ABSTRACT

We examined the involvement of the P2 × 7 receptor and the canonical and noncanonical inflammasomes in the control of single-species or dual-species infection by the periodontal bacteria *Porphyromonas gingivalis* and *Fusobacterium nucleatum* in cells and mice. Stimulation of the P2 × 7 receptor leads to activation of the canonical NLRP3 inflammasome and activation of caspase-1, which leads to cleavage of pro-IL-1β to IL-1β, a key cytokine in the host inflammatory response in periodontal disease. The non-canonical inflammasome pathway involves caspase-11. Thus, wildtype (WT), P2 × 7^{-/-}, caspase-11^{-/-} and caspase-1/11^{-/-} mice were co-infected with both bacterial species. In parallel, bone marrow-derived macrophages (BMDMs) from WT mice and the different knockout mice were infected with *P. gingivalis* and/or *F. nucleatum*, and treated or not with extracellular ATP, which is recognized by P2 × 7. *F. nucleatum* infection alone promoted secretion of IL-1β in BMDMs. Conversely, the canonical pathway involving P2 × 7 and caspase-1 was necessary for secretion of IL-1β in BMDMs infected with *P. gingivalis* and in the mandible of mice coinfecting with *P. gingivalis* and *F. nucleatum*. The P2 × 7 pathway can limit bacterial load in single-species and dual-species infection with *P. gingivalis* and *F. nucleatum* in BMDMs and in mice. The non-canonical pathway involving caspase-11 was required for secretion of IL-1β induced by *F. nucleatum* infection in BMDMs, without treatment with ATP. Caspase-11 was also required for induction of cell death during infection with *F. nucleatum* and contributed to limiting bacterial load during *F. nucleatum* infection in BMDMs and in the gingival tissue of mice coinfecting with *P. gingivalis* and *F. nucleatum*. Together, these data suggest that the P2 × 7-caspase-1 and caspase-11 pathways are involved in the immune response against infection by *P. gingivalis* and *F. nucleatum*, respectively.

1. Introduction

Periodontal disease (PD) is a worldwide public health problem that affects mainly middle and low-income countries (Peres et al., 2019), but it is estimated that almost half of American adults also have mild, moderate, or severe periodontitis (Eke et al., 2012). According to the World Health Organization, about 20% of adults worldwide have some form of chronic periodontitis (Natto and Hameedaldain, 2019), and severe periodontitis is considered to be the sixth most prevalent disease in the world (Eke et al., 2015; Tonetti et al., 2015). Furthermore, PD can contribute to other inflammatory diseases as shown by clinical and experimental studies (Arimatsu et al., 2014; Bui et al., 2019).

Porphyromonas gingivalis is an anaerobic gram negative bacterium present in subgingival plaques and is one of the microorganisms associated with chronic periodontitis (Hajishengallis, 2015). *P. gingivalis* presents several virulence factors that allow the bacteria to colonize the host tissues under hostile environments, to obtain nutrients, to subvert immune responses, and to favor the formation of dysbiotic communities (Hajishengallis, 2015).

Other constituents of the dental biofilm participate in the development of oral inflammation and are associated with the disease, including the bacterium *Fusobacterium nucleatum* (Whitmore and Lamont, 2014). *F. nucleatum* can function as a bridge in the formation of dental plaque, aggregating other microorganisms, but can also invade several cells, including oral epithelial cells, macrophages, and ker-

atinocytes (Gursoy et al., 2008; Han et al., 2000; Weiss et al., 2000; Kolenbrander et al., 2010).

Coinfection of *P. gingivalis* with *F. nucleatum* can facilitate adherence and invasive capacity in cells in the gingival tissue (Li et al., 2015; Saito et al., 2008; Saito et al., 2012). In addition, *F. nucleatum* produces a capnophilic environment that is conducive to the growth of *P. gingivalis* and that metabolizes molecular oxygen and hydrogen peroxide (Diaz et al., 2002).

Inflammation resulting from oral dysbiosis is mediated by neutrophils, macrophages, dendritic cells as well as acquired immunity cells, T and B lymphocytes (Lira-Junior and Figueredo, 2016). Macrophages correspond to about 5–7% of inflammatory infiltrates in injured periodontal tissue. Despite occupying a relatively small proportion, macrophages participate in the first line of defense, possessing phagocytic ability and regulatory functions, recruiting immune cells and activating immune and non-immune cells (Carcuac and Berglundh, 2014; Thorbert-Mros et al., 2015).

We and others (Chotjumlong et al., 2013; Kim et al., 2018) found that purinergic signaling is involved in the immune response to infection by periodontopathogenic bacteria *in vivo* and *in vitro*. Thus, *P. gingivalis* infection increases expression of the purinergic P2 × 7 receptor in infected murine macrophages (Morandini et al., 2014) and in the maxilla of infected mice (Ramos-Junior et al., 2015). This receptor was also required for IL-1 β production, leukocyte recruitment to the site of infection, and control of bacterial load in an air pouch model of infection (Almeida-da-Silva et al., 2019).

Ligation of the ionotropic P2 × 7 receptor by extracellular ATP leads to activation of the NLRP3 inflammasome (NOD-, LRR- and pyrin domain-containing protein) via the canonical pathway. This in turn results in activation of caspase-1, which is responsible for cleaving the 33-kDa pro-IL-1 β and 24-kDa pro-IL-18 into their biologically active forms, 17-kDa IL-1 β and 18-kDa IL-18, respectively (Swanson et al., 2019). The NLRP3 inflammasome has been shown to play a role in the host's inflammatory response in PD (Pan et al., 2019; Yucel-Lindberg and BÅvge, 2013), and the pro-inflammatory cytokine IL-1 β contributes to induction of bone resorption (Chen et al., 2014; Huynh et al., 2017).

Caspase-11 (represented in humans by its orthologs, caspase-4 and caspase-5) is expressed broadly in immune and non-immune cells, and mediates inflammatory responses through the noncanonical pathway, in which the NLRP3 inflammasome is activated by gram negative bacteria such as *Escherichia coli*, *Salmonella typhimurium* and *Burkholderia thailandensis* (Kayagaki et al., 2011; Broz et al., 2012; Aachoui et al., 2013). The activation of caspase-11 occurs during both cytosolic and non-cytosolic bacterial infections, and it is induced by the detection of cytosolic LPS, which is translocated to the host cell's cytosol during infection with extracellular bacteria (Roberts and Yilmaz, 2015; Russo et al., 2018). Both caspase-1 and caspase-11 induce pyroptosis, an inflammatory cell death characterized by pore formation in the cell membrane, cell edema, osmotic lysis and release of cytosolic contents into the extracellular medium (Lamkanfi, 2011). These contribute to the elimination of infectious microorganisms within the cell (Uchiyama and Tsutsui, 2015).

Immune responses to single-species infections (Bui et al., 2016; Hajishengallis et al., 2009; Johnson et al., 2018) and dual-species infections (Saito et al., 2012 Nov; Taxman et al., 2012) by *P. gingivalis* and *F. nucleatum* have been investigated in animal models, such as rats and mice, and in cells. To date, there have been studies on the involvement of the purinergic P2 × 7 receptor and caspase-1 and caspase-11 in the control of single-species infection only by *P. gingivalis*, and no studies on co-infection by *P. gingivalis* and *F. nucleatum* *in vivo* and *in vitro* models. Therefore, we conducted the present study to investigate the canonical and non-canonical pathways of NLRP3 inflammasome activation during co-infection, which are closer to mimicking the conditions of polymicrobial infections in the oral cavity than the single-species infection reported by most studies to date.

2. Materials and methods

2.1. Reagents

All chemicals were purchased from Sigma-Aldrich (San Louis, Missouri, USA), except as noted below. Primer pairs were purchased from Exxtend Biotecnologia Ltda. Sybr Green PCR Master Mix and 96-well MicroAmp Optical reaction plates were purchased from Applied Biosystems (Foster City, California, USA). TRIzol reagent was purchased from Invitrogen Life Technologies (Carlsbad, California, USA). MultiScribe[®] Reverse Transcriptase, dNTP Mix and oligo dT Primers were purchased from Invitrogen Life Technologies. Murine IL-1 β ELISA reagents and Murine TNF- α ELISA reagents were purchased from R&D Systems, (Minneapolis, Minnesota, USA). The 96-well ELISA plates were obtained from Corning[®] (Corning, New York, USA). Anaerocult[®] A was purchased from Merck Millipore (Burlington, Massachusetts, USA). Sulfamethoxazole (0.87 mg/mL) and trimethoprim (0.17 mg/mL) (Bactrim 200/40 mg) were obtained from a pharmacy.

2.2. Bacterial strains and growth conditions

From frozen stocks at –80 °C, *Porphyromonas gingivalis* (strain ATCC 33277) cells were grown on brain and heart infusion (BHI) agar (1.85% BHI; 1.5% agar; 0.5% yeast extract; 0.5 g/L L-cysteine; 0.00005% vitamin K; 0.0005% hemin; 5% defibrinated sheep blood). The ATCC 33277 strain of *P. gingivalis* is more invasive in models of intracellular infection (Lamont et al., 1995). *Fusobacterium nucleatum* (strain ATCC 25586) cells were grown on BHI agar plate and Tryptic Soy Broth (TSB) (1.55% BHI; 1.48% TSB; 1.7% agar; 0.5% yeast extract; 1% menadione solution (0.5 mg/mL); 1% hemin solution (1 mg/mL); 5% defibrinated sheep blood). Both bacterial strains grew in an anaerobic jar system with Anaerocult[®] A anaerobic generators for 7 days at 37 °C. For experiments, isolated colonies of *P. gingivalis* and *F. nucleatum* were selected and inoculated in supplemented specific broth for the growth of each bacterium and grown for 48 h in anaerobic jars under the same conditions as for previous growth [25]. Bacterial quantification was performed using spectrophotometry at 550 nm.

