<sup>2</sup>Tanzania National Parks, P.O. Box 3034, Arusha, Tanzania.

### Abstract

Elephant damage was assessed in 1,007 Acacia trees and responses between *Acacia tortilis* and *A. kirkii* in Ruaha National park were compared in 30 transects randomly placed in 38.8 km<sup>2</sup> on the northern bank of Great Ruaha River (GRR) basing on six browsing categories and four debarking classes. There was no significant difference in browsing ( $F_{1, 10} = 0.6, p > 0.05$ ) and debarking ( $F_{1, 6} = 0.16, p > 0.05$ ) between *A. kirkii* and *A. tortilis*. Trees were classified into three height and twelve diameter classes. About 3613 trees <1 m in height represented response in addition to coppices. The difference between the two species was observed only in regeneration potential ( $F_{1, 58} = 41.4, p < 0.05$ ). In addition, low regeneration potential, severely browsed trees and restricted distribution made *A. kirkii* more vulnerable to elephant feeding compared to *A. tortilis*. The high *A. tortilis* regeneration potential suggests that the study area could become an Acacia bushland or woodland if fire is controlled. Further studies need to investigate, the suppressed regeneration of Acacia trees at Msembe, variations in vegetation utilization along the GRR and effects of fire and small browsers on Acacia species including monitoring of vegetation and animal trends.

**Key words:** Elephants, Acacia, Tree damage, Regeneration, Ruaha River

### Introduction

The African elephant *Loxodonta africana* Blumenbach, being the largest terrestrial mammal, usually causes damage when feeding on trees (Nahonyo, 1996). Species affected most by elephant feeding include *Adansonia digitata*, *Faidherbia albida* and *Commiphora ugogoensis* (Barnes, 1985), *Acacia tortilis* (Mwalyosi, 1990), *Colophospermum mopane* (Lewis, 1991), *Acacia xanthophloea* (Kabigumila 1993), *Acacia seyal*, *Sclerocarya birrea* (Gadd, 2002) and *Acacia elatior* (Ihwagi *et al.*, 2009).

Unlike other herbivores, elephants are adapted to use a wide range of plant species and various parts of these plants (Kerley *et al.*, 2008). Feeding adaptations include use of the trunk, the high shoulder height, bipedal stance, use of tusks to strip bark off trees and gouge in soft stemmed trees or dig some woody and succulent species (Barnes 1982). Effects include debarking, breaking, felling, pushing over or uprooting young trees and seedlings during browsing, or when young bulls engage in social displays (Smallie and O'Connor, 2000), thereby reducing tree species diversity, mortality and undersized growth (Chira and Kinyamario, 2009). Tree damages tend to

increase with elephants densities (Wahungu, 2011) in small isolated protected areas where corridors and dispersal areas are blocked by human settlements and other activities including agriculture (Ngene *et al.*, 2009; Hema *et al.*, 2010). Likewise, elephants tend to open closed woodland thereby increasing accessibility to resources and seed dispersal (Blake *et al.*, 2009; Majid *et al.*, 2010).

Most *Acacia* trees are nutritious hence browsed intensively by many herbivores than other tree species (Fornara and du Toit, 2007). This may cause decreased reproduction and recruitment (Young and Augustine, 2009) and in response many trees develop chemical and physical defenses including growth responses. Growth response includes massive compensations or change in plant phenology that reduce impact of herbivory. Physical defense mechanisms aim at reducing accessibility of leaves by increasing spine length and densities and reduction in leaf size. Thorns or spines/ prickles defend *Acacia* trees from consistent browsing pressure from giraffe, impala, gerenuk and elephant (Dharani, 2006). *Acacia drepanolobium* form symbiotic association by developing swollen galls in which aggressive ants *Crematigaster mimosae*

and *C. nigriceps* colonies restrain (Dino, 2010). The symbiotic ants deter large herbivores from browsing through attacking and causing irritation on their muzzles during browsing.

Responses to elephant browsing in this study refer to coppicing (re-growth of shoots) and regeneration. The word browse included breaking of branches and bole (Okula and Sise, 1986). This study therefore gives an insight on effects of elephants browsing on *Acacia* species and their response in the study area. Understanding elephant browsing effects and responses of *Acacia* species aim at promoting conservation understanding and habitat management to decision makers in protected areas.

