13

14   **ABSTRACT**

15   Metal organic framework (MOF) nanoparticles are recognized for their effective removal of metal ions from aqueous

16   systems. However, the application of nanoparticles in a powder form as synthesized is not practical and recovery is not

17   easy. We prepared a recyclable magnetic MOF nanoparticle phase and used a widely available waste biomass to generate

18   biochar to support magnetic nanoparticles applied in the treatment of aqueous antimony pollution. A mushroom waste

19   biochar was used to support a magnetic UIO-66-2COOH (denoted as BSMU). Adsorption of trivalent antimony (Sb (III))

20   onto the BSMU was evaluated. The results showed that optimum conditions for preparation of the BSMU were the mass

21   ratio of MMOF to biochar 4:1, the temperature 70 ^{0}C, the time 4 h, and the initiator 4 mM. Under such conditions, sorption

22   capacity reached 56.49 mg/g for treatment of Sb (III) solution at 100 mg/L and pH 9.1. Alkaline conditions (such as pH

23   9.1) are more favorable for adsorption than acidic conditions, and coexisting ions including NO_3^-, Cl^-, SO_4^{2-}, and PO_4^{3-} had

24   no significant negative effect in adsorption, and with the use of low dose, higher adsorption density achieved. The

25   adsorption followed a pseudo second order kinetics model and Freundlich isotherm model. It resulted in a higher enthalpy

26   changes (ΔH^{θ}) and activation energy (E_a) of 97.56 and 8.772 kJ/mol, respectively, and enhanced the rate pf random contact

27   between antimony and the BSMU, as indicated by a higher entropy change (ΔS^{θ}) up to 360 J/mol·K. As a result, it readily

28   absorbs antimony. These adsorption properties identified in this study would provide a valuable insights into the application

29   of nanoparticles loaded biochar from abundant biomass in environmental remediation.

43

44   **1 INTRODUCTION**

45 Antimony as a hazardous toxic element and a threat to human health, causes disease such as high blood cholesterol and

46 low blood sugar (Hatefi R., 2013). It has been shown that trivalent antimony (Sb (III)) is more toxic up to ten times than

47 the pentavalent antimony (Sb (V)) (Yao et al., 2020). All over the world, the drinking water standard for antimony is low

48 with world health organization (WHO) setting the regulation standard for antimony in drinking water as 20.0 μg/L (WHO,

49 2011) and in the United States, antimony in drinking water shall not exceed 6.0 μg/L (United States EPA, 2018). In the

50 European Union, drinking water quality guidance value is 5.0 μg/L (Brenner et al., 2012); the standard for drinking water

51 quality issued by China in 2006 limits the concentration of antimony in drinking water to less than 5.0 μg/L (Xiong et al.,

52 2020). The environmental background value for antimony in natural water is very low. The average antimony concentration

53 in world rivers has been reported 1 μg/L (Wang et al., 2011). In some regions, surface water contains a higher background

54 value, as reported median 2.1 μg/L, compared to the median of 0.6 μg/L in groundwater (Alderton D., 2014). Where mining

55 activities exist, localized antimony-contaminated water is produced with antimony concentration is up to 53.6 ± 46.7 μg/L

56 (Fu et al., 2010), and has been reported to reach 9,300 μg/L (Hiller et al., 2012) in groundwater and 239 mg/L (Ritchie et

57 al., 2013) in rivers draining mining areas, with impacts on basin sediments also severe, with antimony concentrations up

58 to 39.0 mg/kg (B. Gao et al., 2012) at a significant distance away from primary sources. Therefore, finding a cost-effective

59 technology for remediation of antimony pollution across diverse geographical locations is still a requirement to move

60 towards zero pollution from current and past industrial activities.

61

62 Adsorption is the most commonly used method for treatment of hazardous substances (Huong et al., 2020; Lin et al., 2020;

63 Guila-Almanza et al., 2021). Many solid phases have been assessed for their effectiveness in treating Sb III contamination

64 and nanoparticles, in particular metal organic frameworks (MOF) nanoparticles show considerable promise. These are

65 porous materials, with an adjustable pore structure, rich functional groups (Seoane et al., 2016; Fan et al., 2018; Chai et al.,

3

66   2021; Mubashir et al., 2021), and have exhibited a good sorption properties for many metal ions, such as Cr, Cu, Pd, and

67   Sb (Vieth and Janiak, 2010), and can reach 99% removal efficiencies for metal ions including Cd^{2+}, Cr^{3+}, Pb^{2+} and Hg^{2+}.

68   However, nanoparticles are prone to deterioration, agglomeration, oxidation and poor dispersion in liquids, thus causing a

69   decline in their reactivity due to the influence of external factors (S.S. Cameotra and Dhanjal, 2010). Furthermore, in their

70   synthesized powder form, application in practice is not convenient and considerable scientific research effort has been mde

71   to provide convenient support materials. For example, O'Neill et al. (O"Neill et al., 2010) prepared a microspheric

72   polyacrylamide as a support framework for MOF. The effectiveness of the supporting role of biochar as nanoparticles in

73   enhancing their stability and chemical function has been demonstrated successfully. For example, Fazal et al. (Fazal et al.,

74   2019) enhanced the removal efficacy of a dye solution by more than 99% using a biochar supported TiO_2, which enhanced

75   the individual performance of biochar and TiO_2 alone from 85.20% and 42.6%, respectively. In our earlier research on Sb

76   (III) sorption, we prepared a chitosan supported MOF (MIL-Fe) (Xiong et al., 2020), which has strong physical stability

77   and a good sorption capacity and uptake. However, further investigation is needed to enhance the effect at an appropriate

78   pH and study the inhibition of sorption from competing ionic, consequently we address the optimization of biochar to

79   support MOF nanoparticles.

80

81   Natural biomass resources or man-made products are abundant, and have been widely used or transformed into other

82   products to solve the problem of environmental protection (Leong et al., 2014; Wang et al., 2016; Chew et al., 2017;

83   Hernández-Cocoletzi et al., 2020; Nagarajan et al., 2020; Ssrab et al., 2020). Biochar is a porous carbon material which

84   can be generated from a range of organic materials such as animal bones, plant roots, sawdust and wheat straw (Sohi et al.,

85   2010). It is characterized by a high carbon content, porous nature, abundance of functional groups and low cost for

86   production. In China, numerous types of organic by-products generated during production of mushrooms are not reused,

87 and are often combusted. China is the world's largest producer of edible fungi and in 2015, the annual yield of edible fungi

88 was 34.761 million tons (Cao, 2019). By seeking alternative applications for the waste materials negative environmental

89 impacts from combustion can be avoided and other environmental problems can be addressed. As such, this study aimed

90 to develop MMOF nanoparticles supported by biochar for remediation of water pollution by antimony.

91

92 In this study, we used mushroom biochar to support magnetic MOF nanoparticles (denoted as MMOF) and prepared a

93 biochar supported magnetic UiO-66-2COOH (denoted as BSMU) composite material. The preparation and adsorption

94 characteristics of the BSMU for removal of Sb (III) were investigated, which included wider characterization of

95 functionality and structure to enhance the performance of magnetic MOF using biochar to adsorb antimony. Our

96 contribution being the development of a novel adsorbent and investigating the mechanism of antimony removal by a

97 mushroom biochar carrier of MOF nanoparticles.

98

99 **2 MATERIALS AND METHOD**

100 **2.1 Materials**

101 The chemicals used in this study included ferric chloride hexahydrate ($FeCl_3.6H_2O$) purchased from Taishan Chemical

102 Plant Co. (Taishan, China), ethylene glycol and N, N,-dimethyl formamide (DMF) from Guangdong Guanghua Polytron

103 Technologies Inc. (Shantou, China), tetraethyl orthosilicate (TEOS), zirconium tetrachloride ($ZrCl_4$), 1, 2, 4, 5-

104 benzenetetracarboxylic acid (BTEC) and 3-Methacryloxypropyltrimethoxysilane (MPS) from Aladdin (Shanghai, China).