2.3. In vivo studies

2.3.1. Mice and in vivo study design

To prevent any effect of estrogens on oral tissue, male C57BL/6 (Wild-Type—WT), P2 × 7^{-/-} (Pfizer, USA), Caspase11^{-/-} (Casp11^{-/-}) and Caspase1/11^{-/-} (Casp1/11^{-/-}) (Genentech, USA), at 6 weeks old (body mass average: 25 g), obtained from the Instituto de Biofísica Carlos Chagas Filho, Universidade Federal do Rio de Janeiro (IBCCF/UFRJ). The animals were weighed for random conditioning, together, per group, in microisolators for seven days for adaptation in an animal experimental vivarium at the IBCCF/UFRJ (24 ± 1 °C; 12-h light/dark cycle). The experimental phase was carried out after the approval of this study by the Animal Use Ethics Committee (CEUA) of UFRJ, under protocol number 080/19. During all stages of the study, the care proposed by the Guide for the Care and Use of Laboratory Animals (1996) was followed, and the number of animals was based on the minimum number needed to achieve the study's aims.

2.3.2. *F. nucleatum* and *P. gingivalis* in vivo infection model

The animals (7 weeks old) were treated with sulfamethoxazole (0.87 mg/mL) and trimethoprim (0.17 mg/mL) in drinking water *ad libitum* for 10 days, followed by 3 days without antibiotics. Then the mice were anesthetized and infected in the oral cavity with 50 μ L of 2% carboxymethylcellulose containing 10⁹ CFU (colony forming units) of each bacterium applied at the surface of the mandibular and maxilla molar teeth using a micropipette and sterile tip (Ramos-Junior et al., 2015). For coinfection, the inoculum containing *P. gingivalis* was ap-

plied 4 h after the inoculum containing *F. nucleatum*, considering that Feuille et al. (1996) observed that this time led to significantly increased capacity of *P. gingivalis* to form large phlegmonous lesions. Three inoculations were applied at 2-day intervals (a total period of 7 days). Inocula containing bacteria were prepared immediately prior to administration. Bacterial inoculation induced an immune response in an animal model similar to periodontal disease in humans (Graves et al., 2012). The animals received the Nuvital® Commercial Diet, CR1, Brazil, and had free access to food and water (filtered and autoclaved) throughout the experiment. At the end of the experimental period, on day 8, the animals were euthanized in a CO₂ chamber and then the upper and lower dental arches were removed for separation into two hemiarcades per cut. Subsequently, gingival tissue and mandible fragment were collected for further analysis and were stored in a biofreezer at -80 °C.

2.3.3. Tissue homogenate preparations

Mandible homogenates were prepared in ice cold using radioimmunoprecipitation assay buffer (RIPA) buffer (pH 7.4) with protease inhibitor cocktail (for use with mammalian cell and tissue extracts; Sigma-Aldrich, San Louis, Missouri, USA). Subsequently, a 1:10 dilution of the homogenates was performed using PBS buffer (pH 7.4) for subsequent measurement of total proteins using a BCA Kit (bicinchoninic acid) (Bioagency, São Paulo, Brazil), following the manufacturer's instructions with absorbance reading at 562 nm.

2.4. In vitro studies

2.4.1. Cell culture

For bone marrow collection and macrophage differentiation, we used 8-week-old C57BL/6 (WT), P2 × 7^{-/-}, caspase11^{-/-} and caspase1/11^{-/-} mice. Bone marrow cells were isolated from the femurs and tibias and were used for macrophage differentiation using L929 cell conditioned media (LCCM) as a source of macrophage colony stimulating factor (M-CSF) (Morandini et al., 2014). As previously described (Morandini et al., 2014; Almeida-da-Silva et al., 2019), cells were resuspended in 10 mL RPMI 20/30 differentiation medium [RPMI1640 supplemented with 20% fetal bovine serum (FBS- Gibco®), 30% LCCM, 100 U/mL penicillin, 100 U/mL streptomycin, 1 mM L-glutamine]. Cells were seeded in culture plates and incubated at 37 °C in a 5% CO₂ atmosphere. Three days later, an additional 10 mL of 20/30 RPMI was added per incubation plate for another four days. On day 7, the adherent cells were collected with 10 mL of sterile ice-cold phosphate buffered saline (PBS, pH 7.4). The cells were centrifuged at 220 g for 5 min and resuspended in 10 ml RPMI culture medium with 10% FBS. The cells were then seeded at 10⁶/mL on the day prior to the experiments. The macrophage purity of these preparations was above 90%, assessed by flow cytometry using Alexa Fluor 488 anti-F4/80 (eBioscience™, Waltham, Massachusetts, USA).

2.4.2. *F. nucleatum* and *P. gingivalis* infection in vitro model

A total of 10⁶ bone marrow-derived macrophages (BMDMs) from C57BL/6 (WT), P2 × 7^{-/-}, caspase11^{-/-} and caspase1/11^{-/-} mice were plated on 24-well plates in 500 µL RPMI 1640 medium (1% FBS). After 18 h of plating, macrophages were infected with *P. gingivalis* and/or *F. nucleatum* at multiplicities of infection (MOI) of 100 and 20, respectively. *P. gingivalis* were added to the cells along with *F. nucleatum*. After 2 h of the bacterium and macrophage interaction, 200 µg/ml of metronidazole and 300 µg/ml of gentamicin was added to each well and incubated for a further 1 h, 37 °C in a 5% CO₂ atmosphere to eliminate non-phagocytic bacteria. The supernatants were then discarded and the cells were washed three times with PBS, then 500 µL of RPMI 1640 medium (1% SFB) was added. At 30 min before completing 6 h of infection, 3 mM ATP was added (or not) to cells. After this treatment, the supernatants were collected and stored at -80 °C. Subsequently, the cells were washed three times with PBS and then 500 µL of RPMI 1640 medium (1% SFB) were added. The cells were incubated at 37 °C in a

5% CO₂ atmosphere for another 12 h. After 18 h of infection, the supernatants were collected and stored at -80 °C and cells were harvested with 500 µL TRIzol reagent. This infection protocol was used throughout the study. The choice of MOIs were based on our results of dose-response experiments (see supplementary data Figs. S1 and S2). MOIs of 100 for *P. gingivalis* and MOI of 20 for *F. nucleatum* appeared to be the ideal doses for the study.

2.4.3. Cytotoxicity assay

Cells were infected as described, and lactate dehydrogenase (LDH) levels were dosed in the supernatant at 6 and 18 h of infection. LDH release was quantified using an LDH Cytotoxicity Assay Kit (Bioclin®, Belo Horizonte, Brazil) according to the manufacturer's instructions.

2.4.4. Cytokine analysis

For *in vivo* tests, the mandible homogenates were initially diluted (1:10) with PBS buffer (pH 7.4). For *in vitro* tests, cell-free supernatants were used without prior dilution. The levels of cytokines IL-1β (cat.DY401, DuoSet ELISA - R&D Systems) and TNF-α (cat.DY410, DuoSet ELISA - R&D Systems) were assayed using ELISA with an R&D Systems® kit as per manufacturer's instructions. Cytokines were quantified as absorbance at 450 nm in an ELISA plate reader, and their concentrations were determined by interpolation of a standard curve. Results were expressed as pg/mL.

2.4.5. RNA and DNA isolation and real-time RT-PCR

RNA and DNA extraction from cells and gingival tissues was performed using TRIzol reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. After the extraction step, samples were analyzed for RNA and DNA quantity and purity by absorbance, without prior dilution, using NanoVue Plus™ (Biochrom, Harvard Bioscience, US, Holliston, MA, USA). For bacterial load quantification, a calculation was performed to achieve DNA concentrations of 40 ng/µL and to standardize sample concentrations prior to DNA amplification. For the mRNA quantification, 1 µg RNA was used for cDNA (complementary DNA) synthesis in Eppendorf Mastercycler Gradient PCR Instrument using Reverse Transcriptase Enzyme. Homology of the selected primers was verified by a study carried out in the BLAST program of the National Center for Biotechnological Information (<http://www.ncbi.nlm.nih.gov/BLAST/>). The finished primer sequence (Table 1) was synthesized (Exxtend Solutions in Oligo, Campinas, SP, Brazil) and purified by desalination. Amplification was performed in a real-time quantitative PCR apparatus using the Sybr Green Reagent in StepOnePlus™ Real-Time PCR System programmed as follows: initial denaturation at 95 °C for 10 min, followed by 40 cycles of denaturation at 95 °C for 15 s and annealing and extension at 60 °C for 1 min for the final elongation of the DNA strands. In all reactions, DNA from reference strains of the studied microorganisms was used as a positive control. To determine the quantification of relative bacterial levels was performed by interpolation with a bacterial standard curve obtained by multiple serial dilutions of 10 with DNA extracted from pure cultures (*P. gingivalis* strain ATCC 33,277 and *F. nucleatum* strain ATCC 25,586) through PureLink®. Genomic DNA Mini Kit (ThermoFisher Scientific, Alto de Pinheiros, SP, BR) according to manufacturer's instructions. To determine the quantification of the relative levels of gene expression, the delta Ct method was used after normalization with endogenous β-actin, which was chosen as the reference gene. Differences in gene expression levels were calculated using the 2^{-ΔΔCt} comparative method using the reference gene, as well as the uninfected bone marrow-derived macrophages (BMDMs) and gingival tissue from C57BL/6 (WT) and knockout animals as controls.