## Material and Methods

### Description of Study Area

RNP is situated in the south-central Tanzania between 33° 49' E and 53° 24' E and 6° 52' S and 7° 57' S (Figure 1) and covers about 19,540 km<sup>2</sup> with the altitude ranging from 750 to 1,863 m asl (TANAPA, 2008). The rainfall is unimodal with an average of 650 mm p.a, which increases with altitude towards Isonkavyola plateau (Bjørstad, 1976). There is a long dry season from May to November and mean annual temperature at Msembe is 24°C.

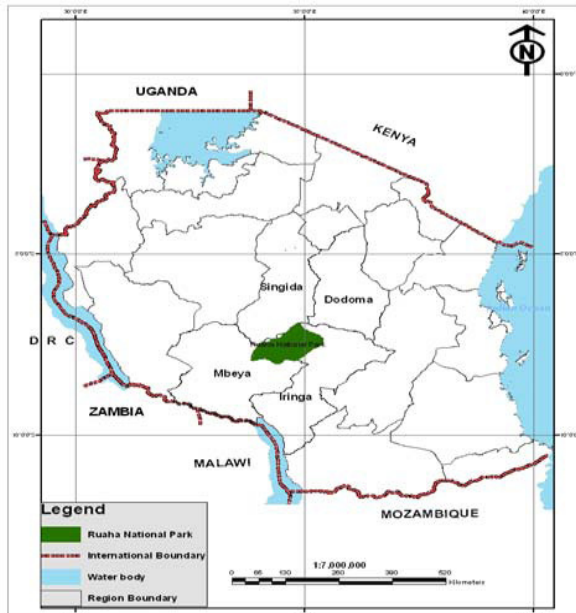

Figure 1: Location of RNP (Source: TANAPA 2008)

The park has four woody vegetation zones including; *Acacia*, Miombo (*Brachystegia*), *Drypetes* and *Combretum*. The area along the GRR supports a high concentration of animals, including elephants during the dry season. Comparatively, *Acacia* trees contain high crude

protein levels than many other trees and are an important source of food for elephants in the area when most of the remaining trees species have shed leaves.

### Sampling and Data Collection

Belt transects were divided into twenty 50m x 20m plots (White and Edwards, 2000). Transects were randomly located perpendicular to the northern bank of the GRR (Figure 2) spaced between 1,200-1,600m using random numbers. A 50m line was established using a predetermined 50m string with knots extending 10m on each side. The ends of the 20m string were flagged before moving them to a 50m mark for a 50m x 20m plot. This formed transect width of the first and subsequent plots. After collecting data, a 50m string was moved with new starting point to another 50m point to demarcate other plots. This procedure was repeated until the 1,000m transect was complete. The direction of transect was maintained using GPS (Garmin Etrex). Coordinates were recorded at the beginning and end of each line using GPS.

The sampling intensity of 1.5% was used to calculate the sample size. Thus, sample size (n) for the study area (A) and 0.02 km<sup>2</sup> sampled area (a) with 1.5% sampling intensity (SI) was  $38.8 \text{ km}^2 \times 0.0125 / 0.02 \text{ km}^2 = 29.91$  plots ( $\approx 30$  belt transects/plots). The study area size (38.8km<sup>2</sup>) was determined using GIS software. In each transect, *Acacia* tree species were identified with a help from an experienced field assistant. Unidentified species were collected for further identification (Dharani, 2006). Four debarking classes; (g<sub>0</sub>) stem not debarked, (g<sub>1</sub>) <1/2 stem circumference debarked, (g<sub>2</sub>) 1/2-3/4 stem circumference debarked and (g<sub>3</sub>) stem completely debarked and six browsing categories; (a) not/slightly browsed (b) 1/4 tree crown browsed (c) 1/2 tree crown browsed (d) 3/4 tree crown browsed (e) whole crown browsed, and (f) tree uprooted (Okula and Sise 1986) were adopted. The tree crown was divided into four quarters and the portion damaged in each quarter was visually estimated and then added up to obtain the total damage of a given tree.

