inspection of each five individuals. Site acronyms are explained in Figure 1. The crown damage classes 0 to 3 base on a ground-based visual assessment of the canopy’s defoliation and discoloration (damage is defined as the sum of discolored and fallen leaves in percent of full foliation; 0 = 0% - 10% damage; 1 = 10% - 25% damage, 2 = 25% - 60% damage, 3 = > 60% damage). *Carpinus betulus* and *Fagus sylvatica* trees that occurred in the same stands are reported for comparison.

5 SYNOPSIS

In the following, I start with a general overview of drought response strategies and their implications for the ability of a species to withstand drought in the light of existing knowledge from literature. Thereafter, I summarize and integrate the main findings of the three manuscripts presented in my dissertation, incorporating them into a profound evaluation of the species' strategies to cope with drought. In doing so, I deduce a drought stress resistance ranking of the studied species to rate the suitability to grow under increasingly dry and hot conditions in sub-continental regions in Central Europe.

5.1 Drought response strategies

Drought resistance in a broad sense describes adaptive features of plants to enable them to either escape, avoid, or tolerate drought stress (Basu et al., 2016; Levitt, 1980). Applied to trees, escape strategies (e.g. by completion of life cycles before the onset of drought) are not an option. Thus, trees either tolerate or avoid drought stress.

This dualism is mirrored in the spectrum of anisohydric (tolerating drought stress) and isohydric strategies (avoiding drought stress; McDowell et al., 2008). *Sensu stricto*, the terms iso- and anisohydry originate from a clear distinction between two stomatal control strategies (Tardieu and Simonneau, 1998), but lately, they have rather been found to represent the extremes of a continuum (Klein, 2014) and to be interrelated with many other functional traits (Leuschner et al., 2019; McDowell et al., 2008). Isohydry involves a stringent stomatal control during drought, keeping the xylem water potential in a range that protects the rather vulnerable xylem from excessive embolism. This implies restricted carbon assimilation during drought and therefore large capacities to store assimilates and water within the plant. Otherwise, isohydric plants are prone to carbon starvation (i.e. the vitality loss and/or mortality due to a negative carbon balance as a consequence of reduced assimilation; McDowell et al., 2008). In contrast, anisohydric plants close their stomata less strictly during drought, allowing for lower xylem water potentials to extract water from drier soils, maintaining carbohydrate assimilation, and relying on high resistances against xylem embolism and leaf turgor loss (McDowell et al., 2008). This strategy allows for a better carbon balance during drought, but low values of minimum leaf water potentials also imply narrow safety margins.

Stomatal closure, closely correlated with leaf turgor loss (Brodribb et al., 2003) and controlled by a complex interplay of physiological mechanisms and chemical signaling

(Guyot et al., 2012; Tardieu and Davies, 1993), is the predominant mechanism to cope with non-extreme drought conditions (Choat et al., 2018; Meinzer et al., 2009). During prolonged drought conditions, however, stomatal closure cannot prevent further tissue desiccation due to residual water loss through bark and cuticle (Choat et al., 2012; Duursma et al., 2019). At this point, the width of the hydraulic safety margin is critical, as it represents the safety buffer between stomatal closure and hydraulic failure (irreversible xylem damage due to embolism). Hydraulic safety margins can therefore be considered as highly informative for comparing the resistance of given species to prolonged drought (Choat et al., 2018).

Summing up the above, hydraulic safety-related traits (like xylem embolism resistance, leaf turgor loss and hydraulic safety margins) in combination with stomatal control strategies give insights in the physiological drought responses of a species. Nevertheless, responses to drought stress also occur on other levels across all organs of a tree. Many species shed their leaves in order to reduce transpiration (Blackman et al., 2019) and adjust carbon partitioning to root growth (McDowell et al., 2008; Ryan, 2011). The prominent role of fine roots in plant-water-relations is well accepted (Brunner et al., 2015), but the role of soil-root-interactions is still underestimated and often neglected in modelling approaches of drought-related mortality (Carminati and Javaux, 2020).

A higher investment to root growth could find expression in deeper rooting to better access remaining soil water reserves, a denser fine root system to extract residual soil water, and higher fine root turn-over. While deeper and denser root systems seem intuitively the most obvious responses to reduced water availability, field studies are inconsistent on this matter (Bakker et al., 2006; Blanck et al., 1995; Chenlemuge et al., 2013; Hertel et al., 2008; Hertel et al., 2013; Kuster et al., 2013; Leuschner et al., 2004; Meier and Leuschner, 2008; Parker and van Lear, 1996; Santantonio and Hermann, 1985). In contrast, increased fine root mortality has been concordantly reported (Brunner et al., 2015; Wang et al., 2018), although a reduction of the absorbing surface in the face of reduced water availability seems counterintuitive. Explanations are either the quick replacement by new, physiologically more active roots to increase the absorptive capacity or the active shedding of fine roots to uncouple more expensive organs from low water potentials in the dry soil ('hydraulic fuse theory'; Alder et al., 1996; Jackson et al., 2000; Kotowska et al., 2015). Alternatively, fine roots may just die due to dehydration and need to be replaced. Being the most distal organs belowground, fine roots are quickly replaceable and relatively cheap in terms of carbon costs (only representing a few percent

of the tree's total biomass; Jackson et al., 1997) and can be shed or sacrificed in a similar manner as leaves upon drought. In any case, increased fine root necromass/biomass ratios indicate an elevated stress level, low drought resistance of the fine roots, and/or a deficient or slow replacement by new fine roots.

The interplay of stomatal control strategies and associated constraints on carbon assimilation, leaf shedding, investments in hydraulic safety, and fine root replacement results in shifts in carbon allocation within the whole tree. In consequence of reduced carbon assimilation, the allocation to replacement of distal organs, reproduction and even carbon storage is often prioritized over radial stem growth (Wiley et al., 2017). In addition, a greater proportion of the fixed carbon is lost through photorespiration during drought stress (Wingler et al., 1999). Therefore, a higher level of drought exposure in the growing season is directly affecting a tree's radial stem growth, which is - in return - a good proxy of a species ability to tolerate stress and maintain assimilation rates. However, narrower annual rings are also associated with acclimation and/or adaptation responses in the stem xylem of the tree to increase drought resistance through the production of thicker pit membranes and less and smaller conduits (Fonti et al., 2013). This reduces hydraulic efficiency but increases hydraulic safety (Hacke and Sperry, 2001). Reduced radial growth could then increase fitness in the longer term, and the growth reduction may represent a strength rather than a weakness in the face of increasing drought exposure (Bréda et al., 2006; Gessler et al., 2020; Lloret et al., 2011).