2.4.6. Flow cytometry immunophenotyping

To examine the profile of inflammatory cells, submandibular lymph nodes were removed. The organs were then macerated using a cell strainer (0.40 µm) in an ice-cold Petri dish using a 1-mL syringe plunger

Table 1

(rough part). Subsequently, the cells were centrifuged at 220 g, 4 °C for 10 min, discarding the supernatants and resuspending pellets in 1 mL RPMI 1640 (3% SFB). Then, the cells were counted in hemocytometer with 0.2% trypan blue. The volume corresponding to 5×10^5 cells, allowing adjustment of the amount of cells to be used for labeling, was pipetted into round-bottom 96-well plates and the cells were centrifuged again at 220 g, 4 °C for 4 min. The supernatants were discarded and the cells were resuspended in 10 μL Fc block (CD16/CD32; 0.5 mg/mL, Clone 93) diluted in FACS buffer (1: 100) and incubated for 15 min at 4 °C. Then, 10 μL/well of the conjugated antibody was added to the respective fluorochrome (diluted in FACS buffer (1: 100)), containing (0.1–10 μg/mL) and the isotype controls diluted (1: 100) and incubated for 30 min, 4 °C under light protection and then, added 200 μL/well of FACS buffer, centrifuged the cells (220 g, 4 °C for 4 min) and we discarded the supernatants. A repeat wash was performed with 200 μL FACS buffer, cells were centrifuged (220 g, 4 °C for 4 min) and the supernatants were discarded. Cells were resuspended in 250 μL/well PBS x 1. Then, the contents of the wells were transferred to FACS tubes and FACSCalibur flow cytometer (BD Biosciences, Franklin Lakes, USA) acquisition was performed. Data were analyzed using FlowJo software (Tree Star Inc., Ashland, OR, USA). The percentage data were multiplied by the total amount of cells of the corresponding sample and then divided by 100. The results were then expressed as total number of cells.

2.5. Statistical analysis

For all variables, normality was assessed using the Kolmogorov-Smirnov test. Parametric variables were evaluated using one-way analysis of variance (ANOVA), followed by *t*-test or Tukey test for comparisons between groups. The Kruskal-Wallis test or Mann-Whitney test was used to evaluate non-parametric variables with corresponding post hoc analysis. Results were presented as mean ± standard error (SEM). *P* values < 0.05 were considered statistically significant. GraphPad® Prism version 5.1 for Windows (San Diego, CA, USA) was used.

3. Results

3.1. P2 × 7 is required for expression and secretion of IL-1β, and control of infection by *P. gingivalis* and *F. nucleatum* in vivo

Considering the role of P2 × 7 receptor in NLRP3 inflammasome activation and subsequent secretion of IL-1β (Swanson et al., 2019), we

examined the participation of P2 × 7 in the expression and secretion of IL-1β in the gingival tissue and mandible, respectively, of C57BL/6 and P2 × 7^{-/-} mice co-infected by *P. gingivalis* and *F. nucleatum*. We observed that there were lower levels of IL-1β mRNA (Fig. 1A) and protein expression of this cytokine (Fig. 1B) in the gingival tissue and mandible, respectively, of P2 × 7^{-/-} co-infected animals than in co-infected wildtype (WT) animals. Levels of *P. gingivalis* (Fig. 1C) and *F. nucleatum* (Fig. 1D), measured as the amount of specific DNA, in the gingival tissue of co-infected P2 × 7^{-/-} animals were larger than in co-infected WT animals.

These results suggest that P2 × 7 is important for the secretion of IL-1β in the mandible of coinfecting mice and for the control of infection by *P. gingivalis* and *F. nucleatum* in gingival tissue of coinfecting mice.

3.2. Caspase-1 contributes to the immune response against *P. gingivalis* while caspase-11 acts primarily against infection by *F. nucleatum* in vivo

Next, we characterized the downstream pathway of canonical activation of the NLRP3 inflammasome by P2 × 7 *in vivo*. We found that neither caspase-1 nor caspase-11 were necessary for IL-1β expression increases induced by bacterial co-infection in the gingival tissue, because the levels of IL-1β mRNA in the gingival tissue of co-infected caspase-1/11^{-/-} mice were similar to those of co-infected WT animals (Fig. 2A). However, both caspase-1 and caspase-11 were important for the secretion of this cytokine in the mandible of animals coinfecting by the bacteria, because the levels of IL-1β in the mandible were lower in this tissue in co-infected caspase-1/11^{-/-} animals than in the co-infected WT animals (Fig. 2B). When evaluating the bacterial load, we found more *P. gingivalis* and *F. nucleatum* DNA in the gingival tissue of the co-infected caspase-1/11^{-/-} animals than in the co-infected WT animals (Fig. 2C and 2D).

When we evaluated the participation of caspase-11 in co-infected animals, we found that caspase-11 was not necessary for the expression of IL-1β in gingival tissue (Fig. 3A) nor for secretion of this cytokine in the mandible (Fig. 3B), since no differences were found between co-infected WT and caspase-11^{-/-} animals. However, we found greater amounts of *F. nucleatum* DNA in the gingival tissue of the caspase-11^{-/-} animals co-infected than in co-infected WT animals (Fig. 3C).

Together, these results suggest that caspase-1 is required for the secretion of IL-1β in the mandible of co-infected mice and acts to control infection by *P. gingivalis* in gingival tissue, whereas caspase-11 is required to control infection by *F. nucleatum* in gingival tissue of coinfecting mice.

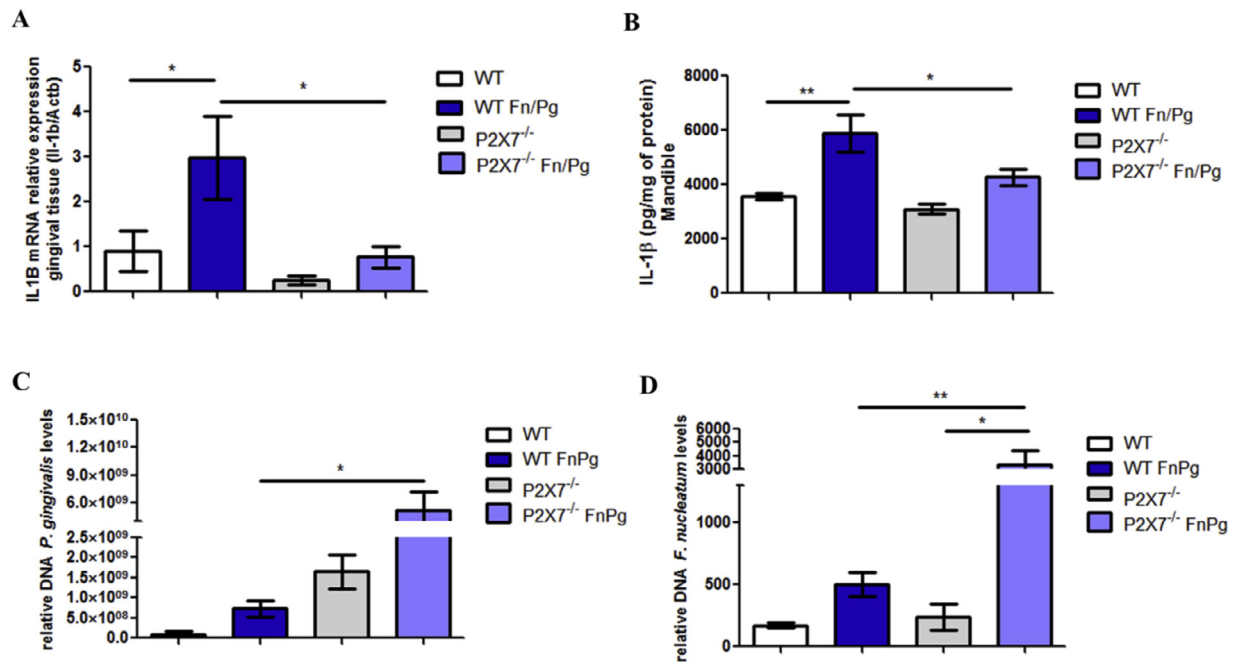

Fig. 1. P2 × 7 is important for the control of infection by *P. gingivalis* and *F. nucleatum* in vivo. (A) Relative levels of IL-1 β mRNA are shown in gingival tissue using real-time PCR. (B) Levels of IL-1 β are shown in the mandible using ELISA. (C) Relative amount of *P. gingivalis* DNA in gingival tissue by real-time PCR. 3.3. Co-infection *in vivo* by *P. gingivalis* and *F. nucleatum* increased the expression of inflammatory markers in gingival tissue and altered the profile of inflammatory cells in submandibular lymph nodes

We verified the effect of oral co-infection by *P. gingivalis* and *F. nucleatum* on the targets of the canonical and non-canonical pathways of NLRP3 inflammasome activation in C57BL/6 mice. We found significantly higher amounts of P2 \times 7 mRNA in the gingival tissue than in uninfected animals (Fig. 4A), as well as significantly higher levels of NLRP3 mRNA (Fig. 4B), caspase-1 mRNA (Fig. 4C), caspase-11 mRNA (Fig. 4D), IL-1 β mRNA (Fig. 4E), and TNF- α mRNA (Fig. 4F).

Taken together, these data suggest that oral coinfection in mice for one week stimulates the expression of molecules of the canonical and non-canonical pathways of NLRP3 inflammasome activation.

