Abstract

The water of East African rift lakes contains large amounts of dissolved chemicals such as carbon dioxide, methane greatly and others like phosphate, silicate, Sulfate, Sulfide, Iron, Ammonia, Alkalinity etc. Lake Kivu is a large, deep rift basin lake located in the western branch of the East African rift zone that contains a methane gas deposit of great economic interest with two main sources: Inorganic carbon dioxide $\text{CO}_2 + 4\text{H}_2 = \text{CH}_4 + 2\text{H}_2\text{O}$ and Organic methanogenesis $\text{CH}_3\text{COOH} = \text{CH}_4 + \text{CO}_2$. Lake Kivu is a stratified, meromictic lake bordering Rwanda and the Democratic Republic of the Congo (DRC). The lake has a surface area of 2,370 Km^2 , a volume of 580 Km^3 and a maximum water depth of 485 m. To characterize the vertical variation of Lake Kivu water chemistry, 8 samples of water were collected using Niskin bottles in Lake Kivu near Gisenyi town. Water samples were therefore collected at different depths: 0 m, 40 m, 90 m, 240 m, 290 m, 340 m, 340 m, and 390 m. Hatch kits were used to analyze water chemistry of samples taken of Sulfate, Sulfide, Iron, Ammonia, Alkalinity, Silica, PO_4 and phosphorus. The results revealed that alkalinity increases in the monimolimnion part due to the precipitation of calcium carbonate in the upper levels of the water column and dissolution in the monimolimnion. The conductivity, dissolved oxygen, temperature and pH were measured by CTD Sonde. Water column data from these studies showed increasing concentrations with depth. The divide between the mixolimnion and monomolimnion is estimated at a depth of around 40 m. Higher amounts of silica observed closer to the shoreline is likely a result of an

influx of siliciclastic sediment and increased silica with depth is likely a result of the dissolution of diatoms below the photic zone.

Keywords: Monimolimnion, mixolimnion, water stratification, chemical agents.

1. Introduction

Lake Kivu is an East African rift lake having a maximum depth of 485 m, a volume of 550 km³, elevation of 1463m, and it has an area of 2370 km². Lake Kivu is located between the Democratic Republic of Congo and Rwanda (Schmid et al., 2004). The water of East African rift lakes contains large amounts of dissolved gases such as carbon dioxide and methane especially in Kivu Lake which is located in Rwanda. Lake Kivu is one of the largest carbon dioxide and methane reservoirs on earth (source). In 2004, the calculated amount of CO₂ and CH₄ dissolved phase is 300 km³ and 55 km³ at standard temperature and pressure (gas volume at 0 degree Celsius and 1 atm) (Schmid et al. 2005). According to Selley (1998), Methane is formed in three ways: 1) mantle-derived, 2) thermal maturation of organic matter and 3) bacterial degradation of organic matter at the shallow depths. In the case of methane in Lake Kivu water column, the dominant methane-forming process is bacteria-mediated methanogenesis of CO₂. Carbon dioxide is the major natural gas in the areas of extensive volcanic activity. There are other gases, ions, and anions that are present in smaller quantities like silica, phosphate, iron, sulfide, ammonia etc. (Degens et al. 1973). The chemistry of water changes with depth from top. For example, Fe concentration below mixolimnion is higher because of anoxia (Schmid et al. 2005). This research intends to study Lake Kivu's water chemistry changes over time versus spatially at depth and the temporal variability as a result of photosynthesis occurring during the day. This study aimed at studying the variations in dissolved oxygen, alkalinity, pH, conductivity, silica, phosphate, iron, sulfide, sulfate, and ammonia in Lake Kivu water over time from the surface to the bottom and how water chemistry between mixolimnion and monimolimnion differs. Data in this study were acquired using Hach kits that are suitable for studying water chemistry of Lake Kivu due to the fact that it is quick, simple, easy to transport, and fast with few field assistants. Contrarily, it has a low detection limit for phosphate and ammonia and is likely less precise than IC/ICP (Ion Chromatography/Inductively Coupled Plasma).

This study will help to identify the influence of surrounding environment on the chemistry of Lake Kivu water and assess the impacts of chemicals on aquatic life. The divide between the mixolimnion and monomolimnion occurs at a depth of around ~65 m (Schmid&Wüest, 2012). The lake is anoxic below 60-65 meter deep. Lake Kivu has large gas reservoir at the depth between 50 and 80m(Schimitz&Kufferah, 1955;Capart,1960), this is of economic importance but also risky. Lake Kivu waters are drained by different fluid sources and/or biochemical processes controlling water chemistry (i.e., water-rock interactions, bacterial activity) that is not homogeneously distributed all over the entire lake (Tasi et al, 2009).