5.2 Species-specific ability to cope with drought and their suitability for future silviculture

5.2.1 Quercus petraea

In agreement with various reports in literature, *Q. petraea* turned out to be the most drought-tolerant of the five species (e.g. Cavin et al., 2013; Kunz et al., 2018; Leuschner et al., 2001; Scharnweber et al., 2011; Zimmermann et al., 2015). Its radial increment is highly resistant to dry conditions (Chapter 4) and it did not suffer crown defoliation or discoloration after severe drought (Chapter 4). The latter relates to its relatively xeromorphic and heat resistant leaves (Epron and Dreyer, 1993; Thomas, 2000). *Q. petraea* is strictly anisohydric (Aranda et al., 2000; Bréda et al., 1993; Epron and Dreyer, 1993), maintaining high transpiration and assimilation rates under moderate drought conditions. This is facilitated by an embolism-resistant xylem (Dietrich et al., 2018; Lobo

et al., 2018), by the capability of xylem anatomical adaptation (Martínez-Sancho et al., 2017) and leaf osmotic adjustments to drier conditions (Leuschner et al., 2001), and by drought-resistant fine roots (Chapter 3) and a deep rooting system (Rosengren et al., 2006), allowing for sustained water uptake. Leaf osmotic adjustments are reflected by the decreasing turgor loss point (P_{TLP}) with increasing climatic aridity (Figure 5.1). This anisohydric strategy has also been described in literature (e.g. Renninger et al., 2015) and enables *Q. petraea* to maintain fairly constant annual stem increment also in drought years (Chapter 4). In addition, the physiological responses to drought in juvenile stages indicate a high drought resistance of saplings in comparison to other broadleaves (Kunz et al., 2016; Thomas, 2000).

Although deep-rooting, *Q. petraea* seems to produce a less dense fine root system in comparison to the other species (Chapter 3; Hertel and Leuschner, 2002) and its fine root mortality under drought is low (Chapter 3). Shifts in carbon allocation to the root system might therefore be less important in *Q. petraea* than in other species.

Figure 5.1: Leaf water potential at turgor loss point (P_{TLP}) of all five species. Sites are sorted in ascending order according to the climatic water balance. The methodology is described in chapter 2, where *Q. petraea* and *F. excelsior* were not included in the figures.

However, the apparent climate-insensitivity of growth in *Q. petraea* is partly caused by the large number of other growth-reducing events, notably pests and mast-fruiting, which may weaken the climatic signal and lead to overestimation of the species' drought tolerance (Chapter 4). Nevertheless, *Q. petraea* is a demanded high-quality timber for construction and furniture and must be seen as an important component of future drought-tolerant production forests in sub-continental Central Europe.

5.2.2 *Acer platanoides*

A. platanoides is an isohydric species that pursues a drought-avoidance strategy. With a strict stomatal control and a very wide hydraulic safety margin (HSM), it sacrifices carbon assimilation for the sake of a safe and intact hydraulic system (Leuschner et al., 2019). This is confirmed by the hydraulic characterization in Chapter 2, and in agreement with results from a study in Central Germany on mature trees, where minimum xylem water potential (P_{\min}) and stomatal conductance were repeatedly measured over several months during summer, confirming a strictly isohydric stomatal control strategy (Messinger, 2017, unpublished). In combination with the highly embolism resistant xylem (Chapter 2), *A. platanoides* must be suited to survive even prolonged drought conditions, as isohydric species are less prone to hydraulic failure under severe drought (Choat et al., 2012; McDowell et al., 2008).

Although *A. platanoides* suffered the strongest radial growth depressions in drought years, it was also highly resilient, recovered quickly (Chapter 4), and showed almost no noticeable crown damage after the droughts of 2018/19 (Chapter 4). This relates to the isohydric behavior, as this “safe” strategy reduces the likeliness of damage to leaf and stem xylem tissue and prevents legacy effects of droughts. The fine root system of *A. platanoides* proved to be highly plastic, it was the only species adjusting (increasing) its fine root density towards the drier sites. However, the vulnerability of fine roots and finest root tips to drought was higher than in the other species (Chapter 3).

In conclusion, *A. platanoides* emerged as the “safe choice” among the studied species. Drought-related mortality seems very unlikely, and a high resilience makes up for the growth sensitivity to drought events. Additionally, a complementary study on saplings (Kunz et al., 2016) attested a high drought resistance in juvenile stages. Its wood properties partly resemble *F. sylvatica* (Roloff et al., 2010), thus, it can be a replacement species on dry sites, where *F. sylvatica* is declining (cf. Zimmermann et al., 2015).

5.2.3 *Fraxinus excelsior*

F. excelsior is known for its exceptionally wide ecological amplitude regarding water availability (Leuschner and Ellenberg, 2017). This is based on its high ecophysiological plasticity regarding leaf and xylem-related functional traits. Its xylem embolism resistance varies in dependence of the site water availability (Lemoine et al., 2001) and it is capable of significant osmotic adjustments in its leaves by accumulating malate and mannitol (Guicherd et al., 1997, Lübbe et al., 2017). These strong adjustments are

reflected in the highly variable turgor loss point (Figure 5.1). Like *Q. petraea*, *F. excelsior* is highly anisohydric with large leaf water potential reductions during drought periods, which enable the species to maintain water extraction in drying soil (Köcher et al., 2009; Leuschner et al., 2019), keeping stomata open even at predawn water potentials near -5 MPa (Carlier et al., 1992; Guicherd et al., 1997). With that said, the low defoliation rate after the two consecutive drought years of 2018/19 is surprising and another indication of a high drought-hardening potential of the leaves via osmotic adjustments. The anisohydric behavior relates to its low drought sensitivity of radial growth that is comparable to *Q. petraea* (Chapter 4; Zimmermann et al., 2015).

F. excelsior has a uniquely high fine root density (Chapter 3), which may secure water uptake in drought periods and increase the species' competitive ability in mixed stands and on very shallow and dry soils.