Diameter at breast height (DBH) and tree heights were measured using Suunto hypsometer, graduated stick and tap measure. Trees were later grouped following Vesey-Fitzgerald, (1973) and Okula and Sise, (1986) classes; (a) young trees < 1 m height were classified as regeneration potential, (b) trees between 1-3m as recruitment potential (category that was in shrub layer and contributes to browse for elephant and other

browsers) and (c) trees > 3m as mature trees. DBH was measured for all *Acacia* trees at 130cm from ground level using a caliper. The diameter for each multi-stemmed trees forking below 130 cm was measured and recorded separately and later grouped into 12 diameter classes. All *Acacia* trees with coppices and trees

< 1m in height were recorded to indicate response from damage. Trees that appeared to have been killed due to elephant browsing and/or debarking were enumerated to determine relationship between tree killed and regeneration potential.

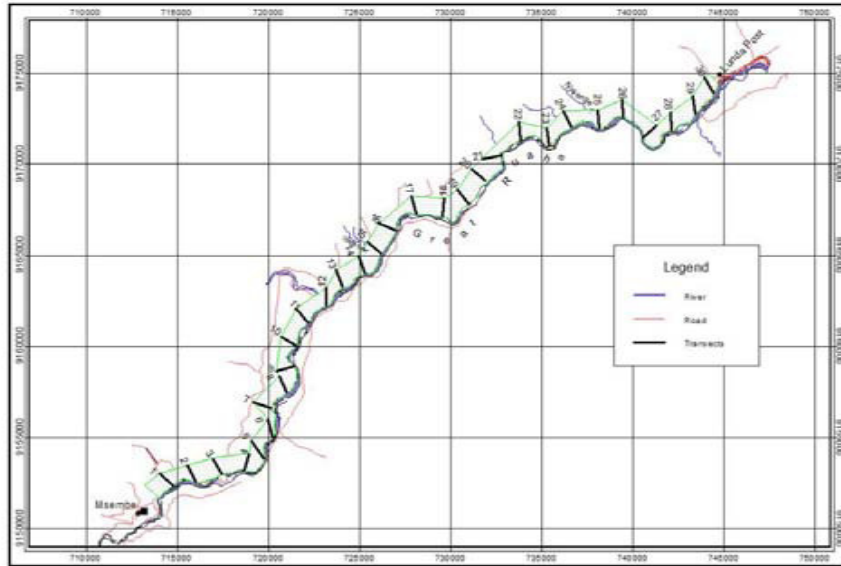

Figure 2: Location of transects in the study area (Source: Mapping and Survey Division 1972)

### Data Analysis

Sampled *Acacia* trees were enumerated but *Acacia tortilis* and *A. kirkii* were only selected for comparison basing on their densities and distributions. Damages were tabulated accordingly and differences in mean counts between damage categories were tested (ANOVA and Microsoft-excel). Densities of *Acacia* trees were calculated as number of trees per ha for each of the two dominant *Acacia* species in all sub-plots across the 30 belt transects/plots. Variations in densities were tested using linear regression and basal area for each sampled *Acacia* tree was computed using the formula;  $g = \pi/4 \cdot d^2$  (Philip, 1994). Where;  $d$  = diameter,  $g$  = basal/cross-sectional area estimated at breast height ( $m^2$ ) and  $\pi$  = pie.

The basal area for multi-stemmed tree was computed separately. Average diameters for multi-stemmed trees were computed for diameter classification. Lastly, diameters were categorized into twelve classes for trees with heights above 1.30 m; (a)  $\leq 1$  (b) 1.01–10 (c) 10.01–20 (d) 20.01–30 (e) 30.01–40 (f) 40.01–50 (g) 50.01–60 (h) 60.01–70 (i) 70.01–80 (j) 80.1–90 (k) 90.01–100 and (l) > 100. Tree volumes were not calculated as most of *Acacia* trees were multi-stemmed with different heights; thus impossible to measure height for each stem. Tree frequencies were presented in

height class distribution and mean frequencies were compared accordingly. Regeneration potential and coppices for *A. tortilis* and *A. kirkii* were tabulated and the differences of their mean frequencies tested using ANOVA. Frequencies of regeneration potential between the two dominant *Acacia* species were tested with dead trees found in transects for any relationship. Data on trees with coppices were not subjected to statistical test due to their low numbers.