We then examined the effect of coinfection by *P. gingivalis* and *F. nucleatum* on the profile of inflammatory cells in the submandibular lymph nodes. We found that coinfection led to an increased number of cells in the submandibular lymph nodes (Fig. 5A). This increase was also due to the number of B cells (Fig. 5B), CD8⁺ cells (Fig. 5C) and CD4⁺ cells (Fig. 5D) that was increased in the infected animals compared with uninfected animals.

3.4. Pathways involved in *F. nucleatum* and *P. gingivalis* induction of IL-1 β secretion in murine macrophages

To explore the mechanisms involved in the canonical and non-canonical pathways of NLRP3 inflammasome activation induced by infection with *P. gingivalis* and *F. nucleatum*, we characterized the pathways during infection *in vitro*, using bone-marrow derived macrophages (BMDMs). Thus, we investigated IL-1 β secretion induced by *P. gingivalis* and *F. nucleatum* infection in BMDMs from C57BL/6 mice. We found that *P. gingivalis* after 6 h and 18 h of infection induced IL-1 β secretion in BMDMs only following treatment with 3 mM ATP, which acts as a second signal for NLRP3 inflammasome activation. After 18 h, the levels of IL-1 β secretion were significantly higher than after 6 h of infection (Fig. 6A).

When the BMDMs were infected for 6 h and 18 h with *F. nucleatum*, infection by itself (without ATP treatment) was sufficient to induce IL-1 β secretion, with the IL-1 β release being much higher after 18 h than after 6 h (Fig. 6B). Potentiation of IL-1 β secretion was observed with ATP treatment after 6 h of infection, but not after 18 h (Fig. 6B).

Infection with some gram-negative bacteria can induce pyroptosis (Broz et al., 2012; Case et al., 2013). Thus, we measured cytotoxicity during infection by measuring LDH levels released from host cells into the extracellular medium. We observed that, after 6 h of infection, neither *P. gingivalis* nor *F. nucleatum* bacteria induced cytotoxicity (Fig. 6C and D).

Since the pannexin-1 channel induces ATP release in macrophages (Pelegriin and Surprenant, 2006) and activates P2 \times 7 purinergic receptors, culminating in IL-1 β release (Iglesias et al., 2008), we evaluated the participation of pannexin-1 in IL-1 β secretion induced by *F. nucleatum* infection. We used carbenoxolone (CBX), widely used as a pannexin-1 inhibitor (Connors, 2012), in BMDMs infected with *F. nucleatum* for 6 h with and without ATP treatment. No changes in IL-1 β levels were observed (Fig. 6E).

Since ATP did not increase the secretion of IL-1 β in BMDMs after 18 h of infection with *F. nucleatum* (Fig. 6B), we examined whether bacterial infection was cytotoxic after 18 h of infection. We found that *F. nucleatum* infection caused a significant increase in LDH release from infected cells, compared with uninfected BMDMs (Fig. 6F).

These results show that, unlike *P. gingivalis* infection, *F. nucleatum* infection by itself (without ATP treatment) promotes IL-1 β secretion in murine macrophages, it does not require the pannexin-1 channel, and it induces cell death after 18 h of infection.

3.5. Contribution of P2 \times 7 to the immune response against *P. gingivalis* and *F. nucleatum*

We next evaluated the participation of P2 \times 7 in IL-1 β secretion induced by bacterial infections in BMDMs derived from P2 \times 7^{-/-} and WT mice. In the absence of P2 \times 7 in BMDMs, there was a significant decrease in IL-1 β levels induced by *P. gingivalis* for 18 h following treat-

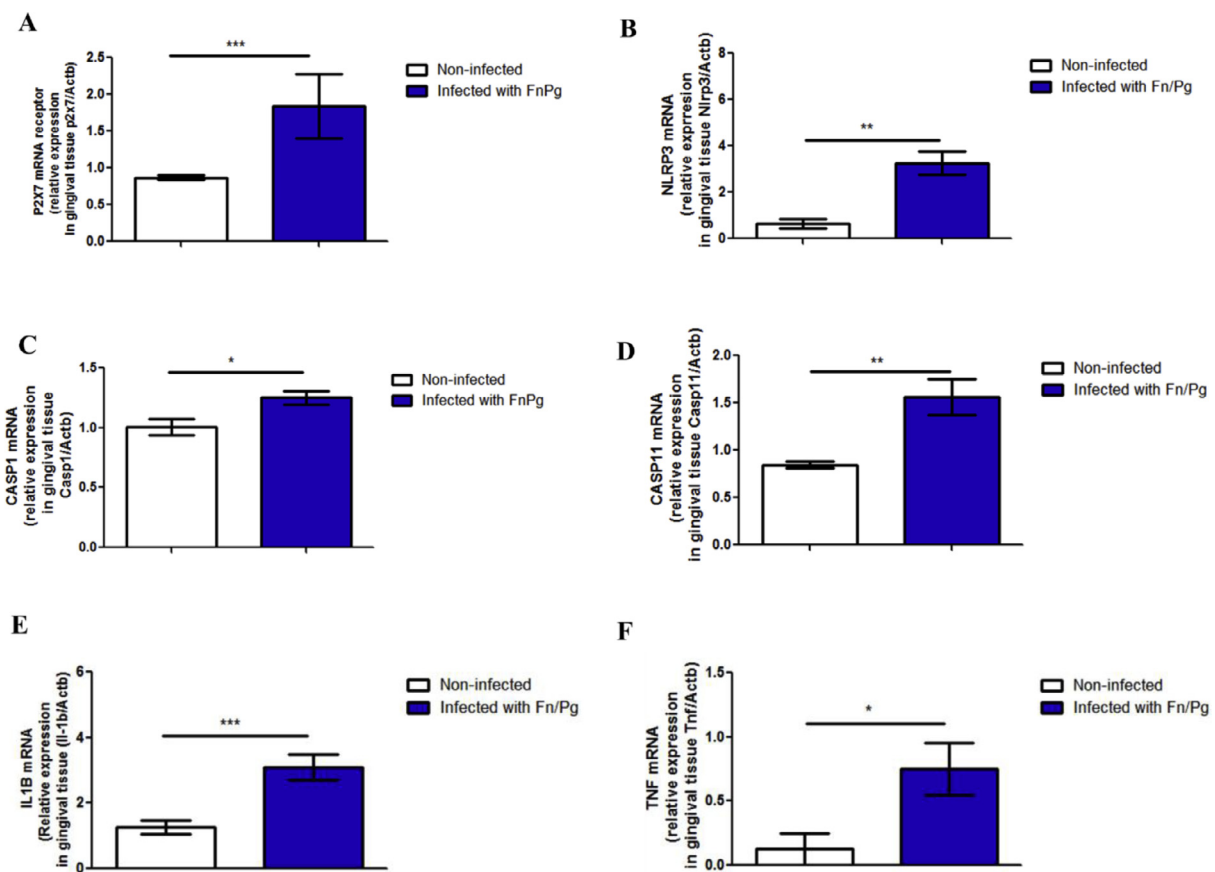

Fig. 4. Oral co-infection increases expression of pro-inflammatory markers. Relative mRNA levels of (A) P2 × 7 receptor, (B) NLRP3, (C) caspase-1, (D) caspase-11, (E) IL-1 β , and (F) TNF- α in the gingival tissue using real time PCR of C57BL/6 (WT) mice co-infected orally or not with 10⁹ CFU of each bacterial species, *F. nucleatum* strain (ATCC 25,586) and *P. gingivalis* (ATCC 33,277). The data represent the mean \pm SEM. (A) WT = 10; WT FnPg = 9 and data were analyzed using the Mann–Whitney test. (B) WT = 4; WT FnPg = 7, (C) WT = 4; WT FnPg = 4, (D) WT = 6; WT FnPg = 7, (E) WT = 14; WT FnPg = 15 and were analyzed using two-tailed unpaired *t*-test. (F) WT = 5; WT FnPg = 7 and data were analyzed using the Mann–Whitney test. * *p* < 0.05; ** *p* < 0.005; *** *p* < 0.001 Pg: *Porphyromonas gingivalis*; Fn: *Fusobacterium nucleatum*.

ment with 3 mM ATP, compared with WT BMDMs infected with *P. gingivalis* and treated with ATP (Figs. 7A and 6A). Conversely, infection with *F. nucleatum* by itself was sufficient to induce IL-1 β secretion in the supernatants of P2 × 7^{-/-} BMDMs and in the supernatant of WT BMDMs (Figs. 7A and 6B). However, *F. nucleatum* was cytotoxic after 18 h of infection (Fig. 6F).

As a control, we measured the effect of infection on secretion of a cytokine that does not depend on activation of the inflammasome. We observed that TNF- α levels were similar in the BMDMs infected with one or both bacterial species in the cells derived from the knockouts with or without treatment with 3 mM ATP (Fig. 7B).

Since P2 × 7 was required for secretion of IL-1 β during *P. gingivalis* infection, we checked the bacterial load in P2 × 7^{-/-} BMDMs and WT BMDMs infected with *F. nucleatum* or *P. gingivalis* alone, or both bacterial species, to determine whether the P2 × 7 pathway had an effect on the bacterial load in murine macrophages. We observed that treatment with 3 mM ATP reduced the bacterial infection in both mono-infected and co-infected WT BMDMs, leading to a significant decrease in the levels of *P. gingivalis* (Fig. 7C) and *F. nucleatum* (Fig. 7D) after 18 h of infection, as measured by their DNA content. In the absence of P2 × 7 in BMDMs, there was an increase in the levels of *P. gingivalis* and *F. nucleatum* in infected cells when compared with WT BMDMs for both mono- and co-infection for 18 h (Fig. 7E and F). Similar results were observed when WT BMDMs and P2 × 7^{-/-} BMDMs were infected separately with single bacterial species or co-infected with both bacterial species for 18 h and treated with 3 mM ATP (Fig. 7G and H).