Its drought-tolerance and the versatile wood for furniture and tool production could qualify *F. excelsior* as a promising candidate for future forestry. However, the species is severely threatened by the fungus *Hymenoscyphus fraxineus*, affecting crown, stem base, and rootstock vitality, causing a pan-European ash dieback. Although the selection of resistant genotypes might be possible (McKinney et al., 2014), and the virulence of the fungus seems to be lower in dry and hot years (Goberville et al., 2016; Grosdidier et al., 2018), the current epidemiologic projections render any recommendations for silvicultural planning impossible in the near future (Enderle, 2019).

5.2.4 *Tilia cordata*

Distinct growth reductions in drought years, clearly visible legacy effects in 1-2 years after drought, and a high growth sensitivity to the SPEI (Chapter 4) indicate a low drought tolerance. This is in line with the increasing fine root necromass/biomass ratio toward drier sites and the marked loss of fine root tips after drought (Chapter 3). In addition, its xylem showed to be highly vulnerable to embolism formation (Chapter 2). However, *T. cordata* was very resilient and fully regained its pre-drought growth levels (Chapter 4, in agreement with Latte et al., 2020) in contrast to co-occurring *F. sylvatica* (Latte et al., 2020; Zimmermann et al., 2015).

Characterizations of *T. cordata* within the isohydry-anisohydry syndrome are inconsistent in literature. Stomatal control is not stringent under drought, relatively high stomatal conductance and water losses classify as rather anisohydric (Moser et al., 2016). This implies a low water use efficiency and is in line with relatively low foliar $\delta^{13}\text{C}$ -signatures (Figure 5.2) in comparison to the other species, because higher levels of gas

exchange accentuate the discrimination in the assimilation of the heavier ^{13}C -isotope. However, *T. cordata* keeps the leaf water potentials in a mediocre range by buffering the water loss with high leaf and stem water capacitance (Köcher et al., 2009; Köcher et al., 2013; Leuschner et al., 2019). This buffer might as well enable this species to operate with a very narrow hydraulic safety margin (Chapter 2). Thus, *T. cordata* is rather a water-spending, semi-isohydric species, avoiding drought stress by improved water storage (instead of strict stomatal control; Leuschner et al., 2019) and deep rooting (Pigott, 1991). In contrast to the other species, *T. cordata* has highly elastic leaf cell walls and is capable of reversible wilting (Leuschner et al., 2019).

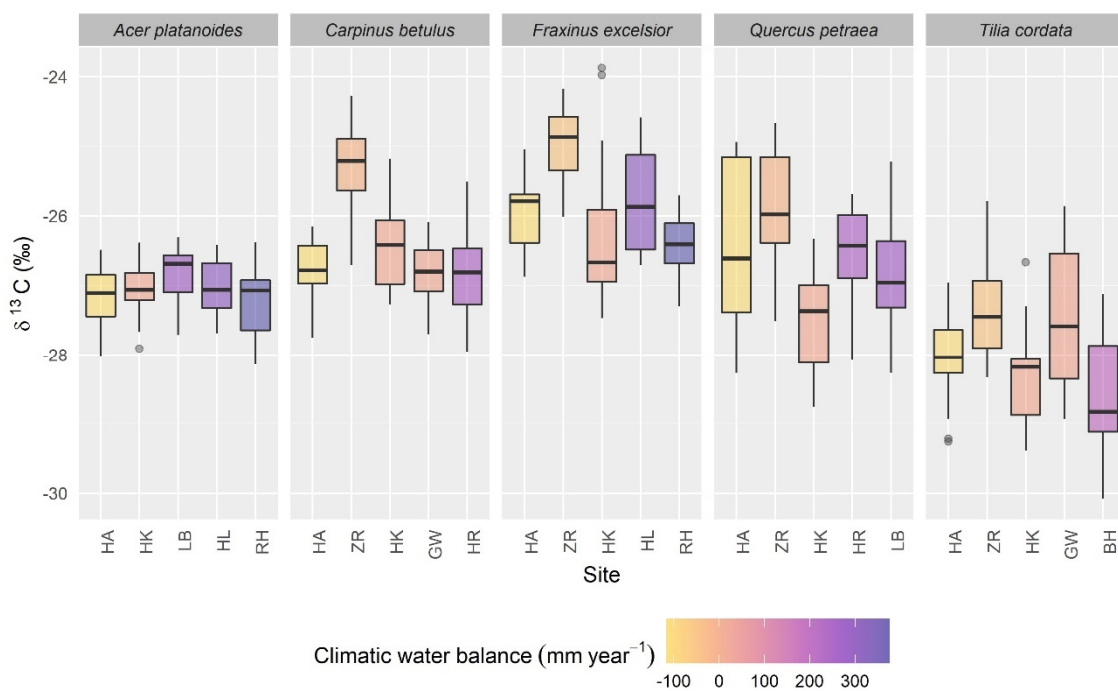

Figure 5.2: Foliar $\delta^{13}\text{C}$ -signatures of the leaf bulk tissue of sun leaves of all five species, given in standard δ notation: δ (‰) = $(R_{\text{sample}} / R_{\text{standard}} - 1) \times 1000$. Measurements were conducted in the laboratory for stable isotope measurements (KOSI) at the University of Göttingen with a Delta plus isotope mass spectrometer (Finnigan MAT, Bremen, Germany), a Conflo III interface (Thermo Electron Cooperation, Bremen, Germany) and a NA2500 elemental analyzer (CE-Instruments, Rodano, Milano, Italy). Sites are sorted in ascending order according to the climatic water balance.

Several reviews on the ecology of *T. cordata* attest a considerable drought tolerance in comparison to several major timber species (Hemery et al., 2010; Jaegere et al., 2016; Pigott, 1991), but this tolerance seems to be restricted to short and moderate drought periods (Jaegere et al., 2016). This is in line with its water-spending, semi-isohydric strategy, relying on internal water storage and the reversibility of leaf-wilting. Due to its thermophilic properties and high resistance to heat (Hemery et al., 2010; Jaegere et al., 2016), as well as its resilience to drought (Latte et al., 2020), it may gain competitive

advantages over *F. sylvatica* in Central Europe. However, its drought resistance seems to be inferior in comparison to *A. platanoides*, *Q. petraea* and *F. excelsior*.