### Results and Discussion

#### *Acacia* Species

A total of eight out of seventeen *Acacia* species previously recorded by Bjørstad (1976), were encountered in the sampled area. The species include *Acacia tortilis* (Forsk) Hayne, *A. kirkii* Oliv (Brenan), *A. senegal* (Willd) Brenan, *A. mellifera* (Vahl) Benth, *A. tanganyikensis* Brenan, *A. robusta* (Burch) Brenan, *A. nilotica* Willd and one *Acacia* species that could not be identified because pods, flowers and leaves were not available. The most common species in the sampled area were *Acacia tortilis* with 4,131 individual trees (89.4%), mean density of  $69 \pm 6$  trees/ha, followed by *Acacia kirkii* with 395 trees (8.5 %) and mean density of  $7 \pm 1$  trees/ha. The remaining *Acacia* species accounted for only 94

trees (2.1%) and mean density of 2 trees/ha. Therefore, *A. tortilis* and *A. kirkii* were selected basing on abundance, mean densities and distribution (*A. tortilis* was recorded in 249 sub-plots while *A. kirkii* occurred in 66 sub-plots of 600 sampled sub-plots).

#### Effect of Browsing on *Acacia* Trees

Elephant damage on *Acacia* was assessed from 1,007 recruitment and mature trees. There were no clear signs of elephant browsing on regeneration class (trees < 1 m) as they were probably uprooted. About 79.3% of *Acacia* trees were not browsed or slightly browsed, 8.9% had 1/4 of the crown browsed, 3.7% with 1/2 of crown browsed, 2.3% had 3/4 of the crown browsed, 5.1% with whole crown browsed and 0.7% of all trees uprooted/pushed (Fig. 3). The last three browsing categories i.e. 3/4 of crown, whole crown browsed and uprooted/pushed that were considered to be severely damaged accounted for only 8.0% of sampled trees. These categories are considered to be severe because the trees nearly died.

Thus, elephant browsing does not pose a big threat to *Acacia* trees, as previously found (Nahonyo, 1996). However, *A. tortilis* was the most browsed tree species (24.9%) in the *Acacia* zone. Low utilization of woody vegetation was probably attributed to low elephant population estimated at  $6,228 \pm 1544$  in 2006 (TAWIRI, 2009). In addition, RNP is naturally protected due to the inclusion of Usangu Game Reserve to extend about 20,000 km<sup>2</sup> since 2008.

Figure 3: Browsing classes for all *Acacia* trees in the study area in RNP

This expansion could have reduced the intensity of elephant activities around permanent water points including GRR because elephants disperse in bigger area. The increased survival of *A. drepanolobium* was noted after expansion of the reserve and opening of corridors probably due to reduced browsing pressure. Yearly drying up of the GRR could have influenced elephant browsing pressure (Van Aarde, 2008). Virtually the river stops flowing during dry period leading to variations

in utilization intensities of *Acacia* trees in the areas adjacent to GRR with consequent impacts near water pools.

Observations from planted *Acacia* trees near the office and staff houses outside the study area indicated severe damage with suppressed regeneration and slow recovery in Msembe area due to elephant browsing pressure (Nahonyo, 1996). Vegetation study (Bjørstad, 1976) in RNP suggests that *A. tanganyikensis* woodland was once well established in Msembe area. But, observations showed the presence of *A. tortilis* regeneration potential replacing *A. tanganyikensis*. Interestingly, elephant dung boli with plastic bags were observed around Msembe area, an indication that elephants could also feed from refuse pits. This might influence elephant ranging patterns in the area leading to increased browsing pressure on planted *Acacia* trees and other woody plants around the offices and staff quarters.