105 Chemicals (chitosan, 2, 2-azobis [2-(2-imidazolin-2-yl) propane/dihydrochloride (VA-044)) were purchased from Macklin

106 Biochemical Company (Shanghai, China). Potassium antimony tartrate was purchased from Tianjin Fengchuan Chemical

107 Reagent Technologies Co., Ltd (Tianjin, China). Details of other chemicals were shown in Text S1. All solutions were

108 prepared with LBY-20 ultrapure water (Chongqing Owen Science and Technology Co., Ltd., China). The glassware and

109 other laboratory ware were acid-washed, rinsed thoroughly with water, and dried prior to use.

110

111 **2.2 Preparation of adsorbent**

112 The Fe_3O_4 nanoparticles (nano-Fe_3O_4) were prepared using a solvothermal reduction and magnetic MOF (UiO-66-2COOH)

113 was prepared by using the hydrothermal method following the process developed in our laboratory(Zhu et al., 2020).

114 Further information about the preparation of nano-Fe_3O_4 and magnetic MOF (denoted as MMOF) is provided in supporting

115 information (see Text S2 and Text S3). The biochar was prepared by a thermal pyrolysis reactor in the laboratory (Li et al.,

116 2019), and the raw material, mushroom by-products, was crushed before processing. A sample of 350 g of mushroom

117 biomass was added to the reactor and the temperature increased from room temperature to 100 $^{\circ}$C at a rate of 7 $^{\circ}$C/min and

118 maintained for 6-8 min. Subsequently, the temperature increased to 750 $^{\circ}$C and the reactor heating immediately stopped.

119 The sample was cooled to room temperature in the reactor, removed, pulverized by a roller ball mill, passed through a

120 vibrating screen, and the sample passing a 80-100 mesh was collected. The BSMU was synthesized in situ by mixing the

121 MMOF and the biochar in the presence of low concentration initiator 2, 2-azabis (2-imidazoline) dihydrochloride, and was

122 carried out in a constant temperature water bath under stirring at 400 rev/min. The product was washed three times with

123 ethanol and water and vacuum dried for 12 hours at 60 $^{\circ}$C, to produce the final bio-char supported MMOF for

124 characterization.

125

126 **2.3 Sorption experiment**

127 The sorption experiment was as follows: a predetermined amount of antimony solution and adsorbent was added into 50

128 ml vials containing antimony stock solution, ultrapure water and buffer solution. Each vial contained a total of 50 mL of

129   solution and was immediately capped before placing on a shaker platform at 150 rev/min for 24 h. Solution pH was adjusted

130   with 0.05 M NaOH and 0.05 M HCl, which was buffered at 4.0, 6.8 and 9.1 using 0.05 M and 0.025 M potassium hydrogen

131   phthalate buffer solution and 0.01 M borate buffer solution, respectively. Preliminary test showed no significant reaction

132   occurring between buffer solution and antimony. Finally, solid adsorbent was magnetically separated from the liquid and

133   filtered using a 0.45 μm membrane, analyzed for residual antimony using an AA-7000 atomic absorbance instrument

134   (Beijing East & West Analysis Instrument Co., Ltd, China) at an sorption wavelength of 217.6 nm (Fan, 2007). Sorption

135   efficiency was evaluated by measuring sorption capacity as a ratio of adsorbed antimony (mg) to added adsorbent (mg/g)

136   as well as removal efficiency (%) of adsorbed antimony (mg/L) to initial antimony (mg/L).

137

138   **2.4 Analysis method**

139   We used Fourier Transform Infrared Spectroscopy (FT-IR) recorded on a Nicolet iZ10 FT-IR Spectrophotometer (Thermo

140   Electron Co., USA) with potassium bromide (KBr) as the dispersant to examine possible chemical bonds in adsorbents and

141   scanning electron microscopy (SEM) images of the sample were obtained using a JEOL JSM-6380LV electron microscope.

142   Specific surface areas of samples were measured using nitrogen sorption isotherms through a standard Brunauer–Emmett–

143   Teller (BET) analysis (Tristar II 3020, Micromeritics Instrument Corporation, USA). X-ray photoelectron spectroscopy

144   (XPS) recorded on an ESCALAB 250 X-ray photoelectron spectrometer (Thermo-Scientific Co., Waltham, MA, USA) was

145   used to analyze the elemental species distribution. The X-ray diffraction (XRD) patterns of the samples were characterized

146   on Rigaku Ultimate IV D/max-r A X-ray diffractometer, which was operated at 40 kV and 40 mA with Cu Ka radiation.

147   Transmission electron microscope (TEM) images of the sample were obtained using 200 KeV JEM-2100F electron

148   microscope instrument (JEOL, Japan). Specific surface areas of samples were measured using nitrogen sorption isotherms

149   through a standard Brunauer–Emmett–Teller (BET) analysis (Tristar II 3020, Micromeritics Instrument Corporation, USA).

150

151 Sorption data was fitted by pseudo-first order kinetics model (see Eq. (1)) and Pseudo-second order kinetics model (see Eq.

152 (2)), which were expressed as follows (Xiong et al., 2020):

$$q_t = q_e(1 - \exp(-k_1 t)) \tag{1}$$

$$q_t = q_e - q_e / (k_2 q_e t + 1) \tag{2}$$

155 Where q_t (mg/g) is a sorption capacity corresponding to a specific reaction time (t, min); q_e (mg/g) is an equilibrium sorption

156 capacity; k_1 (min^{-1}) is a pseudo first-order sorption rate constant; k_2 (g/(mg·min)) is a pseudo second-order sorption rate

157 constant.

158

159 Sorption rate-limiting step was analyzed using the intraparticle diffusion model as follows (Asadabadi, 2021):

$$q_t = \alpha_i + k_{3i} t^{0.5} \tag{3}$$

161 Where q_t is sorption capacity (mg/g) corresponding to time (t, min); α_i is constant of intraparticle diffusion model; k_{3i} is

162 sorption rate constant, mg/g·min$^{-0.5}$.

163

164 Two isothermal sorption models were investigated. Langmuir model is applicable to monolayer sorption (Pehlivan and

165 Cetin, 2009), assuming that maximum ion exchange is determined by saturation of solute molecules in monolayer on

166 adsorbent surface but no energy conversion occur, which is expressed using following equation (Afifi et al., 2016):

$$\frac{C_e}{q_e} = \frac{1}{q_{max} K_L} + \frac{C_e}{q_{max}} \tag{4}$$

168 Where q_e (mg/g) is sorption capacity; q_{max} (mg/g) is the maximum sorption capacity; K_L is Langmuir equilibrium constant;

169 C_e (mg/L) is equilibrium pollutant concentration.

171 The Freundlich isotherm model assumes that sorption occurs on heterogeneous sites on a multi-layer surface (Xu et al.,

172 2011; Tan et al., 2012). Given a multi-phase sorption surface or active site, it is suitable for single-layer (chemical) or multi-

173 layer (physical) sorption, which is expressed using following equation (Afifi et al., 2016):

$$\ln q_e = \ln K_F + \frac{\ln C_e}{n}$$

174 (5)

175 Where q_e (mg/g) is sorption capacity; C_e (mg/L) is equilibrium pollutant concentration; K_F and $1/n$ are constants. K_F id

176 related to sorption capacity. The larger K_F, the more sorption capacity it is. $1/n$ expresses a strength of bonding between

177 absorbent and pollutant. The values between 0.1 and 0.5 show that it is easy sorption. E_a is an activation energy calculated

178 as follows (Zhu et al., 2010):

$$\ln K_2 = \ln A - \frac{E_a}{RT}$$

179 (6)

180 Where K_2 (g·(mg·min)$^{-1}$) is sorption rate constant of Pseudo-second order kinetics; T (K) is sorption temperature; E_a

181 (kJ·mol^{-1}) is activation energy; A is preexponential factor; R is a gas constant, 8.314J·(mol·K)$^{-1}$.

182

183 Thermodynamic parameter values were calculated using the following equations (DuranoLu et al., 2012; Wen et al., 2018):

$$\Delta G^{\theta} = -RT \ln K_C$$

184 (7)

$$\ln K_C = \frac{\Delta S^{\theta}}{R} - \frac{\Delta H^{\theta}}{RT}$$

185 (8)

186 Where ΔH^{θ}, ΔS^{θ}, ΔG^{θ} and K_c are enthalpy changes, entropy changes, Gibbs free energy changes, and thermodynamic

187 equilibrium constant, respectively.