5.2.5 *Carpinus betulus*

In terms of hydraulic properties, *C. betulus* has a relatively resistant xylem, a wide safety margin, and remarkable plasticity (Chapter 2). Especially the P_{88} , (water potential at 88% loss of conductivity), which is assumed to be the threshold for catastrophic hydraulic failure for angiosperms (Choat, 2013; Urli et al., 2013), was very low in this species (Chapter 2). The P_{88} has also been linked to the drought-induced mortality risk of angiosperm trees (Li et al., 2016; Li et al., 2018), thus, *C. betulus* might be resistant to drought-driven mortality. Its stomatal control strategy is intermediate on the iso-/aniso-hydry spectrum (Leuschner et al., 2019), tending towards an aniso-hydric behavior (Li et al., 2016), keeping the stomata open during moderate drought conditions. This is in line with a low turgor loss point found in Chapter 2. However, *C. betulus* tends to shed its leaves earlier in severe droughts in comparison to the other species to keep branch and stem xylem safe. This behavior has been observed in reaction to the 2003 drought (Leuzinger et al., 2005) and as well to the 2018/2019 drought (Chapter 4, Figure 4.17), where *C. betulus* showed high rates of defoliation and prematurely discolored leaves in August and September, but reached full foliation in the following spring again.

In agreement with Leuzinger et al. (2005) who found *C. betulus* to be able to efficiently take up water in the uppermost soil horizon after minor rain events, the fine root density in the topsoil was high (Chapter 3). Although no increase in its fine root necromass/biomass ratio after drought was observed, specific root area and fine root tips were distinctly reduced (Chapter 3). This behavior was similar to *T. cordata*. In combination with a medium to shallow rooting system (Köstler et al., 1968), *C. betulus* shows no outstanding belowground adaptations to prolonged droughts.

Due to the missing dendroecological results of this species, we cannot pass a conclusive judgement on the productivity of *C. betulus* under a drier and warmer climate. Leuzinger et al. (2005), however, found this species to show rapid radial growth during moist periods in the early vegetation period, but it ceased radial growth almost completely in late summer in three consecutive years in Central Europe, demonstrating a high reliance of its increment on ample water supply. Because of its curvy and irregular stem shape, spiral growth and mediocre qualities for woodworking, the utilization of this timber is fairly limited anyway, but its high wood density and caloric value make it useful for the production of certain tools and for energy generation.

However, its hydraulic properties and its known shade-tolerance indicate a low mortality risk and a certain tenacity to cope with unfavorable conditions as admixture in a resilient future broadleaf forest.

5.2.6 Drought stress resistance ranking

In comparison to *Q. petraea*, none of the minor timber species proved to be more drought resistant. However, *F. excelsior* pursues a very similar drought tolerance strategy and seems to be almost on the same level in most aspects. The diffuse-porous species differ clearly from the ring-porous species in their strategies. Especially *A. platanoides* with a strict drought-avoidance behavior, a high embolism resistance, a plastic fine root system, and high resilience to drought events turned out to be a safe choice for a drier and warmer climate. Table 5.1 shows a synoptic ranking of the five species including most of the mentioned drought resistance related aspects and traits and ranks the species in the following order: *Q. petraea* > *A. platanoides* > *F. excelsior* > *C. betulus* > *T. cordata*.

Table 5.1: Overview of drought stress resistance-related traits of the five species. The rates range from very good (++) over good (+) and mediocre (o) to subpar (-) and the reasoning behind the assessments is explained in Chapter 5.1 and 5.2. Grey panels are based on knowledge from literature, black panels represent missing information.

Species	Hydraulic plasticity	Xylem embolism resistance	Hydraulic safety margin	Turgor loss point	Stem water storage and leaf capacitance	Fine root drought resistance	Fine root biomass adaptation	Rooting depth	Drought resistance of radial growth	Drought resilience of radial growth	Long-term stability of radial growth	Rank
<i>A. platanoides</i>	+	++	++	o	■	o	++	+	o	+	+	2
<i>C. betulus</i>	++	+	+	++	+	o	o	o	■	■	■	4
<i>F. excelsior</i>	++	+	o	++	-	o	+	o	++	+	+	3
<i>Q. petraea</i>	■	++	+	++	■	+	o	++	++	+	+	1
<i>T. cordata</i>	o	o	-	+	++	-	o	++	o	+	+	5

5.3 Future directions

Generally, transect field studies across climatic gradients as “space-for-time substitutions” are a valid and established tool in plant ecology to derive climatic limits of changes in increment, physiological responses, and stress indicators in the face of climate change. In the present case, however, the predictive power of climatic aridity on stand water availability was weakened by inhomogeneous soil types. Including plant available water capacity of the soil as explanatory variable is a way to cope with this problem, but simultaneously necessitate a higher number of study sites, which is always limited in field studies with a focus on the comparison of several species. Additionally, differences in nutrient availability across the gradient might have obscured some relationships. The mentioned compromises in the homogeneity of the study sites are primarily a consequence of the infrequent co-occurrence of the targeted minor timbers, rendering the number of suitable study sites very small. Future transect field studies addressing minor timbers could reduce the number of compared species in order to increase the number of stands and facilitate the detection of suitable sites.

The present dissertation provides valuable insights into drought response strategies of the five species and the plasticity of functional traits along a climatic gradient, closing several knowledge gaps with respect to rarely studied minor timbers. However, future studies must consider that resisting drought by either tolerance or avoidance strategies has different implications on growth performance and mortality risks. Clearly, retrospective analyses of radial growth, as in Chapter 4, are limited to living trees and the results therefore might be biased, as they only represent the surviving part of the populations and do not capture mortality rates. To fully capture the impact of increasing drought exposure on a species, both, growth reactions and mortality rates, have to be addressed. To record drought-driven mortality, information on natural (background) mortality of unmanaged stands is required, which is difficult to obtain in regions as Central Europe, where most forests are managed. A causal analysis of drought-induced mortality events which includes physiological measurements would help to identify lethal stress levels and critical elements in the species’ drought response strategy.

Additionally, short term growth reductions in response to drought should be complemented with wood anatomical and physiological investigations in the post-drought phase to assess, whether they are primarily an expression of vitality loss, or are part of a plastic drought response, which leads to morphological, anatomical and physiological acclimation and increases future drought tolerance.