#### Effects of Elephant Browsing on Selected *Acacia* trees

Elephant browsing intensity on *A. tortilis* show that 80.9% of trees were not or slightly browsed, 4.3% severely browsed and 1.0% uprooted/pushed. *A. kirkii* had 75.8% of trees not or slightly browsed and 12.1% with whole crown browsed, while all severely browsed *A. kirkii* trees accounted for 16.1% (see Fig.4). The difference in browsing intensity between *A. tortilis* and *A. kirkii* was not significant ( $F_{1,10} = 0.6$ ,  $p > 0.05$ ), except for browsing classes ( $F_{5,6} = 7.54$ ,  $p < 0.05$ ). This perhaps was attributed to low number of recorded *A. tortilis* (624) and *A. kirkii* (330) trees (above 1 m) although the whole crown of the latter was relatively more severely browsed compared to the former. The relatively high proportion of severely damaged *A. kirkii* trees (16.1%) might be attributed to easy access to individual clustered trees that grows in seasonally flooded areas. Almost all encountered *A. kirkii* trees were multi-stemmed shrub branching at the base (Dharani, 2006). Elephant aggregation in clustered *Acacia* trees supports 'optimal foraging theory' in that herbivores tend to browse more on resource rich areas (Wahungu, 2011). Gadd (2002), made a similar observation on marula trees *Sclerocarya birrea* in South Africa. In addition, localized browsing pressure coupled with low regeneration potential could eliminate *A. kirkii* in some areas if elephants develop preference to these trees.

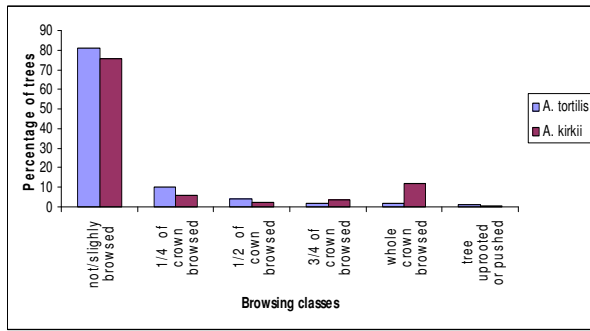

Figure 4: *A. tortilis* and *A. kirkii* browsing classes in the study area in RNP

**Debarking**

A total of 4,560 stems (i.e. 1626 of *A. tortilis* and 2,934 of *A. kirkii*) were assessed for

debarking. Individual stems were examined since only one or few stems in multi-stemmed trees were debarked by elephants. About 98.2 % of all stems were not debarked and less than 0.5% of the stems were severely damaged indicating a low level of elephant damage (see Table 1). On the other hand, *A. tortilis* had 1.2 % of its stems severely debarked compared to only 0.03% of *A. kirkii*. In addition, there was no sign of any stem that was ring barked and the difference in debarking between the two species was not statistically significant ( $F_{1, 6} = 0.157, p > 0.05$ ), perhaps due to low numbers of debarked stems enumerated in both species.

Table 1: Debarking classes for *A. tortilis* and *A. kirkii* stems in in RNP

Debarking classes	Number of stems	
	<i>A. tortilis</i>	<i>A. kirkii</i>
Not debarked	1563	2920
< 1/2 debarked	42	13
1/2 - 3/4 debarked	15	1
Completely debarked	6	0

Relatively, there were more damaged *A. tortilis* stems (1.2%) compared to *A. kirkii* (0.03%) probably due to more single stemmed trees with greater mean diameter ( $17.9 \pm 0.7$ cm) compared to multi-stemmed *A. kirkii* trees with lower mean diameter ( $4.1 \pm 0.12$ cm). Multi-stem growth protect trees from ring barking and smaller branches provide little amount of forage than larger stems (Wanderi, 2007). Elephants preferentially debark *A. tortilis* than *A. kirkii* more frequently (Chira and Kinyamario 2009). A study in Samburu and Buffalo Springs National Reserves in Kenya, showed elephant debarking preference for *A. elatior* to *A. tortilis* due to higher levels of sodium, potassium, calcium and zinc. In addition, *A. elatior* and *A. tortilis* trees with diameters ranging from 25.5 to 51cm were the most debarked, in a similar fashion to these results (Figure 5)

These observations indicate low damage resulting from elephant browsing and debarking as well as insignificant difference in damage between *A. tortilis* and *A. kirkii*. Nonetheless, patchy and clumped distribution and multi-stem growth form make *A. kirkii* more vulnerable than *A. tortilis* which are affected mostly through debarking and uprooting/pushing.