188

## 3 RESULTS AND DISCUSSION

3.1 Characterization of adsorbents

3.1.1 Results of SEM

Nanoparticles included nano-Fe_3O_4, MOFs and MMOF, of which surface morphology is shown in supporting information (see Fig. S1). The BET specific surface area of MOF was 41 m^2/g with pore volume of 0.03 m^3/g. A low BET specific surface area of MMOFs was 71 m^2/g with pore volume of 0.19 m^3/g. The BET specific surface area of the biochar was bound to increase from a smaller value around 11 m^2/g to larger quantity (e.g, 55 m^2/g for $R_{MMOF/Biochar}$=1:1) and the pore volume was 0.06 m^3/g. The surface morphology of nano-Fe_3O_4 nanoparticles took a spherical shape while MOFs showed an irregular shape (see Fig. S1a-b). The size of nano-Fe_3O_4 was 300-400 nm. As shown in the Fig. S1c, the surface morphology of MMOF had the shapes of MOFs and nano-Fe_3O_4, which showed the successful combination of MOFs and nano-Fe_3O_4. The MOF nanoparticles showed good stability, as shown by their shape, and did not change significantly at pH 4.0, 6.8, and 9.1 (see TEM results in supporting information in Fig. S2). The results are beneficial to the application of nanoparticles in different pH conditions. Fig. 1 shows the surface morphology of mushroom biochar and BSMU. It showed biochar as a flaky and folded surface with random sizes and shapes (see Fig. 1a). Fig. 1b-d shows the newly created biochar supported MMOF nanoparticles and shows different amounts of nanoparticles covered the surface of the biochar. The amount was dependent on $R_{MMOF/Biochar}$ value. With the increase of the $R_{MMOF/Biochar}$ value, the amount of surface covered by nanoparticles increased. For example, a lower amount was found at $R_{MMOF/Biochar}$ 1:4 as shown in Fig. 1b. Fig. 1c shows a medium amount at $R_{MMOF/Biochar}$ 1:1 and Fig. 1d shows a further increase at $R_{MMOF/Biochar}$ 4:1. This shows the appearance of the BSMU controlled by the $R_{MMOF/Biochar}$ within a constant mass.
208

209 **Fig. 1** SEM photographs (1000x magnification) for the virgin mushroom biochar (a), BSMU at $R_{MMOF/Biochar}$=1:4 (b),

210 $R_{MMOF/Biochar}$=1:1 (c), and $R_{MMOF/Biochar}$=4:1 (d). The results showed that on the surface of biochar, there were numerous of

211 nanoparticles and its amount increased with the increase of the mass ratio of $R_{MMOF/Biochar}$.

212

213 **3.1.2 Results of FT-IR spectra and magnetization curves**

214 Fourier transform infrared (FT-IR) scan of BSMU at 4000-400 cm^{-1} is shown in Fig. 2a-c. The peak characteristics

215 corresponding to possible groups were analyzed according to infrared spectrum data (Sigma-Aldrich). In MOF, because a

216 carboxyl group was introduced a medium O-H bending of carboxyl group appeared at 1384 cm^{-1}. The addition of an organic

217 ligand benzene ring provided the C = C stretching peak at 1637 cm^{-1}. The biochar had a medium absorption peak at 1639

218 cm^{-1} which is allocated to the N-H bending vibrations of amide group (Bar et al., 2014), and at 1064 cm^{-1} a C-N stretching

11

219   peak of the amine group. When coupled with the MMOF, the N-H bending peak shifted toward low frequency vibrations

220   at 1581 cm^{-1} and the C-N stretching vibration peak toward 1045 cm^{-1}. The peak at 1384 cm^{-1} of the BSMU resulted from

221   original O-H bending of carboxyl group. The reason for the peak change was possibly attributed to the N-H group of

222   biochar and carboxyl group, forming new group such as O = C–N.
223

224   **Fig. 2** FT-IR results of (a) MMOF, (b) Biochar and (c) BSMU, and the result of (d) magnetization curves

225   The BSMU adsorbent can be recycled and its magnetic characteristics were identified by magnetization curves as shown

226   in Fig. 2d but they behaved differently before and after adsorption. The results showed that they were significantly affected

227   by solution pH. The original magnetization intensity of the BSMU was 36.25 emu/g. After adsorption reaction at pH 4.0,

228   the magnetization intensity was reduced to 26.06 emu/g, which was closer to the 26.46 emu/g at pH 6.8. At alkaline

229   condition (pH 9.1) there was less of a reduction to a value 31.96 emu/g.

230

231   **3.1.3 Results of XRD**

232   The phase composition of the synthesized biochar, nano-Fe_3O_4, MOFs and the BSMU was confirmed with XRD analysis.

233   Fig. 3 shows the results of their patterns. As seen from the patter of biochar shown in the Fig. 3a, the peaks at 20-30 ^{o} are

234   attributed to (0 0 2) of amorphous carbon (Perez and Dumont, 2020). Also, a broad hump at 2θ = 40–50° suggest the

235 presence of an amorphous carbon structure (Hao et al., 2021). The peaks at 2θ = 18 °, 30 °, 35 °, 43 °, 53 °, 57 °and 62 °

236 are attributed to (111, 220, 311, 400, 422, 511 and 440) of Fe_3O_4, which are very well matched with the standard peaks

237 ((PDF 99–0073). As seen from Fig. 3b, the MOF had the peaks found at 2θ=7 ° (111), 8° (002), 12° (022), 14° (113), 17°

238 (004), 22° (115), 25° (224), 33° (137) are attributed to the UIO-66 (Xie and Wan, 2019). The patterns were consistent with

239 the report in previous literature (Zhao et al., 2016; Yang et al., 2019). The broadening of the characteristic peaks at 2θ=7°-

240 9° showed the lower relative crystallinity. The BSMU had different XRD pattern from individual component at 2θ=10°-

241 40° showing two broadening peaks which would be attributed to interaction active of components.
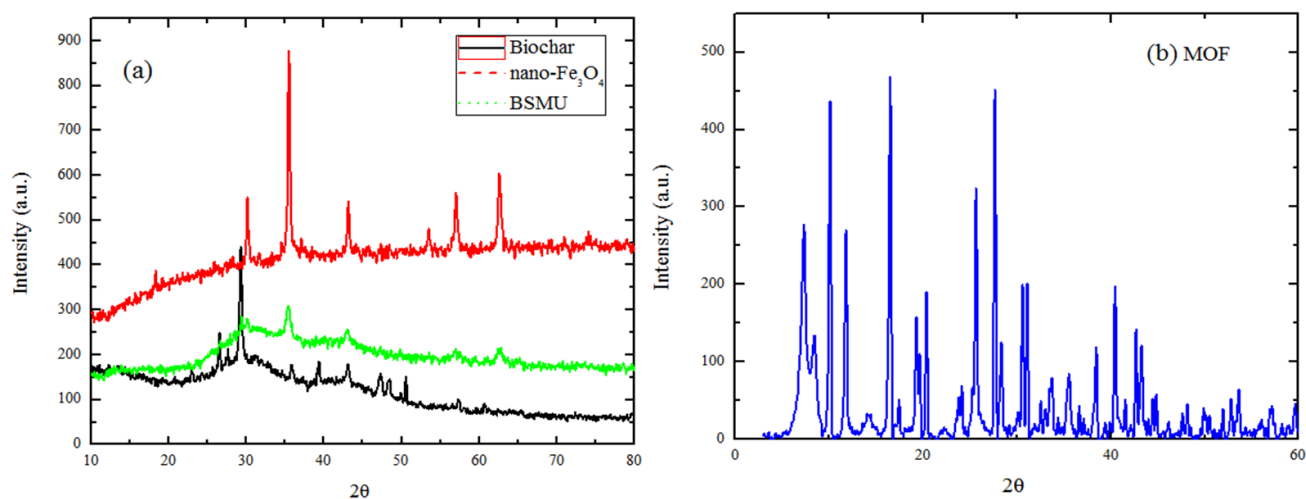

243 **Fig.** 3 XRD results of (a) nano-Fe_3O_4, biochar and BSMU, and (b) (MOF)

244 **3.2 Effect of synthetic factors**

245 Parameters affecting the preparation and the adsorption of antimony onto the BSMU, such as reaction temperature, reaction

246 time, initiator concentration, and mass ratio of MMOF nanoparticles to biochar (denoted as $R_{MMOF/Biochar}$) were investigated.