6 GENERAL APPENDIX

6.1 Index of Figures

- Figure 1.1:** Distribution ranges of the four minor timber species (*A. platanoides*, *C. betulus*, *F. excelsior*, and *T. cordata*) and two major timbers (*Q. petraea* and *F. sylvatica*) based on the synthetic chorology database of Caudullo (2017). 15
- Figure 1.2:** Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from the west to the east. The nine study sites are marked with red dots. The background colors and isohyets indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm north-east of Göttingen is the Harz mountain range. For further information on the study sites, refer to the detailed tables 2.1, 3.1, and 4.1 in the following chapters. 22
- Figure 2.1:** Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from west to east. The study sites are marked with red dots, the background colours indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm northeast of Göttingen is the Harz mountain range. 41
- Figure 2.2:** Hydraulic safety-related traits: (A) Xylem water potential at 50 % loss of conductivity (P_{50}), (B) xylem water potential at 12/88 % loss of conductivity ($P_{12/88}$), (C) leaf water potential at turgor loss point (P_{TLP}), and (D) hydraulic safety margins of the three tree species at all study sites. Sites are sorted in ascending order according to the climatic water balance. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to max. 1.5 times the interquartile range. Different letters denote significantly different means between sites within a species based on Tukey-adjusted p-values with degrees of freedom based on Satterthwaite’s approximation from linear mixed effects models with post-hoc tests for pairwise differences. 49
- Figure 2.3:** Hydraulic efficiency-related traits: (A) A_{Xylem}/A_{Leaves} -ratio of branches (Huber value), and (B) xylem area-specific hydraulic conductivity of branches (K_S) of the three tree species at all study sites. Sites are sorted in ascending order according to the climatic water balance. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to max. 1.5 times the interquartile range. Different letters denote significantly different means between sites within a species based on Tukey-adjusted p-values with degrees of freedom based on Satterthwaite’s approximation from linear mixed effects models with post-hoc tests for pairwise differences. 50
- Figure 2.4:** (A) Coefficient of quartile variation of the studied traits across all species and measurements; (B) variance decomposition between different levels of organization (between species, between populations, and between individuals; see Appendix A, Table 2.4 for full model output). Given are the xylem water potential at 50% loss of conductivity (P_{50}), the leaf water potential at turgor loss point (P_{TLP}), A_{xylem}/A_{leaf} – ratio of branches (Huber value, HV) and xylem area-specific hydraulic conductivity (K_S). ‘Residual’ denotes the unexplained variance of the models (i.e. variability between branches + estimation and measurement uncertainty). 51

- Figure 2.5:** Distribution ranges of the three minor timber species (*Acer platanoides*, *Carpinus betulus*, and *Tilia cordata*) based on the synthetic chorology database of Caudullo et al. (2017). 60
- Figure 2.6:** Xylem vulnerability curves illustrating percent loss of conductivity vs. xylem water potential. Plotted lines represent conditional predictions for single branches (colored, dotted), single trees (colored), and sites (black) based on species-wise non-linear mixed-effects models (pointsymmetrically, sigmoidal). 61
- Figure 2.7:** (A) Xylem water potential at 50 % loss of conductivity (P_{50}), (B) leaf water potential at turgor loss point (P_{TLP}), (C) A_{Xylem}/A_{Leaves} -ratio of branches (Huber value), and (D) xylem area-specific hydraulic conductivity of branches (K_S) of the three tree species on all study sites. Sites are given in ascending order of plant-available water capacity of the soil. Box-whisker plots include median and interquartile ranges (Q1–Q3); whiskers extend to 1.5 times the interquartile range. 62
- Figure 2.8:** Pearson correlation matrix of environmental and tree-specific predictors and functional traits. Given are Pearson correlation coefficients per species in the top right triangle and the corresponding data in the lower left triangle. MAP = mean annual precipitation (period 1991–2017); CWB = climatic water balance; MAT = mean annual temperature; AWC = plant-available water storage capacity of the soil; DBH = Stem diameter at breast height; $P_{50}/P_{12}/P_{88}$ = xylem water potential at 50/12/88 % loss of conductivity; $Slope_{vc}$ = slope of the vulnerability curve at the inflexion point; P_{TLP} = leaf water potential at turgor loss point; K_S = xylem area specific hydraulic conductivity of branches; HV = Huber value (A_{Xylem}/A_{Leaves} -ratio of branches). K_S and HV are natural log-transformed, traits measured on branch/leaf-level are means per tree. All variables are scaled by their standard deviation and centered around zero. 63
- Figure 2.9:** Tendency of a hydraulic safety-efficiency trade-off across species between K_S (xylem area-specific hydraulic conductivity) and P_{50} (xylem water potential at 50 % loss of conductivity). Shown are mean values per site and species with standard errors and p-value and R^2 of a linear regression across all species and sites. 64
- Figure 3.1:** Map of the study area between Göttingen and Halle/S. in central Germany with the precipitation gradient from the west to the east. The nine study sites are marked with red dots. The colors indicate the mean annual precipitation (MAP 1991–2017). The area with MAP over 1000 mm NE of Göttingen is the Harz mountain range. 81
- Figure 3.2:** Fine root biomass (a), necromass (b), and necromass/biomass (N/B) ratio (c) of the five tree species in the topsoil (0–10 cm) in April 2017 and September 2018. Box-whisker plots with median and interquartile ranges (Q1–Q3); whiskers extend to 1.5 times the interquartile range. Indicated significant differences between the inventories for each species are based on a non-parametric signed-rank-test; ***: $p \leq 0.001$, *: $p < 0.05$. Note the log-scaled y-axes in (b) and (c). 90
- Figure 3.3:** Specific root surface area (SRA) and root tips per fine root biomass of the five tree species in the topsoil (0–10 cm) in April 2017 and September 2018. Box-whisker plots for all species and both inventories with median and interquartile ranges (Q1–Q3); whiskers extend to 1.5 times the interquartile range. Indicated significant differences between the inventories for each species