These results suggest that P2 × 7 was necessary for the secretion of IL-1 β induced by *P. gingivalis* and that P2 × 7 controls the infection by *P. gingivalis* and *F. nucleatum* in murine macrophages.

3.6. Role of P2 × 7, caspase-1, and caspase-11 in the immune response against *P. gingivalis* and *F. nucleatum* infection

We next characterized the involvement of caspase-1 in inflammasome activation during infection. For this, we used BMDMs derived from caspase-1/11^{-/-} and WT mice. After infection of BMDMs with *F. nucleatum* for 6 h, we found a significant decrease in IL-1 β levels in the supernatants of infected caspase-1/11^{-/-} BMDMs compared with infected WT BMDMs (Fig. 8A). The same significant decrease was observed in the supernatant of caspase-1/11^{-/-} BMDMs infected for 6 h with *P. gingivalis* and treated with ATP, compared with mono-infected WT BMDMs (Fig. 8A and see supplementary data Fig. S3A). We did not detect any effect on TNF- α secretion in BMDMs of caspase-1/11^{-/-} that were infected singly or dually with the two bacterial species, treated or not with ATP, compared with infection or treatment of WT cells (Fig. 8B).

Since caspase-11 participates in the non-canonical pathway of NLRP3 inflammasome activation and it is involved in clearance of some infections (Roberts and Yilmaz, 2015; Russo et al., 2018; Huang et al., 2019), we examined the effect of the absence of caspase-11 in BMDMs derived from caspase-11^{-/-} mice on secretion of IL-1 β . We found that mono-infection with *F. nucleatum* and co-infection with *F. nucleatum* and *P. gingivalis* in caspase-11^{-/-} BMDMs resulted in significant decreases in the levels of IL-1 β secreted, compared with infections in WT BMDMs,

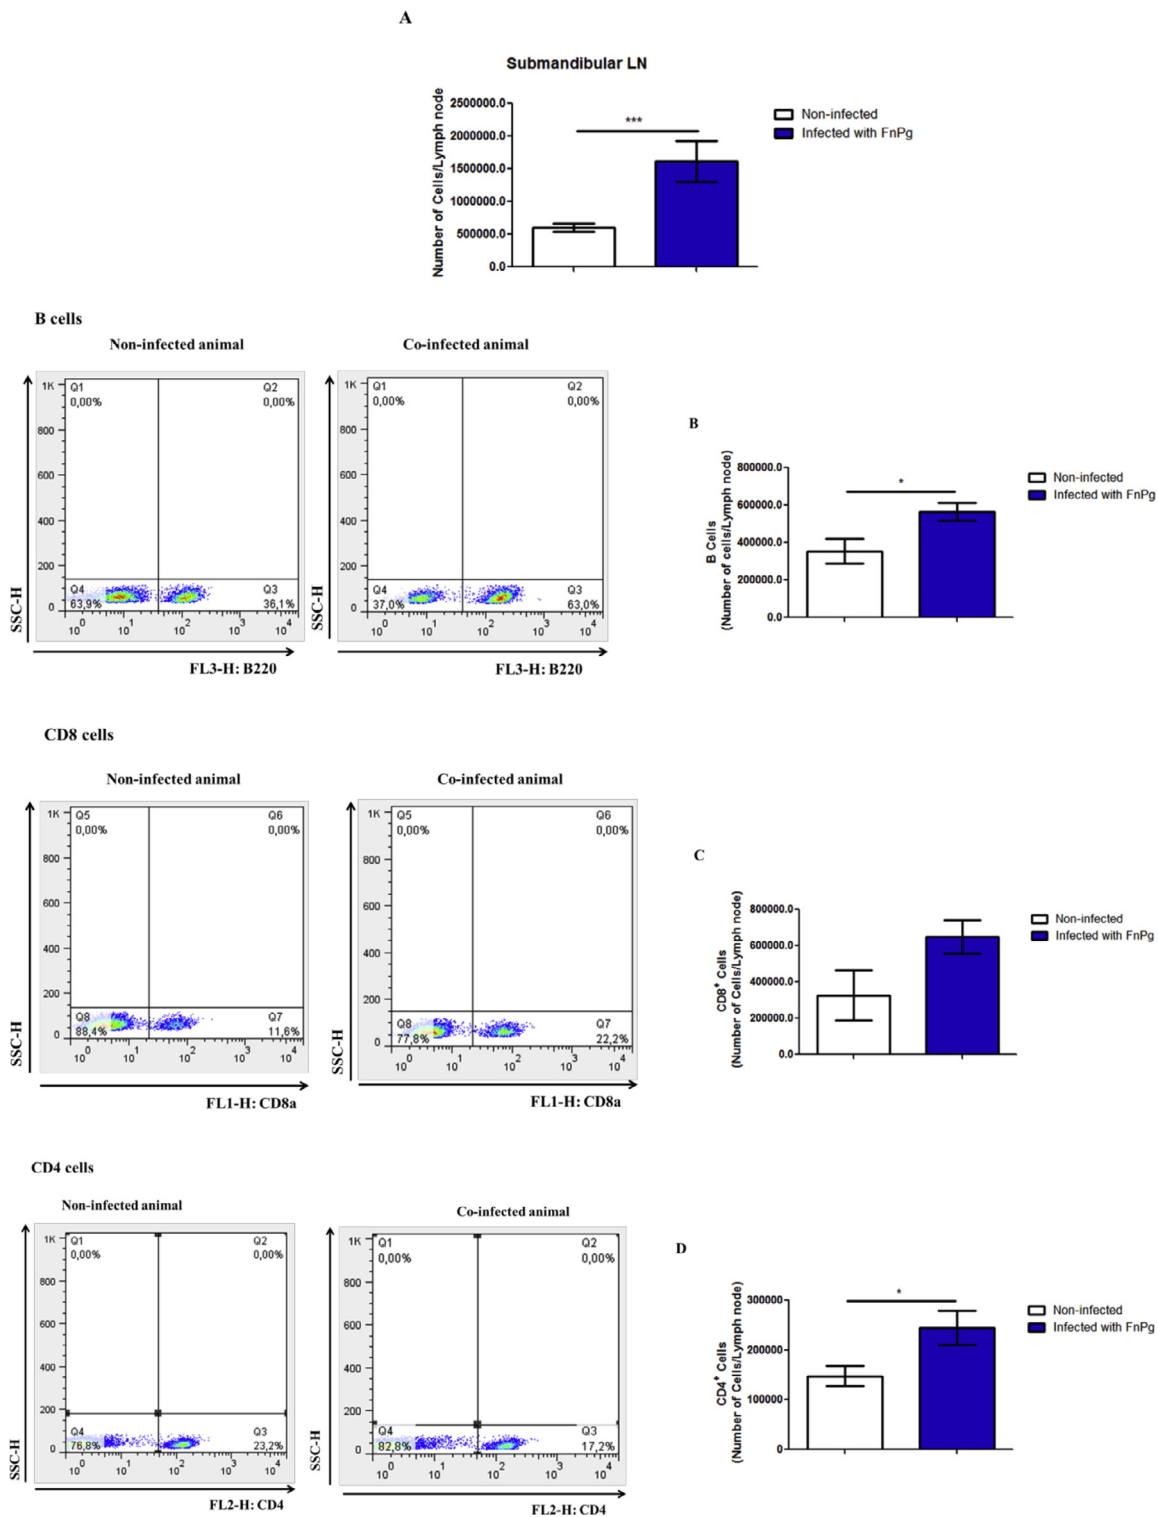

Fig. 5. Oral co-infection with periodontopathogens increases the number of B cells, CD4⁺ and CD8⁺ cells in the submandibular lymph node. (A) $n = 3$ per group; (B) $n = 6$ per group at 6 h of infection and $n = 3$ per group at 18 h of infection; (C) $n = 4$ per group; (D) $n = 5$ per group; (E) $n = 3$ per group; (F) $n = 6$ per group. * $p < 0.05$; ** $p < 0.005$; *** $p < 0.001$. ### $p < 0.001$ in relation to the other groups. ns: not significant. Pg: *Porphyromonas gingivalis*; Fn: *Fusobacterium nucleatum*.

with and without ATP treatment (Fig. 8C). However, when BMDMs from caspase-11 $^{-/-}$ that had been monoinfected with *F. nucleatum* or coinfected with both bacterial species were treated with ATP, there was a significant increase in IL-1 β secretion compared with secretion from caspase-11 $^{-/-}$ BMDMs monoinfected with *F. nucleatum* and coinfected without treatment with ATP, suggesting that *F. nucleatum* infection induces two IL-1 β secretion pathways: one is caspase-11-dependent and ATP-independent, and other is caspase-1-, ATP- and P2 \times 7-dependent. When examining caspase-11 $^{-/-}$ BMDMs monoinfected with *P. gingivalis* treated or not with ATP, there was no difference in IL-1 β levels compared with WT BMDMs monoinfected with *P. gingivalis* (see supplementary data Fig. S3B).