**Acacia Tree Densities along Transects**

Statistical test between distance from the river along transects and tree densities indicated a weak relationship for *A. tortilis* ( $R=0.06$ ), but a strong relationship for *A. kirkii* tree densities ( $R=0.7$ ). There was a weak relationship between the distance from river for *A. tortilis* ( $R=0.3$ ) and for *A. kirkii* ( $R=0.1$ ) (see Table 2). This trend suggests that regeneration potential of both species is influenced by factors other than distance from the river. This variation cannot be attributed to elephant feeding only since the transect length (1 km) was too short, given low level of browsing and debarking.

Figure 5: Debarking by diameter classes of combined *A. tortilis* and *A. kirkii* in RNP

Table 2: Relationship between distance from the river and *Acacia* trees in RNP

	R	R <sup>2</sup>	Equations
Trees < 1m (Regeneration potential)			
<i>A. tortilis</i>	0.349	0.122	Y = 0.315 x + 41.9315
<i>A. kirkii</i> trees > 1m	0.099	0.010	Y = 0.0004x + 0.8718
<i>A. tortilis</i>	0.063	0.004	Y = -0.0006x + 10.7368
<i>A. kirkii</i>	0.746	0.557	Y = 0.0086x + 0.9789

The observed relationship was probably an influence of soil factor because areas close to river banks are well drained and seasonal flooding is uncommon. Generally, more *A. kirkii* trees were recorded in areas with seasonal shallow water channels and temporary flooding. In contrast, *A. tortilis* is adapted to a wide range of soil types (except seasonally waterlogged) hence widely distributed in the study area. There were fewer *A. tortilis* in areas with dense bush of *Cordia gharaf*, *Maytenus* and *Vernonia* species near the river bank and on ridges with *Combretum* trees, where most transects ended. *A. tortilis* being a shade intolerant species could not grow in thick bush, while in *Combretum* area; fire could have played a role in limiting regeneration and growth in addition to soils.

#### Population Structure and Composition

Basal area, tree heights and tree diameters were used to classify *Acacia* trees in different sizes since it was impossible to age them using other methods. Mean diameters for *A. tortilis* and *A. kirkii* were 17.9±0.7 and 4.1±0.2cm respectively with the overall mean diameter of 12.9±0.5cm. There was a significant statistical difference between *A. tortilis* and *A. kirkii* in basal areas ( $F_{1,22}=11.8$ ,  $p < 0.05$ ) and no significant difference was observed between diameter classes ( $F_{11, 12}$ ,  $p > 0.05$ ). Most *A. kirkii* trees were multi-stemmed shrubs with smaller stem diameters, while *A. tortilis* had relatively fewer stems but with larger diameters. Distribution of basal area by diameter classes represented population structure of *A. tortilis* and *A. kirkii* for trees above 1.30m height (Fig. 5). All *A. tortilis* had stems distributed in all diameter classes with 20.01-30cm and 30.01- 40 cm accounting for a large basal area and diameter classes presenting decreasing number of bigger trees. The structure of the curve is not a negative exponential or inverted J-curve shape. Negative exponential curve or inverse J-shape curve indicate a healthy regeneration of a woodland or forest. *A. kirkii* chart is also different from an inverted J-shaped curve, with a high basal area in one diameter class (1.01-10cm), lower in 20.01-30, lowest in 40.01-40cm and none in the remaining classes (Figure 6).