are based on a non-parametric signed-rank-test; ***: $p \leq 0.001$, **: $p \leq 0.01$, *: $p < 0.05$. Note the log-scaled y-axes.	91
Figure 3.4: Fine root biomass (a), necromass (b), and necromass/biomass ratio (c) in the topsoil (0–10 cm) of the five species in relation to mean annual precipitation (MAP) in the 2017 and 2018 inventories. Data points are tree-level values, lines represent conditional predictions of the linear mixed effects model (the predictions of the fixed effect “MAP” for each species plus an intercept for each level of the random factor “site”). Note the log-scaled y-axis. The corresponding p and pseudo- R^2 values are summarized in Table 3.3. Graphs for the morphology variables are given in Figure 3.6 in the Appendix B.	92
Figure 3.5: Fine root biomass (a), necromass (b) and necromass/biomass ratio (c) in the topsoil (0–10 cm) of the five species in relation to actual precipitation in the year prior to sampling in the 2017 and 2018 inventories. Data points are tree-level values, lines represent conditional predictions of the linear mixed effects model (the predictions of the fixed effect “MAP” for each species plus an intercept for each level of the random factor “site”). Note the log-scaled y-axis. The corresponding p and pseudo- R^2 values are summarized in Table A1.	105
Figure 3.6: Specific root area (a), fine root tips per root mass (b), and average fine root diameter (c) in the topsoil (0–10 cm) of the five species in relation to mean annual precipitation (MAP) in the 2017 and 2018 inventories. Data points are tree-level values, lines represent conditional predictions of the linear mixed effects model (the predictions of the fixed effect “MAP” for each species plus an intercept for each level of the random factor “site”). Note the log-scaled y-axis. The corresponding p and pseudo- R^2 values are summarized in Table 3.3.	106
Figure 3.7: Principal components analysis (PCA) biplot of the 2017 fine root inventory. All data are aggregated on site and species level.	107
Figure 3.8: Principal components analysis (PCA) biplot of the 2018 fine root inventory. All data are aggregated on site and species level.	107
Figure 4.1: Map of the study region between the cities of Göttingen and Halle/S. in Central Germany with the precipitation gradient from west to east. The study sites are marked with red dots, the background colors indicate the long-term mean growing season precipitation (MGSP, April – September, 1967 - 2016) in mm. The area with MGSP >500 mm north-east of Göttingen is the Harz mountain range.	120
Figure 4.2: Temporal variation and long-term trend (25 year moving average) of growing season precipitation, temperature and SPEI (standardized precipitation-evapotranspiration index) in the period 1965-2016 in the study region (averaged over all study sites).	123
Figure 4.3: Correlation between radial growth (ring width index values) and the SPEI (standardized precipitation-evapotranspiration index) for months in the previous and current year for the four species at eight sites. The SPEI is calculated on a timescale of 3 months, because the drought conditions in the current month mainly depend on precipitation and evapotranspiration patterns in the current and the two preceding months. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars:	

- $p > 0.05$). The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation. For site abbreviations see Figure 4.1. 130
- Figure 4.4 (next page):** Moving window analysis of climate-growth relationships in the four species at eight sites for the period 1967-2016. Shown are the central years of the respective 20-year periods, testing for the correlation between six aggregate climate variables and annual ring width indices. Given is the size and sign of the correlation coefficient for the six relationships (red: negative relation, blue: positive relation, black frame: $p < 0.05$). Summer stands for June-August, Winter for December-February, spring for March and April. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 131
- Figure 4.5:** Change in the climate-growth correlation coefficients between the 1967–1991 and the 1992-2016 period. The “+”/“-“ signs indicate positive/negative changes in the correlation coefficients, respectively. Bold red signs represent significant changes ($p < 0.05$), grey shading stands for missing data. Note: A positive change in the correlation coefficient can mean the switch from no to a positive correlation, or a switch from a negative to no correlation, a negative change means a shift in the opposite direction; see Figure 4.4 for a more detailed picture of temporal changes in the correlation coefficients. 133
- Figure 4.6:** Relationship between annual ring width indices and summer SPEI (= standardized precipitation-evapotranspiration index of the month August, calculated for a 6-months window) for the four species in dependence on mean growing season precipitation (MGSP) of the stand for the 25-year periods 1967-1991 and 1992-2016. Significant correlation coefficients are marked by red 95%-confidence interval bars. Each dot represents one site per species; MGSP refers to the corresponding 25-year periods. The blue regression lines with 95% confidence interval display significant relationships between correlation coefficient and MGSP, non-significant regression lines are not shown. 134
- Figure 4.7:** Results of superposed epoch analyses on the response of radial growth of the four species at the eight sites to drought events with a $\text{SPEI}_{\text{summer}} < -0.84$. Shown is the deviation of mean ring width in an 11-year period with the drought years in the center from the mean ring widths in all analyzed 11-year epochs of the chronology. Significant departures ($p < 0.05$) are shown in dark grey with red frame. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 135
- Figure 4.8:** Resistance and resilience of radial growth of the four species to selected droughts in an 11-year window with the drought year in the centre of the period. All drought events with a $\text{SPEI} < -0.84$ (based on the SPEI of the month August with consideration of a six-months window) in the study period were considered. The indices were calculated using detrended ring width indices pooling for every species over all sites and all identified drought years. Resistance is the growth depression in a drought year compared to the 5 years prior to drought, resilience the ratio of mean radial growth in the five post-drought years relative to the growth in the five years prior to drought. Different small letters indicate significant differences between species based on Tukey-adjusted p -values from linear mixed effects models with degrees of freedom based on Satterthwaite’s approximation. Number of trees was $n = 57$ for *A. platanoides*, $n = 83$ for *F.*

- excelsior*, $n = 80$ for *Q. petraea*, and $n = 29$ for *T. cordata*; the number of studied drought events varied between 9 and 13, depending on sites. 136
- Figure 4.9:** Ring width index chronologies for the four species at the eight sites, age-detrended with regional curve standardization (RCS). The blue line is a 25-year smoothing spline. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high)..... 146
- Figure 4.10:** Ring-width chronologies for the four species at the eight sites using the raw data from 9-13 tree individuals per stand which were averaged using Tukey's bi-weight robust mean. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 147
- Figure 4.11:** Correlation between radial growth (ring width index values) and the precipitation totals of months in the previous and current year for the four species at eight sites. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars: $p > 0.05$) based on 1000x bootstrapping against randomly chosen precipitation-growth pairs. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 148
- Figure 4.12:** Correlation between radial growth (ring width index values) and mean temperature of the months in the previous and current year for the four species at eight sites. Months abbreviated with lower case letters refer to the previous year, months with capital letters to the current year. Given is the size of the correlation coefficient and the significance of the relation (black bars: $p < 0.05$; grey bars: $p > 0.05$) based on 1000x bootstrapping against randomly chosen temperature-growth pairs. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 149
- Figure 4.13:** Negative pointer years of the four species on the eight sites in the period 1967-2016 according to Cropper-values following the approach of Neuwirth et al. (2007) with normalization in a 5-year moving window. Thresholds for weak, strong, and extreme negative pointer years were 0.8, 1.2, and 1.5 standard deviations of growth decline, respectively, for at least 60% of the population. Site are arranged according to mean growing season precipitation from drier to moister. 150
- Figure 4.14:** Percental reduction in BAI in the drought year 1976 relative to the average BAI of the five preceding years for the four species at the eight sites. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 151
- Figure 4.15:** Resistance and resilience of basal increment of the four species to selected droughts in an 11-year window with the drought year in the centre of the period. All drought events with a SPEI < -0.84 (based on the SPEI of the month August with consideration of a six-months window) in the study period were considered. The indices were calculated using raw BAI data pooling for every species over all sites and all identified drought years. Resistance is the growth depression in a drought year compared to the 5 years prior to drought, resilience the ratio of mean radial growth in the five post-drought years relative to the growth in the five years prior to