247 The influence of these parameters was evaluated by measuring sorption density (mg/g) and Sb (III) removal efficiency (%)

248 for treatment of Sb (III) solution at 20 mg/L. The results are shown in Fig. 4.

249

250 With stirring time 2 h, initiator concentration 2 mM /L, temperature 60 ºC, the effect of $R_{MMOF/Biochar}$ from 1:1 to 4:1 was

251 investigated. The result is shown in Fig. 4a. Low $R_{MMOF/Biochar}$ value decreased sorption density: at $R_{MMOF/Biochar}$ 1:4, the

252 sorption density was the lowest; at $R_{MMOF/Biochar}$ 4:1, it reached the maximum removal efficiency and sorption capacity, 91 %

253 and 9.1 mg/g, respectively. Obviously, the increased MMOF could increase the adsorption efficiency. However, to simply

254 use more MMOF would result in a higher overall cost in application, thus in this study, we selected the ratio

255 ($R_{MMOF/Biochar}$=4:1) as the target parameter.

256

257 For a chemical reaction, the temperature and reaction time are all important factors to ensure a sufficient reaction. As

258 illustrated in Fig. 4b-c, At $R_{MMOF/Biochar}$ 4:1, in the range of 30 °C to 80 °C, an appropriate temperature was needed to reach

259 good sorption: Low temperature such as 30 °C was not beneficial to sorption possibly due to the insufficient reaction,

260 resulting in an 84% removal efficiency; Increasing temperature to 70 °C, the removal efficiency was up to 92% and sorption

261 capacity to 9.3 mg/g but a further increase did not result in a better sorption effect. At temperature 70 °C and $R_{MMOF/Biochar}$

262 4:1, the reaction time was evaluated over a 0.5 h to 8 h period. With the increase of reaction time from 0.5 h to 2.5 h, the

263 removal efficiency increased and the sorption capacity was up to 9.2 mg/g at 2.5 h, but over 2.5 h, reaction time had no

264 significant influence in the sorption. Therefore, temperature 70 °C and reaction time 2.5 h were selected as the optimum

265 conditions for preparation of the BSMU.

266

267 Initiator is often added to the system to prepare MOF or MOF nanoparticles loaded organic monomer in order to initiate

268 copolymerization, possibly enhancing stabilization of the nanoparticles (Bo Wang, 2016; Yunchun Liu, 2018; Linbing Sun,

269 2019; Zhenyu Lou, 2021). As seen from our investigation, initiator had a good effect on the stabilization of the MMOF

270 loaded biochar by examining its appearance and adsorption performance. As shown in the photo of Fig. S3 in the supporting

271 information without the initiator, the adsorbent is a heterogeneous mixture. The initiator enhanced the dispersion and

stability of the nanoparticles on the biochar and resulted in good sorption performance. In detail, the effect of initiator

concentration in the range of 0 to 8 mM on sorption was investigated at $R_{MMOF/Biochar}$ 4:1, temperature 70 $^{\circ}$C, reaction time

2.5 h. The result is shown in Fig. 4d. Obviously, it had a higher sorption density in the presence of initiator and at 4 mM

the sorption capacity achieved the maximum. With the increase of the initiator concentration up to 4 mM, the removal

efficiency increased to the maximum value, 93%. Further increasing initiator concentration, no notable enhancement

occurred and at 8 mM there was a slight decrease. Therefore, we selected 4 mM as an optimum initiator concentration.
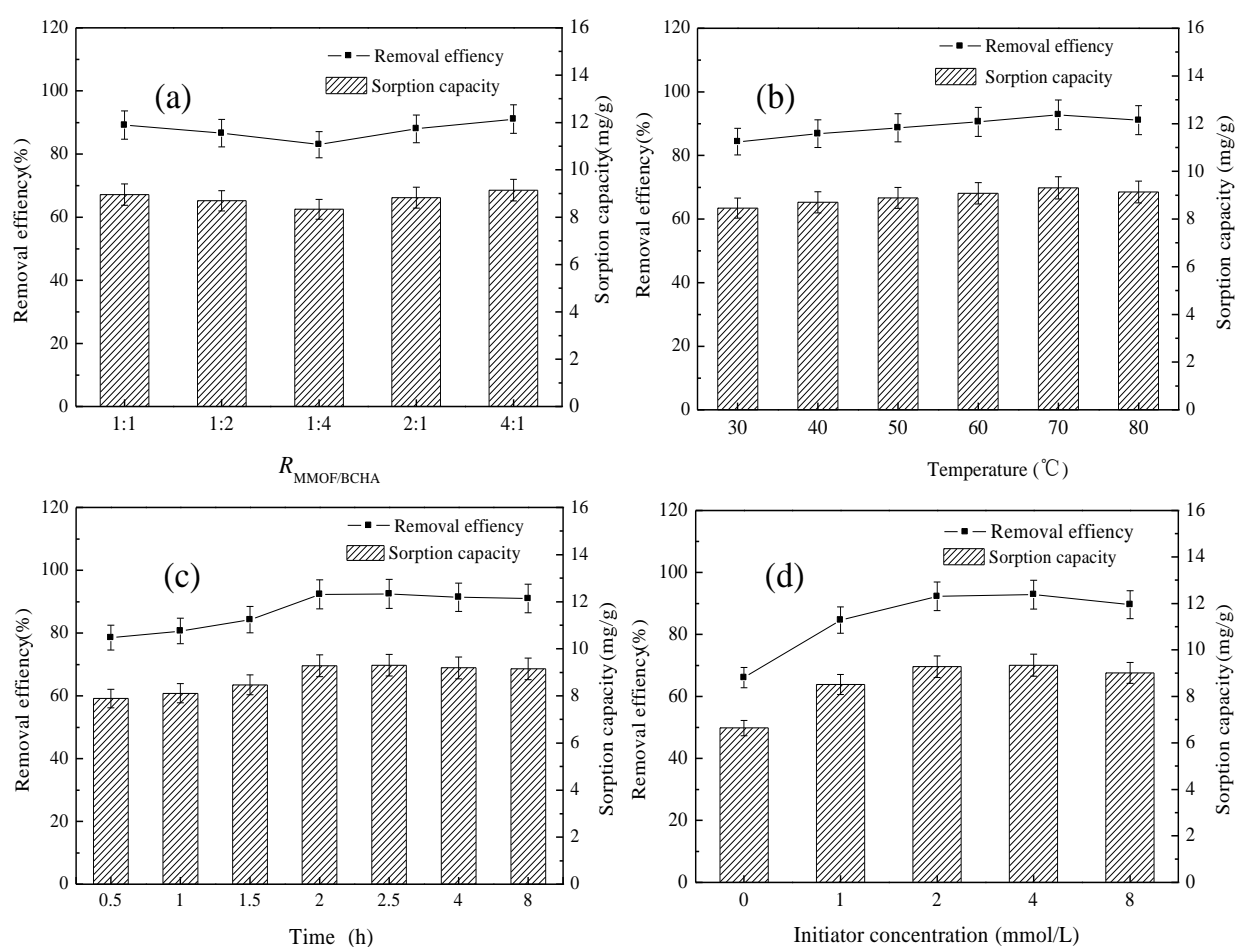

Fig. 4 Effect of preparation conditions on sorption density: (a) mass ratio of $R_{MMOF/Biochar}$, (b) temperature, (c) time, and (d)

initiator concentration. The results showed that a wider range of synthetic conditions of biochar supported MMOF could

be applied.