Figure 6: Basal area (m<sup>2</sup>) by diameter classes of *A. tortilis* and *A. kirkii* in in RNP

The mean tree height for *A. tortilis* and *A. kirkii* was 7.4±0.2m and 4.5±0.2m, respectively. The tree height class distribution curve for *A. tortilis* exhibit approximately a negative exponential curve (inverted J-curve), with a greater number of individual trees (84.6%) in regeneration potential (trees <1m) followed by mature trees (trees >3 m) (11.7%) and the recruitment potential (trees 1-3m) with a lowest number of trees (3.7%). On the other hand, *A. kirkii* trees had lower regeneration potential (16.6%), 43.9% in recruitment potential and 39.5% in mature class. The diameter class distribution for *A. tortilis* suggests interrupted regeneration and recruitments continuity at different stages of tree growth resulting into a bell shaped curve (Figure 7).

Figure 7: Tree height class distribution of *A. tortilis* and *A. kirkii* in RNP

The recruitment gaps could be a result of disturbances through browsing, fires and

prolonged drought which might have killed young seedlings or retarded their growth through recruitment potential. For *A. kirkii*, the basal area and diameter distribution curve reflects the multi-stemmed growth form of the species with many smaller stems and few single stemmed trees above 30cm in diameter. This suggests that, the use of basal area and diameter alone in determining population structure of multi-stemmed trees species could lead to erroneous conclusion.

The low basal area in the 0-1cm diameter class could indicate low recruitment from the regeneration potential, in addition to smaller diameters of trees in this class. This is supported by the large proportion (94.1%) of *A. tortilis* and *A. kirkii* seedlings with height below 0.3m and low number of trees with a height between 1 and 3m, suggesting a suppressed growth of seedlings into recruitment potential class. Fire and browsing could as well have affected the recruitment potential since the class falls in the 1-3m height, a preferred browsing range by elephant (Mtui and Owen-Smith, 2006). Thus, elephant browsing could have killed or suppressed recruitment of trees into mature class. Moreover, *A. kirkii* tree height indicate low number of individual trees in regeneration potential, highest in recruitment potential followed by mature trees class. This distribution suggests poor potential for future trees recruitment and consequently into mature trees.

### **Growth Responses from Acacia Species Coppices**

A total of 23 out of 1,007 trees resprouted after elephant damage. Most of the resprouted trees were *A. tortilis* (87.0%), three other combined *Acacia* species (13.0%), and none of *A. kirkii* had coppices. The low proportion of *Acacia* trees with coppices was a result of drought since the study was conducted at the end of the prolonged dry season. Furthermore, genotypic differences between species (Sennerby-Forsse and Zsuffa, 1993) could be associated with absence of *A. kirkii* trees with coppices after damage by elephants. *A. kirkii* is adapted to seasonally flooded soils, while *A. tortilis* grow in a wide range of soil types with deeper roots to access water. Many *Acacia* species have little or no coppicing ability when mature hence some of the sampled trees could not resprout after elephant damage. Moreover, *Acacia* trees may need more than two seasons to coppice. Other observation (Chira and Kinyamario 2009) suggests that five woody

plant species (*Acacia ataxacantha*, *A. brevispica*, *Grewia bicolor*, *G. tembensis* and *G. virosa*) coppiced in a fairly short time after were browsed by elephants.

### **Regeneration Potential**

A total of 3,613 trees (<1m and mean height of  $0.25 \pm 0.003$ m) were enumerated. *A. tortilis* formed a large proportion (97.1%) of total regeneration potential with only 1.8% *A. kirkii*. There was a significant difference in regeneration potential between *A. tortilis* and *A. kirkii*, ( $F_{1, 58} = 41.36$ ,  $p < 0.05$ ). *Acacia* species are known to have a capacity to regenerate rapidly from seedlings (Western and Maitumo, 2004) but their survival is dependent on soil, fire, herbivores and climatic variations (Wahungu, 2011; Stave *et al.*, 2006). Thus, adaptation to different soil types might cause a huge difference in regeneration potential. *A. tortilis* grows in a wide range of soils while *A. kirkii* is restricted to seasonally flooded areas (Dharani, 2006). Seed dispersal by elephant and other agents is likely to favour *A. tortilis* than *A. kirkii* due to its versatility to different soil types.