Since caspase-11 activation can lead to pyroptosis (Huang et al., 2019), we evaluated the cytotoxicity in caspase-11 $^{-/-}$ BMDMs infected with *F. nucleatum*, as we already observed that *F. nucleatum* infection induces cytotoxicity after 18 h of infection in BMDMs (Fig. 6F). We found that, in the absence of caspase-11 in BMDMs monoinfected with *F. nucleatum* or co-infected with both species for 18 h, LDH levels were lower compared with *F. nucleatum*-monoinfected or coinfected WT cells (Fig. 8D). We then examined whether caspase-11 was involved in control of infection by *P. gingivalis* and *F. nucleatum* in BMDMs. We ob-

served that the absence of caspase-11 led to an increase in *F. nucleatum* levels in co-infected caspase-11 $^{-/-}$ BMDMs at 18 h, compared with the co-infected WT cells (Fig. 8E), suggesting that caspase-11 is involved in the immune response during *F. nucleatum* infection. In caspase-11 $^{-/-}$ BMDMs infected with *P. gingivalis* for 18 h, there was no difference in the levels of *P. gingivalis*, compared with monoinfected WT BMDMs (see supplementary data Fig. S3C). Caspase-1/11 $^{-/-}$ BMDMs monoinfected with *P. gingivalis* for 18 h and treated with ATP showed significantly higher levels of *P. gingivalis* than monoinfected WT BMDMs treated with ATP (Fig. 8F).

Taken together, these results suggest that the immune response through the canonical pathway of NLRP3 inflammasome activation involving P2 \times 7 is predominant in the response against *P. gingivalis*. The activation of caspase-11 is required during *F. nucleatum* infection to induce NLRP3 inflammasome activation followed of IL-1 β secretion and cell death independently of caspase-1, and appears to be the predominant immune response against *F. nucleatum*.

To determine whether oral co-infection affected the expression of bone demineralization markers during one week of infection, we measured RANK and RANK-L expression in the gingival tissue of C57BL/6 (WT) mice. Interestingly, we found greater expression of bone deminer-

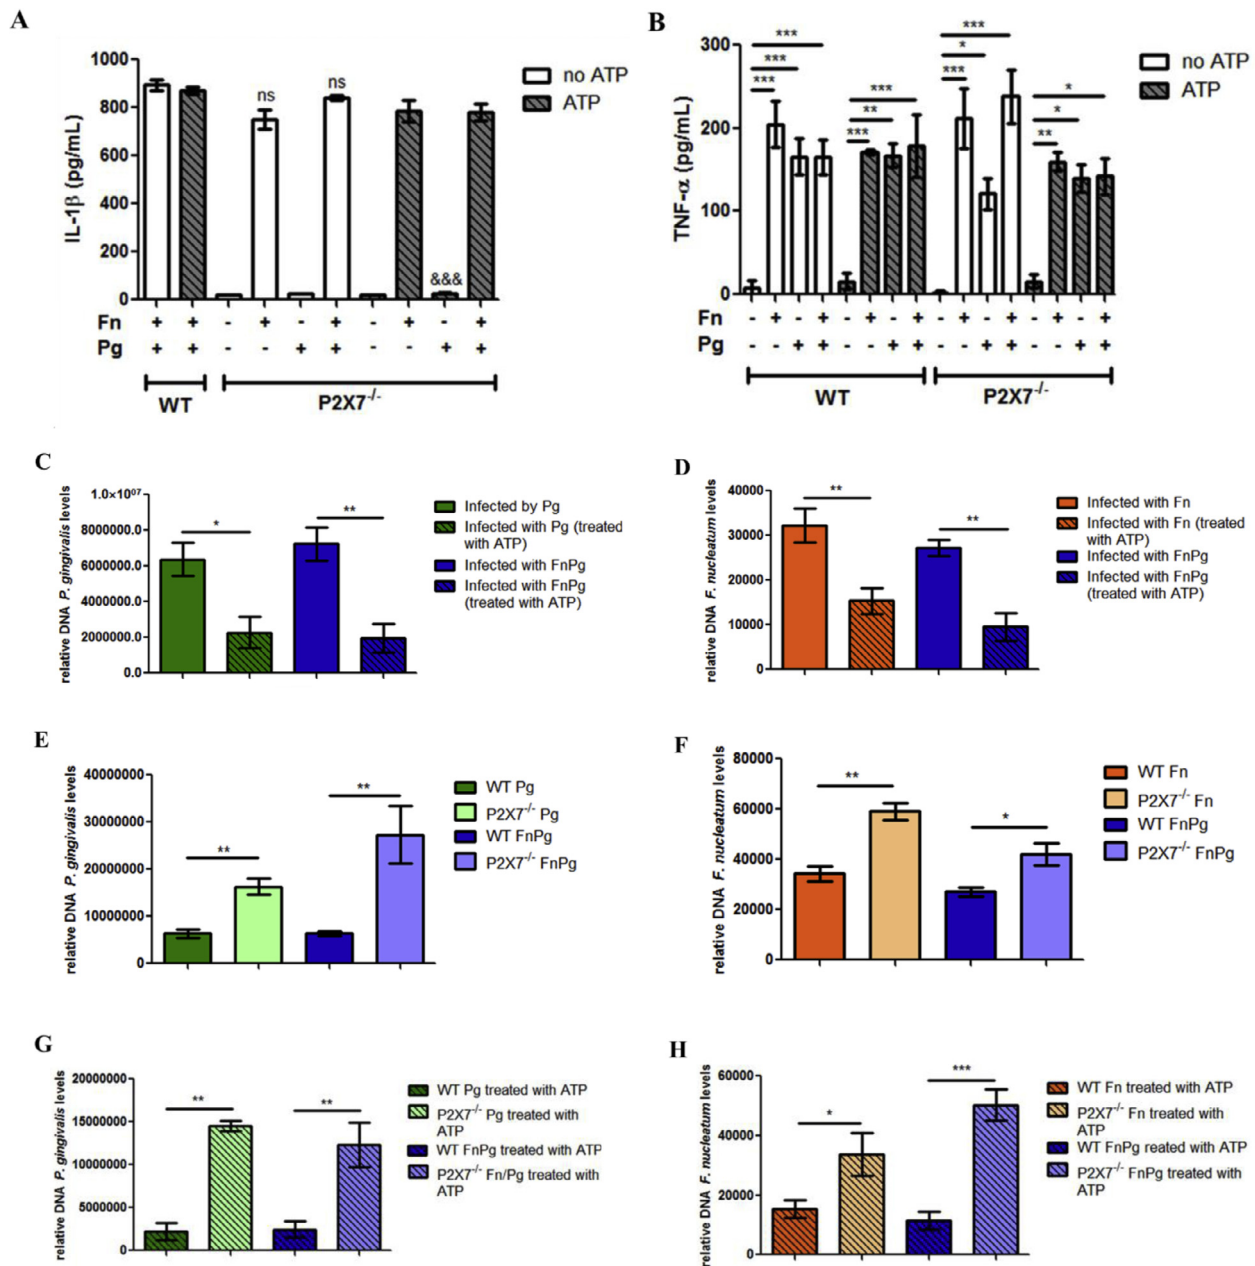

Fig. 7. P2 \times 7 controls the infection by *P. gingivalis* and *F. nucleatum* in murine macrophages. (A) Levels of IL-1 β and (B) levels of TNF- α in the supernatants of BMDMs of C57Bl/6 (WT) and P2 \times 7^{-/-} animals after 18 h of *in vitro* infection with *P. gingivalis* (ATCC 33,277) (Pg) (MOI 100) and/or *F. nucleatum* (ATCC 25,586) (Fn) (MOI 20) treated or not with 3 mM ATP (30 min before completing 18 h of infection). (C) and (D) Relative amount of Pg DNA and Fn DNA, respectively, using real-time PCR in BMDMs from C57Bl/6 (WT) animals after 18 h of *in vitro* infection by Pg (MOI 100) and/or Fn (MOI 20). (G) and (H) Amount of Pg DNA and Fn DNA, respectively, using real-time PCR in BMDMs from C57Bl/6 (WT) and P2 \times 7^{-/-} animals after 18 h of *in vitro* infection by Pg (MOI 100) and/or Fn (MOI 20) treated or not with 3 mM ATP (in the last 30 min of the total 6 h of infection). The data represent the mean \pm SEM and were analyzed using one-way ANOVA, followed by the Tukey test. (A) and (B) $n = 3$ per group; (C), (D), (E) and (F) $n = 4$ per group; (G) $n = 3$ per group; (H) $n = 4$ per group. * $p < 0.05$; ** $p < 0.005$; *** $p < 0.001$. (A) *** $p < 0.001$; &&& $p < 0.001$ compared to the WT cells infected with Pg and treated with ATP (Fig. 6A). ns: not significant compared with their respective (WT) mono and co-infected controls, without ATP treatment (Fig. 6B). Pg: *Porphyromonas gingivalis*; Fn: *Fusobacterium nucleatum*.

alization markers, RANK and RANKL mRNA in infected (Fig. 9A and B), than in uninfected animals. Since the cytokine IL-1 β contributes to alveolar bone demineralization (Chen et al., 2014; Huynh et al., 2017), we then examined the effect of the P2 \times 7 receptor on bone demineralization markers. Interestingly, we observed that, in the gingival tissue of P2 \times 7^{-/-} animals, there were lower levels of RANK mRNA than in co-

infected WT animals (Fig. 9C), although the same result was not found for RANKL mRNA, which was similar in the gingival tissue of co-infected P2 \times 7^{-/-} and WT animals (Fig. 9D).

These data show that, during this period of coinfection, there was an increase in the expression of bone demineralization markers stimulated by coinfection.

4. Discussion

Many studies have shown the importance of IL-1, particularly IL-1 β , in the development of periodontal disease (Aral et al., 2020; Cheng et al., 2020). In an experimental model of periodontitis in the primate *Macaca fascicularis*, IL-1 and TNF antagonists reduced the recruitment of inflammatory cells and osteoclasts in the vicinity of the bone, and reduced bone loss, thereby demonstrating that these pro-inflammatory cytokines are important for the development of periodontitis (Assuma et al., 1998). In our study, we found that coinfection with *P. gingivalis* and *F. nucleatum* in mice increased expression of pro-inflammatory cytokines IL-1 β and TNF- α in gingival tissue and increased protein levels of IL-1 β in the mandibles of infected mice. Our study is the first to combine both animal and cell culture to describe the molecules involved in inflammasome ac-

tivation during co-infection of *P. gingivalis* and *F. nucleatum*. This model more closely represents the polymicrobial etiology of periodontitis than most previous studies performed using mono-infections.