3.3 Effect of adsorbent dosage at different pH

The BSMU had a different sorption effect for antimony removal under a varying pH, which differs from sorption of antimony by other adsorbents. It has been shown previously that Sb (III) sorption is relatively insensitive to pH and is generally best in an acid environment. However, there are circumstances where suitable adsorbents can be found for acid, neutral and alkaline pH. For example, ferric hydroxide had a better sorption effect in an acidic environment (He et al., 2015). The Zirconium oxide (ZrO_2)-carbon nanofibers have best performance at pH 7.0 (Luo et al., 2015). The MIL-Fe and chitosan supported MIL-Fe metal organic materials perform best in alkaline conditions (Cheng et al., 2020; Xiong et al., 2020). However, Zirconium-based metal−organic frameworks (NU-1000) and goethite show have a negligible influence of pH on Sb (III) sorption over the range pH 2 to 11 (Li et al., 2017). Therefore, pH effect is dependent on type of adsorbent, and determining the response for the new material synthesized here is critical. It is suggested that the effect of pH is dominated by the antimony species and the electro kinetic properties of adsorbent (Ungureanu et al., 2015). The pH effect tested in this study was investigated at Sb (III) concentration 20 mg/L, pH (4.0, 6.8 and 9.1), the BSMU dose between 20 mg to 100 mg, temperature 303 K, rapid stirring 150 rev/min and sorption time of 24 h. The results are shown in Fig. 5. As illustrated in Fig. 5a-b, sorption density descended in the order pH: 9.1 > 6.8 > 4.0 for all adsorbent doses. As seen from the investigation, an alkaline condition was beneficial to sorption and an acidic condition had an inhibition effect. As expected, with the increase of the adsorbent dose, the removal efficiency of antimony increased and a low adsorbent dose resulted in a higher sorption density. The decay of adsorption capacity (q_D) with adsorbent dosage could be expressed using an exponential decay model as follows:

$$q_D = a e^{-D/k} + b \qquad (9)$$

Where q_D is sorption capacity (mg/g) corresponding to a fixed adsorbent dosage; a is amplitude constant; D is adsorbent dosage; k is decay constant and b is offset value.

304

The parameters of exponential decay model are shown in Table S1. The fitting correlation coefficient (R^2) achieved 0.998,

0.986 and 0.986 at pH 4.0, 6.8 and 9.1, respectively. At pH 4.0, the decay constant was 57.984, which was larger than others

(41.974 for pH 6.8 and 42.156 for pH 9.1). It was not conductive to the adsorption under acid condition.
Fig. 5 Effect of the BSMU dosage and pH 4.0, 6.8, and 9.1 on (a) sorption removal efficiency and (b) sorption capacity.

Solid line is fitting line of exponential decay model.

311

A comparison in sorption performance of antimony among biochar, MMOF and BSMU was made at pH 9.1, a BSMU dose

of 1000 mg/L, stirring speed 150 rev/min, temperature 30 $^{\circ}$C, sorption time 24 h and Sb (III) concentration 20 mg/L. The

result is shown in supporting information (see Fig. S4). As illustrated in Fig. S4a, it showed that removal efficiency was

53% with biochar (sorption capacity=10.62 mg/g), 83% with MMOF (sorption capacity=16.63 mg/g), 92% with biochar

supported MMOF (sorption capacity=18.43 mg/g). This demonstrated that the biochar supported MMOF increased the

sorption performance of either MMOF or biochar alone. As previously indicated, the optimum proportion of components,

the $R_{MMOF/Biochar}$ of the BSMU was 4:1, which reduces the amount of MMOF and optimizes both sorption and synthesis

minimizing the MMOF needed with positive implications for reducing the costs of final application. The effect of sorption

time in the range of 0.5 h to 24 h on sorption density was investigated, using pH 4.0, 6.8 and 9.1, a BSMU dose of 1000

321　mg/L and stirring speed 150 rev/min, temperature 303 K. The result is shown in Fig. S4b, where sorption equilibrium time

322　was reached after only 4 h. After the sorption equilibrium, the sorption capacity did not change significantly, which

323　indicated that antimony could not be released to the aqueous environment again, demonstrating the stability of bound

324　antimony.

325

326　**3.4 Effect of antimony concentration**

327　The effect of three initial Sb (III) concentrations (10 mg/L, 30 mg/L and 50 mg/L) on sorption was investigated at pH 9.1,

328　the BSMU dose of 1000 mg/L and stirring speed 150 rev/min, temperature 303 K. The result is shown in Fig. S5a-b. As

329　expected, sorption increased with increasing antimony concentration and removal efficiency increased with sorption time.

330　For example, at antimony 50 mg/L, the sorption capacity was up to 33.9 mg/g, and greater than that at 30 mg/L and 10

331　mg/L. With the increase of the concentration of antimony, the sorption tended to be saturated thus increasing sorption

332　capacity. However, at higher concentrations the residual antimony was not removed and removal rate did not increase. At

333　any concentration, the variation of adsorption capacity with adsorption time followed pseudo second order kinetic model.

334　The details on the kinetics were discussed in the later section.

335

336　**3.5 Influence of coexisting ions**

337　The BSMU had a stronger resistance to the negative influence of co-existing anions. In general, the coexisting anions such

338　as NO_3^-, Cl^-, SO_4^{2-}, F^-, and PO_4^{3-}, do not often inhibit Sb (III) sorption, seen for example with Sb (III) sorption onto

339　bentonite (PO_4^{3-}, SO_4^{2-} and NO_3^-) (Xi et al., 2011), zirconium-based metal−organic frameworks (PO_4^{3-}, SO_4^{2-} F^-, and

340　NO_3^-) (Li et al., 2017) and a tannin based adsorbent (Cl^-, PO_4^{3-}, SO_4^{2-} and NO_3^-) (Hugo et al., 2018). However, in the

341　presence of iron-based materials, the influence of coexisting ions on Sb (III) sorption does occur. For example, the sorption

342 of Sb (III) by a Ce (III)-doped Fe_3O_4 magnetic particles, showed a minor influence from PO_4^{3-} while Cl^- and SO_4^{2-} enhanced

343 sorption effect (Qi et al., 2017). For an iron-based metal organic framework (Fe-MIL-88B), the PO_4^{3-} caused a 12 %

344 reduction in the removal of Sb (III)(Cheng et al., 2020). Furthermore, it was up to 30.43% for a chitosan supported Fe-MIL

345 metal organic frameworks (Xiong et al., 2020). In comparison, Sb(V) was affected significantly by competing anions,

346 especially PO_4^{3-}, reducing the efficiency of antimony removal (Xi et al., 2011; He et al., 2015). Although these iron-based

347 materials include both Fe (II) and Fe (III), it is difficult for the Sb (V) and Sb (III) to co-exist in the same system because

348 the presence of Fe (II) as a strong reducing agent preventing the oxidation of Sb (III) to Sb(V) and indirectly affecting

349 antimony sorption (Xiong et al., 2020). In this study, we examined the influence of coexisting anions on the sorption of Sb

350 (III) onto the BSMU. Our investigation was conducted at pH 9.1, a BSMU dose of 1000 mg/L and stirring speed 150

351 rev/min, temperature 303 K with coexisting ions including NO_3^-, Cl^-, SO_4^{2-}, and PO_4^{3-}. The ionic strength was in the range

352 0.01 M to 1.0 M. The result is shown in Fig. S6 which shows no significant ionic influence at all ionic strength. The PO_4^{3-}

353 had a relatively high negative influence compared to the other anions, followed by the SO_4^{2-}, but the degree of reduction

354 was not more than 5%. Therefore, the performance of BSMU was less influenced by coexisting ions, which has been

355 considered as an indicator of sorption influence by a specific binding or inner-sphere surface complex binding (Xi et al.,

356 2011).

357

358 **3.6 Sorption kinetics and isothermal analysis**

359 The sorption of antimony onto the BSMU followed the pseudo second-order kinetics rather than the pseudo first-order

360 kinetics as indicated by correlation coefficients (R^2). As illustrated in Fig. 6a-b and Table S2, good fit lines for pseudo

361 second-order kinetics at each antimony concentration yielded relatively high R^2 values up to over 0.98. Measured

362 equilibrium sorption capacity was in good agreement with calculated. On the contrary, poor fit to pseudo first-order kinetics

363 yielded R^2 values lower than 0.90 at each antimony concentration, which was significantly lower than the R^2 values derived

364 from the pseudo second-order kinetics model fit. This suggests that the sorption of antimony on the BSMU followed pseudo

365 second-order kinetics and antimony was absorbed onto the surface of the BSMU via chemical interaction.