- drought. Different small letters indicate significant differences between species based on Tukey-adjusted p-values from linear mixed effects models with degrees of freedom based on Satterthwaite's approximation. Number of trees was $n = 57$ for *A. platanoides*, $n = 83$ for *F. excelsior*, $n = 80$ for *Q. petraea*, and $n = 29$ for *T. cordata*; the number of studied drought events varied between 9 and 13, depending on sites. 152
- Figure 4.16:** Within-population growth synchronicity of the four species at the eight sites in the period 1967-2016. Given is the interseries correlation (\bar{R}) as derived from a moving 20-year window analysis of ring width index series. The color spectrum from orange to green indicates the position of the site in the gradient of mean growing season precipitation (orange: low, green: high). 153
- Figure 4.17:** Frequency of crown damage classes in late summer of 2019 (September) in the stands of the four species at eight sites after the extreme 2018/19 drought as derived from the inspection of each five individuals. Site acronyms are explained in Figure 1. The crown damage classes 0 to 3 base on a ground-based visual assessment of the canopy's defoliation and discoloration (damage is defined as the sum of discolored and fallen leaves in percent of full foliation; 0 = 0% - 10% damage; 1 = 10% - 25% damage, 2 = 25% - 60% damage, 3 = > 60% damage). *Carpinus betulus* and *Fagus sylvatica* trees that occurred in the same stands are reported for comparison. 154
- Figure 5.1:** Leaf water potential at turgor loss point (P_{TLP}) of all five species. Sites are sorted in ascending order according to the climatic water balance. The methodology is described in chapter 2, where *Q. petraea* and *F. excelsior* were not included in the figures..... 168
- Figure 5.2:** Foliar $\delta^{13}\text{C}$ -signatures of the leaf bulk tissue of sun leaves of all five species, given in standard δ notation: $\delta (\text{‰}) = (\text{R}_{\text{sample}} / \text{R}_{\text{standard}} - 1) \times 1000$. Measurements were conducted in the laboratory for stable isotope measurements (KOSI) at the University of Göttingen with a Delta plus isotope mass spectrometer (Finnigan MAT, Bremen, Germany), a Conflo III interface (Thermo Electron Cooperation, Bremen, Germany) and a NA2500 elemental analyzer (CE-Instruments, Rodano, Milano, Italy). Sites are sorted in ascending order according to the climatic water balance. 171

6.2 Index of Tables

- Table 2.1:** Site and tree characteristics of the studied stands sorted by species and in ascending order of the local climatic water balance (CWB). MAP = mean annual precipitation (period 1991–2017); MAT = mean annual temperature; MGSP = mean growing season precipitation (April–September); CWB = climatic water balance; soil texture is defined according to the nomenclature of the FAO (Food and Agriculture Organization of the United Nations); AWC = plant-available water storage capacity of the soil; DBH = Stem diameter at breast height. Tree age, DBH, and tree height are given as means with standard deviation. Tree age of all sampled individuals was determined with dendrochronological analyses for increment cores with the exception of *C. betulus*, which was not part of the dendrochronological study; age information was here derived from forestry inventory data of the local forestry offices 42
- Table 2.2:** Means \pm SE of measured traits per species pooled over all study sites. Different letters denote significantly different means based on Tukey-adjusted p-values from linear mixed effects models with post-hoc tests for pairwise species differences with degrees of freedom based on Satterthwaite's approximation. $P_{50/12/88}$ = xylem water potential at 50/12/88 % loss of conductivity; P_{TLP} = leaf water potential at turgor loss point; HSM = hydraulic safety margin; Huber value (HV) = A_{Xylem}/A_{Leaves} -ratio of branches; K_S = xylem area specific hydraulic conductivity of branches. 48
- Table 2.3:** Results of the linear mixed effects models examining the relationships between environmental variables and functional traits. P_{50} = xylem water potential at 50% loss of conductivity; P_{TLP} = leaf water potential at turgor loss point; HSM = hydraulic safety margin; Huber value (HV) = A_{xylem}/A_{leaf} – ratio of branches; K_S = xylem area specific hydraulic conductivity of branches. Given are the scaled estimates for CWB (climatic water balance) and AWC (plant-available water storage capacity of the soil), as well as the standard deviation for the tree-wise random intercept (Tree SD), the residual standard deviation (Res. SD), and marginal and conditional R^2 of the models (Marg. R^2 and Cond. R^2). Bold estimates represent significant effects (*, $P < 0.05$; **, $P < 0.01$), (a) denotes marginally significant effects ($P < 0.1$). The full output of the models is given in Appendix A, Table 2.5. 53
- Table 2.4:** Full output table of the linear mixed effects models for the variance decomposition (Fig. 4b). Given are the fixed effect estimates for the intercept (i.e. the *Carpinus* average), the differences of *Acer* and *Tilia* to *Carpinus*, with their standard errors, estimated degrees of freedom (edf) based on Satterthwaite's approximation and P -values, as well as the estimates of the three variance components (tree level, population level and residual SD). 65
- Table 2.5** (next page): Full output table of the linear mixed effects models examining the relationships between environmental variables and functional traits (corresponds to Table 2.3). Given are the scaled estimates for CWB (climatic water balance) and AWC (plant-available water storage capacity of the soil), the standard errors of the estimates (SE), the estimated degrees of freedom (DF) based on Satterthwaite's approximation, P -values, and lower and upper border of likelihood-profile-based confidence intervals (CI low and CI high). 65