Most of trees < 1m (94.1%) were under 0.3m height, 3.7% between 0.3 - 0.5m, while only 2.2% between 0.5-1m, resprouted after damage by fire and partial browsing. The higher proportions of trees < 0.3m height suggest probable annual suppression of seedling growth. According to Barnes (1985), smaller browsers such as impala and kudu reduced *Acacia erioloba* seedlings mean height but could not reverse growth to ground level, whereas fire and elephant reversed the growth of seedlings to ground level. Pellew (1983) affirm that elephants in Serengeti National Park ignored trees < 1m height whereas in Hluhluwe-Imfolozi Park elephants had little effect to smaller trees < 1m (Boundja and Midgley 2007). Elsewhere, elephants frequently browsed on seedlings < 1m (Jachmann and Bell, 1985) but it's difficult to know if elephants fed on or ignored regenerating trees in RNP. Therefore, fire and small browsers were the likely factors influencing growth of *Acacia* seedlings in the study area apart from climatic variations.

Regeneration potential of dead *A. tortilis* and *A. kirkii* trees killed as a result of elephant browsing did not show a strong relationship (*A. tortilis*,  $R = 0.16$  and *A. kirkii*,  $R = 0.01$ ). This indicates that the regeneration potential was probably not influenced by elephants browsing pressure. Besides, *A. tortilis* seedlings were observed in open grassland where no mature trees were killed by elephants. In some transects, trees killed by elephants were

enumerated without any single *Acacia* seedlings. This could be an indication that re-establishment by regeneration in areas where *Acacia* trees are killed take sometimes. Thus, death of mature trees would be expected to allow germination and regeneration of seedlings. This study confirmed that *A. nilotica* seedlings grow under their mature parent trees or *A. tortilis* mature tree crowns.

### Conclusion and Recommendation

The observed significant difference in regeneration potential was not detected in debarking and browsing between the two dominant *Acacia* species, *A. tortilis* and *A. kirkii*. Statistical tests on coppicing proved difficult due to the low number of *A. tortilis* trees that sprouted and none of *A. kirkii* trees had coppices. The effects of elephant browsing and responses after damage were apparent, but not statistically significant. This led to failure to reject the hypothesis that, dominant *Acacia* species are equally damaged and respond equally to elephant damage.

The low level of elephant damage indicate less threat to *Acacia* species with the exception of *A. kirkii*, that was locally affected due to patchy and clumped distribution. The variation in *Acacia* trees densities with increasing distance along transects was probably influenced by soil, vegetation cover and fire, and not elephant browsing. *A. tortilis* showed a high potential for future recruitment compared to *A. kirkii*. This is indicated by high *A. tortilis* regeneration potential. Fire and small browsers could likely suppress regeneration potential whereas variability in soil and climate could determine both coppicing and regeneration of *Acacia* trees. Fire as a management tool can suppress or enhance recruitment of *A. tortilis* depending on the purpose of management intervention. The area between Msembe and Lunda could develop into *A. tortilis* bush/woodland if factors that suppress recruitment potential are identified and controlled appropriately. If an area is left into *Acacia* bush/woodland it could adversely affect important species of mammals such as Grants gazelle *Nanger granti* and cheetah *Acynonyx jubatus* that prefer open grassland.

### Management Implication

Elephant utilization on *Acacia* trees is likely to vary along the Great Ruaha River depending on the availability of surface water in dry seasons; hence it is important to conduct a study on effects of elephant browsing on

vegetation around permanent water points. It is therefore recommended that:

A study on the impact of browsing by other animal species and of *Acacia* species regeneration potential need to be done across seasons to establish the actual causes for suppressed tree regeneration, in addition to the influence of human activities on elephants and other browsers around Msembe.

- Another study should focus on the *Acacia* vegetation zone to get a better understanding of *A. kirkii* regeneration and coppicing as a response after damage.
- A study on effects of fire on regeneration of *Acacia* trees to be conducted to ascertain the use of fire as a management tool.
- Moreover, close monitoring of changes taking place in vegetation in area should be done continuously to predict the likely future vegetation cover and how the changes would affect the associated animal species in two distinct seasons.

### Acknowledgement

We thank TANAPA's management for financial support and for allowing us to conduct studies in RNP. We also thank Prof. R.P.C. Temu and Prof. S. Hassan for commenting on the draft manuscript.