366

367 The data for sorption of Sb (III) onto the BSMU was analysed using the Freundlich and Langmuir isotherm models at

368 temperatures from 297 K to 313 K, and degree of fit was assessed using the correlation coefficient. As shown in Fig. 6c-d

369 and Table S3, it showed that sorption data followed Freundlich isotherm model better as indicated by R^2 over 0.95 than

370 0.90 for Langmuir isotherm model, which suggested the sorption of antimony onto the BSMU was a multilayer sorption.

371 The Freundlich constant ($1/n$) is an indicator to determine whether it is favorable sorption (Zhao et al., 2010). The range

372 0.1 to 0.5 suggests a favorable sorption but a hard sorption when over 2.0 (Zhao et al., 2010). The $1/n$ constants for all

373 temperatures were all smaller than 0.5, indicating a favorable sorption and a high affinity between antimony and the BSMU.

374 The K_f was related to the sorption capacity (DuranoLu et al., 2012). With the increase of the temperature, the K_f increased,

375 showing the sorption was endothermic in nature. In comparison, the BSMU had the same sorption kinetics and isothermal

376 model as for the MMOF, which better followed pseudo second-order kinetics and the Freundlich sorption model (see Fig.

377 S7 and Table S4-5 in supporting information).

378
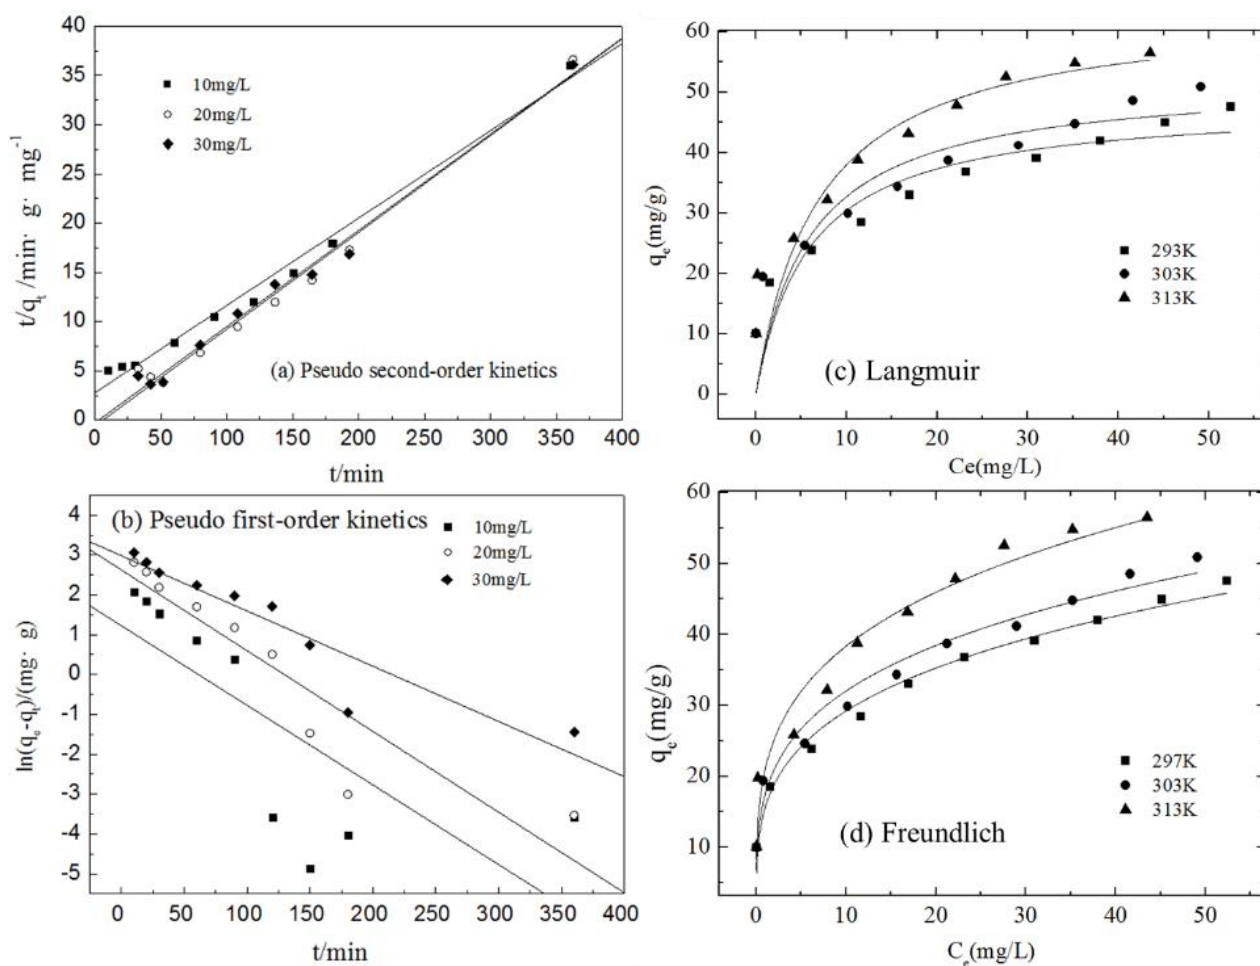

Fig. 6 Fit lines of sorption kinetics and isothermal models: (a) Pseudo second-order kinetics model, (b) Pseudo first-order

380   kinetics model, (c) Langmuir isothermal model, and (d) Freundlich isothermal model

381

382   The sorption of antimony onto the BSMU was more sensitive to the temperature and consumed more energy than the

383   adsorption with the MMOF. At temperatures 288 K to 313 K, sorption heat for antimony by the BSMU and the MMOF at

384   Sb(III) concentration 20 mg/L, solution pH=9.1, sorption time 24 h, was investigated. As seen from ΔG^{θ} values shown in

385   supporting information (see Table S6), the values are all negative, which suggested that the sorption with the BSMU and

386   the MMOF were both thermodynamically spontaneous. It also showed that ΔG^{θ} of the sorption with the BSMU was more

387   sensitive to the increase in temperature while for the MMOF it did not change significantly. The activation energy of

388   sorption with the BSMU and the MMOF was 8.772 kJ/mol and 5.024 kJ/mol, respectively. Activation energy is usually

389 used as one of the criteria to distinguish physical sorption and chemical sorption, with physical sorption being easy to

390 reverse and reaches equilibrium rapidly. Consequently the energy demand is very small, not more than 4.184 kJ/mol (Sag

391 and Kutsal, 2000) because the forces involved are weak such as Weak van der Waals forces (Duranoğlu et al., 2012).

392 Chemisorption has a non-activated and activated step for which the rate varies with temperature (Sag and Kutsal, 2000).

393 From the results of our investigation, the activated chemisorption needs more activation energy and it can be seen that the

394 energy required for the BSMU was higher than that needed for the MMOF, which was closer to the value for physical

395 sorption. Therefore, antimony sorption by the BSMU would be driven by chemisorption. In detail, the ΔH^{θ} of chemical

396 sorption is considered >29 kJ/mol and that of complexation is between 8 and 60 kJ/mol (Mungasavalli et al., 2007;

397 Duranoğlu et al., 2012). A higher ΔH^{θ}=97.56 kJ/mol for the BSMU, suggested the sorption of Sb (III) onto the BSMU

398 would be through a chemical sorption process. The ΔH^{θ}=21.44 kJ/mol for the MMOF indicated that the sorption would be

399 driven by complexation. They are positive values showing their sorption was endothermic in nature. The positive value of

400 the ΔS^{θ}=360 J/mol·K for the BSMU was three times larger than the ΔS^{θ}=113.72 J/mol·K for MMOF, implying the

401 contact randomness between antimony and the BSMU increased. Overall, the sorption of Sb (III) onto BSMU is

402 significantly different from onto the MMOF.