Table 3.1: Site and tree characteristics of the nine study sites with the each 2–5 species occurring in the stands, sorted in ascending order of mean annual precipitation (MAP).	83
Table 3.2: PET, precipitation, and temperature in the three months prior to the sampling dates in 2017 and 2018. Given are the totals of potential evapotranspiration (PET) and precipitation (P), the deviation of P from the long-term mean (1991–2017) in percent, and the absolute deviation of the average temperature of the three-month period from the long-term mean (1991–2017) in that period in °C.	86
Table 3.3: Results of linear mixed effects models for fine root traits in dependence of mean annual precipitation (MAP). Given are estimates of the fixed effect (fine root trait ~ species:MAP), marginal pseudo- R^2 for the fixed effect (calculated according to Nakagawa and Schielzeth (2013)) and p -values. p -values below 0.05 are given in bold. All fine root traits were log-transformed in advance except for root diameters.....	93
Table 3.4: Results of the principal components analysis for the spring inventory in 2017. Given are the loadings of the selected variables along the four axes with the highest explained variance in the dataset. Bold numbers mark the variables with the highest loading (>0.4) on the respective axis. The values in brackets give the cumulative fraction of variance explained by the variable. MAP = mean annual precipitation, MAT = mean annual temperature, DMI = de Martonne aridity index of the three months prior to sampling.	94
Table 3.5: Results of the principal components analysis for the drought inventory in 2018. Given are the loadings of the selected variables along the four axes with the highest explained variance in the dataset. Bold numbers mark the variables with the highest loading (>0.4) on the respective axis. The values in brackets give the cumulative fraction of variance explained by the variable. MAP = mean annual precipitation, MAT = mean annual temperature, DMI = de Martonne aridity index of the three months prior to sampling.	95
Table 3.6: Results of linear mixed effects models for fine root bio- and necromass in dependence of actual precipitation in the year prior to sampling (act.PRCP). Given are estimates of the fixed effect (fine root trait ~ species:MAP), marginal pseudo- R^2 for the fixed effect (calculated according to Nakagawa and Schielzeth (2013)), and p -values. p -values below 0.05 are given in bold. All fine root traits were log-transformed in advance.....	104
Table 4.1: Stand structural, soil physical and chemical and climatic characteristics of the stands selected to study the four species. Note that the species in many cases occurred in different stands at given sites, and thus different site characteristics are reported. Mean DBH (diameter at breast height), height and age of the studied trees in the stand are given with standard deviations. Soil properties include mean pH, C:N-ratio, Carbon content (C %), and soil texture of the top 60 cm of the profile, and the profile total (0-120 cm) of the soil capacity for plant-available water (AWC). Long-term annual means (1967-2016) of precipitation (MAP), growing season precipitation (MGSP, April - September), temperature (MAT), and growing season temperature (MGST) are also given. The table is sorted by species and in ascending order of growing season precipitation.....	121
Table 4.2: Statistics of ring-width series (raw data) and index-based chronologies (all truncated to the period 1967-2016) of the four species at the different sites. MRW = mean ring width of all series	

\pm SD, AC (1) = first order autocorrelation \pm SD, MBAI = mean basal area increment of all series \pm SD, Rbar = inter-series correlation, MS = mean sensitivity, EPS = expressed population signal. The different sites of a species are sorted in ascending order of mean growing season precipitation..... 128

Table 4.3: Results of linear mixed effects models exploring the relationship between various environmental variables and the tolerance indices growth resistance and resilience. Given are the scaled estimates for the effect of MGSP (mean growing season precipitation) and AWC (soil capacity for plant-available water), as well as the standard deviation for the random effect “Site” (Site SD), the residual standard deviation (Res. SD), and marginal and conditional R^2 values of the models. None of the fixed effects was significant at $p < 0.05$. As data were available for *T. cordata* only at three sites, this species is omitted here..... 137

Table 5.1: Overview of drought stress resistance-related traits of the five species. The rates range from very good (++) over good (+) and mediocre (o) to subpar (-) and the reasoning behind the assessments is explained in Chapter 5.1 and 5.2. Grey panels are based on knowledge from literature, black panels represent missing information. 173

6.3 Danksagung

Finishing this project would have been impossible without the invaluable help of colleagues, friends and my family. I am grateful for having you around!

First of all, I'd like to thank Prof. Dr. Christoph Leuschner and Prof. Dr. Bernhard Schuldt for offering me the opportunity of this challenging PhD project and for all the competent support, patience, advice, optimism and trust over the years.

I further wish to thank Prof. Dr. Dirk Hölscher for his support as part of my thesis advisory committee and Prof. Dr. Holger Kreft, Prof. Dr. Hermann Behling and Prof. Dr. Erwin Bergmeier for their willingness to be part of my examination board.

Special thanks go to Roman Link for endless support in any statistics-related troubles and for all the provided help, to Heinz Coners for all the technical support, to Dietrich Hertel for competently answering all my "belowground" questions, and to Robert Weigel for all his "dendro-ideas".

I am incredibly thankful for all the help in field- and labwork by Ana Sapoznikowa, Leonhard Klinck, Hannah Korp, Greta Weithmann, Amauta Halvorsen, Natalia Sierra Cornejo, Kyra Zembold, Jutta Czernitzki, Irmgard Gerstmann, Annegret Kellner and Mechthild Stange.

Credits go to all my colleagues in Göttingen for fruitful discussions and, similarly important, trash- and small-talk in coffee and lunch breaks.

Finally and most importantly, my greatest thank goes to my parents for their everlasting support and encouragement and to Tina for all the patience, for the countless hours of support in the final sprint, and for being the most amazing person in the world.

6.4 Curriculum Vitae

Sebastian Mario Fuchs

born on 26.01.1988 in Schwalmstadt, Germany

Education

2016 - 2021 PhD student at the University of Göttingen, Department of Plant
Ecology & Ecosystem Research

2012 - 2015 Master of Science in Biodiversity, Ecology and Evolution, University
of Göttingen

2008 - 2011 Bachelor of Science in Biology, University of Göttingen

2007 Allgemeine Hochschulreife (high-school diploma), Waldorfschule
Kassel

Work experience

2020 - dato Research associate at the Northwest German Forest Research Institute
(NW-FVA), Department of Environmental Control, Göttingen

2019 Research associate at University of Würzburg, Department of
Ecophysiology and Vegetation Ecology

2016 - 2019 Research associate at University of Göttingen, Department of Plant
Ecology & Ecosystem Research

2015 Assistant in a research project on plant-water-relations in Costa Rica

2012 - 2015 Assistant in teaching, research and field work at the University of
Göttingen, Department of Plant Ecology & Ecosystem Research

2012 Internship in environmental education at National Park Jasmund,
Island of Rügen

2010 - 2011 Assistant in teaching, research and field work at the University of
Göttingen, Department of Plant Ecology & Ecosystem Research

2007 - 2008 Civil service in organic farming in Morschen