Our group has investigated the role of the P2 \times 7 receptor during host immune responses against intracellular pathogens (Morandini et al., 2014; Ramos-Junior et al., 2015; Almeida-da-Silva et al., 2019; Moreira-Souza et al., 2017). The P2 \times 7 receptor induces intracellular microbicidal responses, including reactive oxygen species (ROS) production, lysosome-phagosome fusion and IL-1 β production (Moreira-Souza et al., 2017; Savio and Coutinho-Silva, 2019). Considering that extracellular ATP is a damage-associated molecular pattern (DAMP) that activates the purinergic P2 \times 7 receptor, we treated mono- and co-infected macrophages with ATP, and observed a reduction in both bacterial loads. In contrast, macrophages derived from P2 \times 7 $^{-/-}$ mice that were

Fig. 9. Oral co-infection increases expression of osteoclastogenic markers. (A) RANK mRNA and (B) RANKL mRNA, in the gingival tissue using real time PCR of C57BL/6 (WT) mice co-infected orally or not with 10^9 CFU of each bacterial species, *F. nucleatum* strain (ATCC 25,586) and *P. gingivalis* (ATCC 33,277). (C) Relative levels of RANK mRNA and (D) of RANKL are shown in the gingival tissue using real-time PCR from C57BL/6 (WT) and $P2 \times 7^{-/-}$ animals infected or not infected orally with 10^9 CFU of each strain *P. gingivalis* (ATCC 33,277) and *F. nucleatum* (ATCC 25,586). (C) WT FnPg = 10, $P2 \times 7^{-/-}$ FnPg = 8; (D) WT FnPg = 8, $P2 \times 7^{-/-}$ FnPg = 5. The data were analyzed using one-way ANOVA, followed by the Tukey test. * $p < 0.05$; *** $p < 0.005$; **** $p < 0.001$ Pg: *Porphyromonas gingivalis*; Fn: *Fusobacterium nucleatum*.

mono- or co-infected and treated with ATP showed no reduction in bacterial loads, thereby demonstrating that the $P2 \times 7$ receptor was involved in controlling both *P. gingivalis* and *F. nucleatum* load in murine BMDMs. During a mouse model of oral co-infection, we observed increased expression of $P2 \times 7$ in gingival tissues. This receptor was required for controlling the bacterial load of both *P. gingivalis* and *F. nucleatum* in gingival tissue. It was shown by our group that infection with *P. gingivalis* increased the expression of $P2 \times 7$ *in vitro* (Morandini et al., 2014) and *in vivo* (Ramos-Junior et al., 2015), and contributed to control of *P. gingivalis* infection *in vivo* (Almeida-da-Silva et al., 2019).

The cytokine IL-1 β is a key mediator of the host's response to infections (Eskan et al., 2008). In a study by Almeida-da-Silva et al. (2019), it was shown that IL-1 β leads to *P. gingivalis* elimination by autocrine IL-1 receptor activation *in vivo* and in THP-1 cells (Almeida-da-Silva et al., 2019). Secretion of the active form of IL-1 β is due to the activation of inflammatory caspases and this activation is regulated by the inflammasome (Gros Lambert and Py, 2018). The ATP- $P2 \times 7$ pathway is one of the most potent stimuli for NLRP3 inflammasome activation (Munoz-Planillo et al., 2013), which is followed by secretion of IL-1 β . We observed that $P2 \times 7$ was required for the expression and secretion of IL-1 β in the mandible of co-infected animals, suggesting that IL-1 β is involved in controlling the intracellular bacterial load. Our data support the notion that the $P2 \times 7$ receptor is an important modulator of intracellular oral pathogens (De Andrade et al., 2019; Almeida-da-Silva et al., 2016; Coutinho-Silva and Eduardo Baggio, 2021) such as *P. gingivalis* and *F. nucleatum*. Future studies will further evaluate the possible mechanism involved in $P2 \times 7$ -mediated elimination of oral bacteria.

Evaluation of the downstream pathways of NLRP3 activation via $P2 \times 7$ showed an increase in the mRNA expression of NLRP3, caspase-1 and caspase-11 in the gingival tissues of co-infected animals compared to controls. Bostanci et al. (2009) found increased expression of NLRP3 in the gingival tissue of patients with gingivitis compared with healthy individuals (Bostanci et al., 2009). Park et al. (2014) observed that the expression of NLRP3 and caspase-1 was increased in the gingival tissue of patients with periodontitis compared with healthy individuals

(Park et al., 2014). In our study, we observed *in vivo* that the absence of both caspase-1 and -11 led to increased bacterial loads of both *P. gingivalis* and *F. nucleatum* in the gingival tissue. When we verified the production of IL-1 β in the mandibles of caspase-1/11 $^{-/-}$ animals, IL-1 β levels were lower than those of the co-infected WT animals. However, caspase-1 and caspase-11 were dispensable for IL-1 β mRNA expression in the gingival tissue of mice infected with both bacterial species. Similarly, Almeida-da-Silva et al. (2019) found higher loads of *P. gingivalis* in exudates of caspase-1/11 $^{-/-}$ mice infected with *P. gingivalis* in an air pouch model, compared with infected WT animals (Almeida-da-Silva et al., 2019). Our findings and previous studies support the idea that inflammasome activation leading to IL-1 β secretion is an important host immune response against oral bacterial infections.

Infection by some Gram negative bacteria induces the expression of pro-caspase-11 mRNA, and caspase-11 detects and is activated intracellularly by LPS from these bacteria (Huang et al., 2019). Activated caspase-11 promotes the fusion between the phagosomes containing the pathogen and lysosomes, and inhibits replication of the pathogen in the intracellular environment (Akhter et al., 2012). We observed that caspase-11 controlled the load of *F. nucleatum* in the gingival tissue of co-infected animals and in co-infected murine macrophages.

Aachoui et al. (2013) demonstrated that caspase-11 protected animals from infection by the intracellular pathogens *Burkholderia thailandensis* and *B. pseudomallei* (Aachoui et al., 2013). Perlee et al. (2020) also noted that caspase-11 was important for the control of *Klebsiella pneumoniae* in the lungs, and resulted in the presence of IL-1 β in pulmonary homogenates (Perlee et al., 2020). Unlike our results for *F. nucleatum* infection, we found that caspase-11 did not affect the bacterial load of *P. gingivalis* in murine BMDMs (see supplementary data Fig. S3B and C). This is thus the first study to report the involvement of caspase-11 in a mono- and co-infection model *in vivo* and *in vitro* by *P. gingivalis* and *F. nucleatum*.

As previously observed, *P. gingivalis* infection of BMDMs or gingival epithelial cells (GECs) (Almeida-da-Silva et al., 2019; Yilmaz et al., 2010) on its own does not activate the NLRP3 inflammasome, but re-

quires an exogenous danger signal such as extracellular ATP to activate the inflammasome and induce IL-1 β secretion (Olsen and Yilmaz, 2016). Our data corroborate those of previous studies showing that murine BMDMs infected with *P. gingivalis* do not secrete IL-1 β unless these infected cells are also treated with ATP. In contrast, we found that, in murine BMDMs, *F. nucleatum* infection by itself was sufficient to induce secretion of IL-1 β , suggesting the non-canonical pathway of NLRP3 activation by caspase-11 for the secretion of IL-1 β . We previously showed that *F. nucleatum* infection by itself also induced IL-1 β secretion in GECs (Bui et al., 2016). When murine macrophages were infected with *F. nucleatum* and treated with ATP, the levels of IL-1 β increased further, suggesting that ATP had an additional effect on the activation of NLRP3 via the canonical inflammasome in *F. nucleatum*-infected cells. Corroborating our findings, Taxman et al. (2012) reported high levels of IL-1 β induced by *F. nucleatum* infection of murine BMDMs in the absence of ATP, and that ATP treatment potentiated IL-1 β secretion (Taxman et al., 2012). For IL-1 β secretion to occur, cell lysis is not necessary (Evavold et al., 2018). Together, our data and those of previous studies support the view that *P. gingivalis* and *F. nucleatum* induce inflammasome activation and IL-1 β secretion through different pathways.

Because we showed that there was no further increase in IL-1 β levels after 18 h of infection by *F. nucleatum* and ATP treatment, we then analyzed possible bacterial cytotoxic effects. We found that infection with either *F. nucleatum* or *P. gingivalis* was not cytotoxic after 6 h of infection; however, infection with only *F. nucleatum* was cytotoxic after 18 h of infection. Consistent with our results, Fleetwood et al. (2017) found that there was no LDH release from BMDMs infected with *P. gingivalis* for 24 h (Fleetwood et al., 2017); and similar results were obtained by Jung et al. (2015), who studied *P. gingivalis* infection in THP-1 cells (Jung et al., 2015). Our data are consistent with the view that *P. gingivalis* can modulate host biology in order to promote its own survival and establish persistent infections (Yao et al., 2010; Roberts et al., 2017).