403

404 **3.7 Analysis of Reaction Mechanism**

405 Three steps could be identified from the overall sorption of antimony onto the BSMU, indicating that the sorption was

406 controlled by either surface or intraparticle diffusion (Duranoğlu et al., 2012). If the q_t and $t^{0.5}$ is a linear relationship

407 through zero, it suggests that the intraparticle diffusion is the sole rate-limiting step but the presence of changes in gradient

408 suggests the sorption process also includes a complex chemical reaction (Russo et al., 2020). As seen from Fig. 7a, three

409 stages are highlighted: a surface or film diffusion process (step 1), a gradual sorption (step 2) of intraparticle or pore

410   diffusion, and a final equilibrium (step 3) (Russo et al., 2020). Since it did not pass through the origin, the sorption of

411   antimony onto the BSMU was not only determined by a rate-limiting based intraparticle diffusion, but also by other

412   chemisorption processes. In comparison, the BSMU had the same sorption steps with the MMOF that the q_t and $t^{0.5}$ was a

413   linear relationship and fitted a three-stage process (see Fig. S8 in supporting information), showing the intraparticle

414   diffusion is not the only rate-limiting step to control the sorption of antimony onto MMOF.

415

416   The Sb(III) may exist in the form of uncharged and insoluble antimony hydroxide Sb(OH)$_3$ over a wide pH range (2-10.4)

417   in aqueous solutions (Ungureanu et al., 2015). Neutral charge Sb(OH)$_3$ inhibits electrostatic attraction, and new interaction

418   mechanisms are needed through a possible hydrogen bonding (Ungureanu et al., 2015; Xiong et al., 2020) or others such

419   as surface complexation (Vithanage et al., 2013). If the adsorbent was defined as $\equiv \mathrm{MeOH}$ and the metal Sb was denoted

420   as M, the properties of the surface of the adsorbent change with pH because of reaction $\equiv \mathrm{MeOH} + \mathrm{H}^+ \leftrightarrow \equiv \mathrm{MeOH}_2^+$ and

421   $\equiv \mathrm{MeOH} \leftrightarrow \equiv \mathrm{MeO}^- + \mathrm{H}^+$. Variation of initial solution pH in the range of 3 to 11 during sorption without buffering

422   was tested in this study with the BSMU dose of 1200 mg/L, stirring speed 150 rev/min, temperature 303 K and sorption

423   time 24 h. The result is shown in supporting information (see Fig. S9). As illustrated in the figure, it showed that an initial

424   pH value increased after sorption at pH 6 or less and increased when at a pH equal or greater than 6.0. This shows that after

425   addition of the BSMU, H$^+$ was consumed by reaction with the sorbent so that the pH increased

426   ($\equiv \mathrm{MeOH} + \mathrm{H}^+ \leftrightarrow \equiv \mathrm{MeOH}_2^+$ is the main reaction) but when the initial pH was lower than 6, further increasing the pH

427   value, the release of H$^+$ to solution decreased pH significantly ($\equiv \mathrm{MeOH} \leftrightarrow \equiv \mathrm{MeO}^- + \mathrm{H}^+$ is the main reaction process).

428   Finally, allowing an effective interaction between $\equiv \mathrm{MeO}^-$ and antimony thus enhancing the sorption efficiency.

429

430   The interaction occurring between oxygen and antimony in solution-surface interactions has been highlighted (Vithanage

431　et al., 2013; He et al., 2015; Li et al., 2017), and from analysis by FT-IR, X-ray photoelectron spectroscopy and Raman

432　spectroscopy, the main sorption sites are attributed to hydroxyl and carboxyl functional groups. For example, through

433　replacement of hydrogen, antimony could bound with oxygen of adsorbent (Vithanage et al., 2013). The FT-IR results of

434　BSMU before and after sorption are shown in Fig. 7b. There were some significant peaks at 3423 cm^{-1}, 2930 cm^{-1}, 1617

435　cm^{-1}, 1577 cm^{-1},1494 cm^{-1}, 1384 cm^{-1}, 1043 cm^{-1}, 873 cm^{-1}, and 624 cm^{-1}. After sorption, these characteristic peaks showed

436　significant changes: at 3423 cm^{-1} and 2930 cm^{-1}, corresponding to –NH and –OH (Zhang et al., 2011; Wang; et al., 2015),

437　respectively, they moved towards low frequency and exhibited wider peak at all pH. This suggested the H of hydroxyl

438　groups would be replaced by antimony species, –NH was protonated, $\equiv \mathbf{MeOH}_2^+$ was formed, all of which would the

439　reason for H^+ loss. The C-H and O-H at 1494 cm^{-1} and 1384 cm^{-1} (Sigma-Aldrich; Rodrigues et al., 2015), respectively,

440　increased at pH 4.0 while decreased at pH 6.8 and pH 9.1. Under alkali condition, carboxyl ionization could enhance the

441　link of negatively charged oxygen with antimony. It showed the peak at 599 cm^{-1} assigned to Fe−O vibration (Ting Wang,

442　2013; Wang; et al., 2015). After sorption, the peak moved toward low frequency to 593 cm^{-1} at pH 4.0, 595 cm^{-1} at pH 6.8,

443　595 cm^{-1} at pH 9.1. In addition, the Zr-O would also be a sorption sites as indicated by the XPS analysis (Li et al., 2017).

444

445　It was much effective for Sb (III) removal under an alkaline condition, which is inseparable from the binding of Sb and

446　oxygen. The XPS results of a high-resolution scan of the O 1s of BSMU oxygen, and the Sb 3d of BSMU and Sb (III)

447　reaction sample (denoted as BSMU-Sb) at pH 6.8 were used to provide insights to the adsorption mechanism. The results

448　are shown in Fig. 7c-e. As illustrated in Fig. 7c the O 1s XPS spectra for BSMU, has two significant peaks appearing at

449　around 531.7 and 530.3 electron volts (eV) which were fitted into three oxygen components including a lattice oxygen

450　bond at 530.28 eV (O_{latt}), carbonyl (C = O) group oxygen or absorbed oxygen at 531.49 eV (O_{adc}), and a hydroxyl group

451　oxygen at 531.84 eV (O_{OH}). As illustrated in Fig. 7d, the Sb 3d result of BSMU-Sb showed that the Sb 3d XPS peak was

452 split into Sb 3d$_{3/2}$ and Sb 3d$_{5/2}$ states corresponding to the Sb (III) oxide at around 540.1 eV and 530.6 eV, respectively,

453 which showed that antimony can be adsorbed by the BSMU, which were divided into four Sb oxide compounds of which

454 binding energy peak at 530.32 eV, 531.08 eV, 532.03 eV and 540.10 eV. The oxygen peaks position changed and new Sb

455 3d$_{5/2}$ peaks generated, which showed that Sb and BSMU was successfully bonded. As illustrated in Fig. 7e, two significant

456 Fe 2p peaks at 710.7 eV and 724.5 eV corresponded to the characteristic peaks of Fe$_3$O$_4$ (Im et al., 2015). While the Sb

457 (III) can be oxidized to Sb (V) in the presence of some ambient oxygen, the binding energy signal peak of Sb (V) at a

458 higher value (over 540.2 eV) did not occur in this study because the coexistence of Sb (V) and Fe (II) was not possible

459 when 2 Fe^{2+}+Sb^{5+}→2Fe^{3+}+Sb^{3+} where Fe (II) is strongly reductive and can react with Sb (V) thus preventing the oxidation

460 of Sb (III) to Sb (V) (Huang et al., 2006). This results showed that the adsorption reaction existed in the absence of Sb (V).
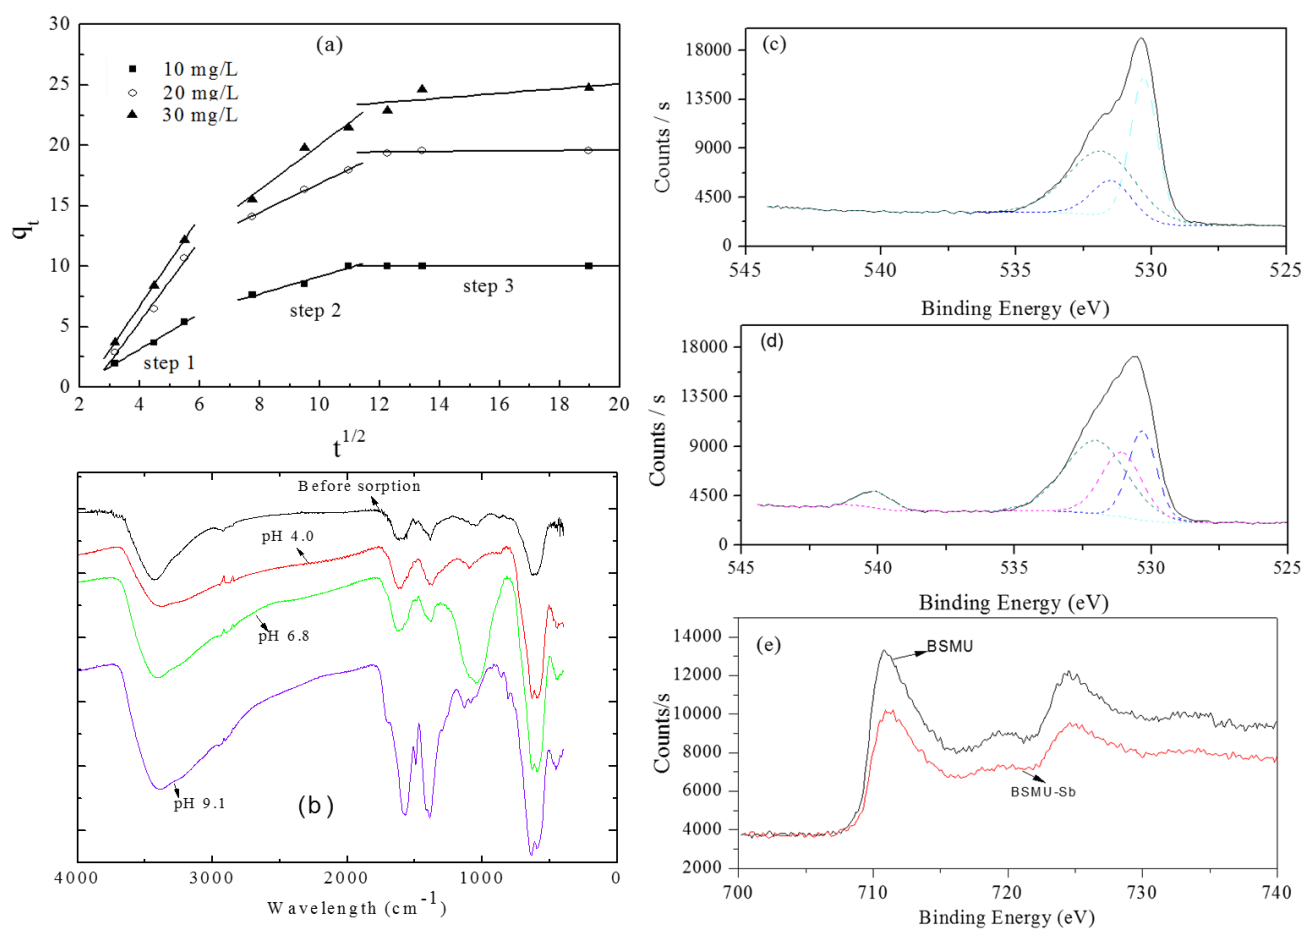

461

462 **Fig.** 7 Intraparticle diffusion plots for Sb (III) sorption on the BSMU at different adsorbent concentration

463

4 CONCLUSIONS

In this study, we evaluated the adsorption of mushroom biochar supported MMOF nanoparticles for removal Sb (III) from

solution. It showed a great potential for enhancing the adsorption of Sb (III) with biochar or magnetic UIO-66-2COOH.

The BSMU was demonstrated to be an effective composite adsorbent to remove Sb (III) and exhibited much higher removal

capacity toward Sb (III) than biochar, MOF and MMOF. Through adsorption model and elemental analysis, it suggested

that the chemical interaction between carboxyl (-COOH), hydroxyl (-OH), and amine (-NH) groups of absorbent and the

Sb (III) species led the adsorption reaction. It has good application across different reaction conditions. Over a broad pH,

it works well and is superior to the traditional adsorbent only in acidic conditions. The presence of coexisting ions has little

effect on Sb (III) removal. Further studies of recycling and process scale up are needed to strengthen its practical application.

Supporting information

Text S1

The used chemicals, mainly included ascorbic acid and potassium bromide, were purchased from Kemiou Chemical Reagent Co. (Tianjin, China). Hydrochloric acid (HCl) and concentrated sulfuric acid (H_2SO_4) were purchased from Zhuzhou Xingkong Chemical Co. (Zhuzhou, China). Ferrous sulfate, sodium salt trihydrate, 1, 10-Phenanthroline monohydrate, acetic acid, ammonium hydroxide, and sodium acetate anhydrous came from Sinopharm Chemical Reagent Co. (Shanghai, China). Anhydrous ethanol came from Hunan Huihong Reagent Co., Ltd (Hunan, China).

Text S2

Fe_3O_4 nanoparticles (nano-Fe_3O_4) were prepared using a solvothermal reduction by the following procedure: 1.62 g of $FeCl_3.6H_2O$ and 4.32 g of $C_2H_3NaO_2$ were dissolved in 60 mL of ethylene glycol, which was stirred at room temperature for 30 mins until a homogeneous solution was achieved. The solution was subsequently transferred to a polytetrafluoroethylene (PTFE)-lined autoclave to maintain reaction at 200 °C for 8 hours. The solid products were separated under an external magnetic field at room temperature and then washed three times with ultra-pure water and ethanol. After vacuum drying for 24 hours at 60 °C, the nano-Fe_3O_4 was produced.

Text S3

MOF (UiO-66-2COOH) was prepared by using the hydrothermal method following the process developed by our publish[25]: the materials with the molar ratio of $ZrCl_4$, BTEC and ultra-pure water (50.4 g) at 1:1.7:280 were mixed and was treated by a reflux heating for 24 hours at 100 °C. When it was cooled to room temperature, white gel was washed repeatedly with ultra-pure water for removal of the excess acids and then re-dispersed in ultra-pure water for 16 hours to

undergo reflux heating at 100 °C. Then, the product was centrifuged and washed three times with ethanol and water. After

vacuum drying for 24 hours at 60 °C, the MOF was obtained. The nano-Fe₃O₄ was further modified by a silica core shell

through the Stober method using the following procedure: 1.0 g of Nano-Fe₃O₄ and 320 mL of ethanol were dispersed in

80 mL of water. The solution then underwent ultrasonic dispersion for 30 min, prior to the addition of ammonia hydroxide

solution (5 mL). After mechanical stirring for 15 minutes, 20 ml of TEOS was slowly added 5 ml at a time every three

hours, which maintained a reaction while being stirred under nitrogen for 18 hours at 50°C. Then, the MOF was mixed

with nano-Fe₃O₄ at their mass ratio 1:2 and stirred in water bath at 50 °C for 6 hours. Finally, the product was collected

with an external magnetic field and washed three times with ethanol and water. After vacuum drying for 24 hours at 60°C,

the magnetic MOF (MMOF) was obtained.

Table

Table S1 Fitting parameters of Sb (III) sorption capacity vs. adsorbent coagulant dosage by exponential decay model

pH value	Exponential Decay Model Parameters			
	Amplitude constant (a)	Decay constant (k)	Offset value (b)	R^2
4.0	38.162	57.984	5.189	0.998
6.8	31.786	41.974	8.447	0.986
9.1	22.416	42.156	7.975	0.986

Table S2 Fitting results of Sb (III) sorption onto the BSMU at various antimony concentration by kinetics models

Adsorbent C_0 (mg/L)	Measured q_e (mg/g)	Pseudo first-order kinetics			Pseudo second-order kinetics		
		Calculated q_e	k_1	R^2	Calculated q_e	k_2	R^2

10	9.99	7.17	-0.02	0.58	8.94	0.09	0.99