In our study, we found that IL-1 β secretion induced by *F. nucleatum* in murine BMDMs did not depend on pannexin-1, a non-selective cell plasma membrane channel (Adamson and Leitinger, 2014; Pelegrin and Surprenant, 2007). This channel is highly expressed in human and murine macrophages, is associated with the ligation of P2 \times 7, and is involved in activation of caspase-1 with subsequent release of IL-1 β (Pelegrin and Surprenant, 2006). However, pannexin-1 mediates some IL-1 β release after non-canonical activation of NLRP3 via caspase-11, independently of P2 \times 7 (Lamkanfi and Dixit, 2014; De And Martinon, 2015).

We observed that P2 \times 7 was necessary for ATP-induced IL-1 β secretion in *P. gingivalis*-infected BMDMs for 18 h, as we previously reported (Morandini et al., 2014; Ramos-Junior et al., 2015; Almeida-da-Silva et al., 2019). However, *F. nucleatum* infection resulted in IL-1 β secretion independently of ATP treatment in 18 h of infection. Moreover, we observed that, at 18 h of infection, *F. nucleatum* is cytotoxic. When evaluating the downstream pathway of NLRP3 activation via P2 \times 7 *in vitro*, we found that IL-1 β levels were lower in caspase-1/11 $^{-/-}$ BMDMs after single-species and dual-species infection by *F. nucleatum* and *P. gingivalis*, regardless of ATP treatment. Ramos-Junior et al. (2015) found that the absence of both caspases 1 and 11 did not affect the expression of IL-1 β in BMDMs infected with *P. gingivalis* (Ramos-Junior et al., 2015).

Caspase-11 promotes IL-1 β secretion via the NLRP3 inflammasome (Kayagaki et al., 2011; Rathinam et al., 2012). In our study, we found that caspase-11 was important for the secretion of IL-1 β in murine BMDMs induced by *F. nucleatum* infection, without treatment with ATP, while caspase-11 did not affect the levels of IL-1 β induced by *P. gingivalis*. Similar to our findings, Kayagaki et al. (2011) found that LPS-primed caspase-11 $^{-/-}$ BMDMs, when infected with *C. difficile* toxin B (CTB) or *E. coli* or *C. rodentium* or *V. cholerae*, failed to secrete IL-1 β (Kayagaki et al., 2011). In our mouse co-infection model, the absence of caspase-11 did not influence the secretion of IL-1 β in the animals' mandibles, suggesting activation of the inflammasome NLRP3 via the

canonical inflammasome. Similar results were found using co-infected murine macrophages treated with ATP. Casson et al. (2013) found that *Yersinia pseudotuberculosis* also depends on caspase-11 for the secretion of IL-1 β and induction of cell death (Casson et al., 2013). Caspase-11 limits the intracellular replication of bacteria such as *S. typhimurium* and *Burkholderia species* in epithelial cells and macrophages (Stowe et al., 2015).

Caspase-11 directly induces pyroptosis independently of NLRP3 or caspase-1 (Kayagaki et al., 2011; Huang et al., 2019; Man et al., 2017). In our study, caspase-11 was also involved in the cytotoxicity induced by *F. nucleatum*. Caspase-11-dependent cell death induction by *F. nucleatum* also represents a way to control the bacterial load in infected cells. However, caspase-11 was not involved in *P. gingivalis* load control in murine BMDMs (see supplementary data Fig. S3B and C). Gram-negative bacteria such as *P. gingivalis* (Coats et al., 2009) and *Yersinia pestis* (Brodsky et al., 2010) have the ability to change the composition of lipid A from their LPS, thereby preventing the activation of caspase-11 and manipulating the host's immune response. This hypothesis may explain the inability of *P. gingivalis* to activate the inflammasome via caspase-11 as we previously discussed (De Andrade et al., 2019). Our study is the first to describe the role of the non-canonical inflammasome during *F. nucleatum*-induced IL-1 β secretion and control of bacterial load.

The inflammasome plays a critical role in periodontal disease, as NLRP3-deficient mice fail to develop the disease in mouse models of study (Yamaguchi et al., 2017), and polymorphisms leading to increased expression of NLRP3 and IL1B are linked to periodontitis susceptibility in humans (De Alencar et al., 2020). Characterization of the mechanisms of inflammasome activation during periodontitis should contribute to a better understanding of the pathophysiology of the disease. In fact, a number of studies suggested the use of NLRP3 pharmacological inhibitors for the treatment of various diseases including diabetes, arthritis and cardiovascular diseases (Marchetti, 2019; Van Hout et al., 2017; Zahid et al., 2019). Our study supports the notion that the NLRP3 inflammasome should be considered as a potential target for treatment and/or prevention of periodontitis.

T cells and B cells appear to be important sources of RANKL in periodontal disease (Kawai et al., 2006). When we examined the profile of inflammatory cells in the submandibular lymph nodes of animals coinfecting with *P. gingivalis* and *F. nucleatum*, we found an increase in the total number of cells in the submandibular lymph nodes. This enhancement was partially due to the increase in the number of B cells, CD8 $^{+}$ T cells and CD4 $^{+}$ T cells compared with uninfected animals.

The Th1 subset appears to be involved in stable injuries in periodontal disease. B cells were observed predominantly in the progression of periodontal lesions, along with profiles of Th2 cells (Gemmell and Seymour, 2004; Okui et al., 2014). However, further studies are needed to verify the involvement of each subset of T cells and also the presence of B cells in different periods of periodontal disease, since there is some disagreement among recent studies (Okui et al., 2014). Our results showed that, after one week of infection, it was already possible to see an increase in the number CD4 $^{+}$ T cells, responsible for stimulating the production of pro-inflammatory cytokines. Future studies should track the activation and migration of lymphocytes from regional lymph nodes to gingival tissues and correlate the presence of cells to specific immune responses.

Zitzmann et al. (2005) reported an increase of B cells instead of T cells in gingivitis lesions in an experimental model of gingivitis (Zitzmann et al., 2005). Mahanonda et al. (2016) found memory B cells in the gums of patients with gingivitis, suggesting previous activation by periodontal microorganisms (Mahanonda et al., 2016). In another study, B cells in response to a bacterium associated with periodontal disease *in vivo* led to upregulation of RANKL expression (Han et al., 2009). Gemmell et al. (2002) found that BALB/c mice co-infected with *F. nucleatum* and *P. gingivalis* displayed a higher percentage of cytokines from CD8 $^{+}$ T cells than from CD4 $^{+}$ T cells in the spleen (Gemmell et al., 2002).

The process of alveolar bone resorption in humans and animal models involves RANKL (receptor-activator of nuclear factor- κ B ligand), which binds to RANK (receptor activator of nuclear factor κ B) in osteoclast precursors, leading to differentiation into active cells that produce proteolytic enzymes that degrade bone (Chen et al., 2014; Hajishengallis and Korostoff, 2017). We found a slight significant increase in the expression of RANK and RANKL in the gingival tissue of co-infected animals. Molon et al. (2014) reported increased RANKL expression in C57BL/6 mice monoinfected with *P. gingivalis* and coinfecting with *F. nucleatum* in a gavage infection model (De Molon et al., 2014), while Lin et al. (2017) found that oral infection with *P. gingivalis* induced an increase in the area of bone resorption; they also observed increased levels of secreted RANKL (Lin et al., 2017).

Clinical data show that RANKL is enhanced in patients with chronic periodontitis and aggressive periodontitis, compared with healthy and gingivitis groups (Bostanci et al., 2007). Although we did not evaluate the secreted levels of RANK and RANKL, we found an inducing signal for the expression of these molecules during early stages of coinfection. The expression of these bone demineralization markers could increase even more during chronic stages of the co-infection. Whether the expression of these markers are further modulated or whether they are more prominent during co-infection, compared to mono-infection models (Almeida-da-Silva et al., 2019; Yilmaz et al., 2010), remains to be elucidated.

5. Conclusion

Our study provides evidence that the canonical $P2 \times 7$ -caspase-1 pathway is necessary for the secretion of IL-1 β induced by *P. gingivalis* in BMDMs and in mice, while $P2 \times 7$ ligation leads to control of bacterial load of *F. nucleatum* in BMDMs and in mice, possibly through other mechanisms. Caspase-11 is an essential effector for the non-canonical activation of the NLRP3 inflammasome induced by *F. nucleatum* infection, resulting in the secretion of IL-1 β in murine macrophages. Caspase-11 is also necessary for induction of cell death by *F. nucleatum* infection, independently of caspase-1. Thus, our study contributes to a better understanding of the host's immune response to coinfection with these periodontopathogenic bacteria. The immune responses and molecules evaluated in this study ($P2 \times 7$ receptor, caspase-1, caspase-11, NLRP3) may be important targets for future research into therapeutic strategies for treatment and prophylaxis of periodontal disease.

Authors' contributions

Kívia Queiroz de Andrade, Robson Coutinho-Silva and David M. Ojcius conceived the project, Kívia Queiroz de Andrade performed the experiments and made the analyses, reviewed the literature, wrote the first draft of the manuscript, and prepared the figures. Robson Coutinho-Silva and David M. Ojcius and Cássio Luiz Coutinho Almeida-da-Silva critically reviewed the paper and Robson Coutinho-Silva and David M. Ojcius supervised the project.

Ethical approval

Experimental protocol was approved by the Animal Use Ethics Committee (CEUA) of UFRJ, under protocol number 080/19.

Funding

The Brazilian funding agencies Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) (grant number 306,839/2019–9), Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES)–Finance Code 001, and Fundação de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ) (grant number E-26/202.774/2018) are greatly appreciated for their research grants and fellowships. This study was partially supported by funds provided by The Regents of the

University of California, Tobacco-Related Diseases Research Program, Grant Number T29FT0540 to CLCAS. The opinions, findings, and conclusions herein are those of the authors and not necessarily represent those of The Regents of the University of California or any of its programs.

Declaration of Competing Interest