2. Methods

Eight water samples were collected at depths extending from the surface to the depth of 390meters and at interval depth of(0 m, 40 m, 90 m, 240 m, 290 m, 340 m, 340 m, 390 m) using Niskin bottles suspended on the calibrated cord in Lake Kivu near Gisenyi city with help of Kilindi boat. Conductivity, Temperature and Depth (CTD)Sonde data were also collected along the depth profile. Water samples were analyzed in the Lake Kivu Monitoring Program laboratory using Hatch kits. The measured elemental concentrations are ofSulfate, Sulfide, Iron, Ammonia, Alkalinity, Silica, and Phosphate as the major chemical constituents of Lake Kivu water.

Silica measurement

The method used is Silico-molybdate Method (SILICA, High Range (0 to 75.0 mg/L)).Samples were collected in clean plastic bottles. The samples were analyzed just after collection and stored up to 28 days at 4 °C or below. The analysis was preceded by warming the samples to room temperature before analyzing. Silica and Phosphate in the sample reacted with molybdate ion under acidic conditions to form yellow silicomolybdic acid complexes and phospho-molybdic acid complexes. Citric acid was added to destroy the phosphate complexes. Silica is then determined by measuring the remaining yellow color.

Alkalinity

Samples were collected in a clean glass or plastic bottles with tight-fitting caps. The bottle was completely filled with water and immediately tighten the cap to prevent agitation of the sample

and air exposure. Then, Analyzed the samples as soon as possible for best results. The alkalinity was measured by using digital titrator for Phenolphthalein and Total Alkalinity from 10 to 4000 mg/L as CaCO₃.

Sulfide

Samples of water were collected in clean plastic or glass bottles and filled completely and cap tightly to avoid excessive agitation or prolonged exposure to air and analyzed samples immediately. The analysis used Methylene Blue Method for SULFIDE (0 to 0.70 mg/L S²⁻).

Phosphate.

Water samples were collected in plastic or glass bottles that have been cleaned with 1:1 Hydrochloric Acid Solution and rinsed with deionized water. PhosVer 3 (Ascorbic Acid) Method for PHOSPHORUS, REACTIVE (0 to 2.50 mg/L PO₄³⁻) was used.

Iron

Samples of water were collected in plastic containers. No acid addition is necessary if analyzing the sample immediately. To preserve samples, the pH was adjusted to 2 or less with nitric acid (about 2 mL per liter). The method used is FerroVer Method for IRON (0 to 3.00 mg/L) .

Sulfate

Water samples were collected in clean plastic bottles and warm to room temperature before analysis. The analysis was done using SulfaVer 4 Method for SULFATE (0 to 70 mg/L).

The biological degradation of organic matter in shallow depths uses oxygen. In anaerobic condition, nitrate and sulfate are used by bacteria in organic matter degradation producing carbon dioxide, methane and hydrogen sulfide. The hydrogen sulfide precipitates with iron and removed from the lake, and diffuses upward where it oxidizes back to sulphate.

4. Discussion

Water chemistry varies significantly along the depth profile. Lake Kivu exhibits a unique vertical density stratification that is driven by dissolved gasses (Schmidt & Wuest, 2012) and the influx of saline groundwater. Except for anaerobic microbial processes, biologic activity only occurs in the mixolimnion (upper 60-65 m of the lake) (Schmidt & Wuest, 2012).

Higher concentration (9.2 mg/l) of silica observed closer to the shoreline is likely a result of an influx of sediment derived from weathered bedrock (Figure 15), particularly near the outlets of streams and rivers. The increased concentrations of silica in the deeper water than surface waters are a result of the dissolution of diatoms below the photic zone and the precipitation of calcite after being dissolved in water. The amounts of dissolved oxygen at the surface during the day are likely a result of photosynthetic processes (Figure 9). The conductivity infers to the salinity of the water, it is increasing downward due to the increased salts as a result of inflows of saline groundwater (Figure 10). Alkalinity increases in the monimolimnion likely due to the precipitation of calcium carbonate in the upper levels of the water column and dissolution in the mixolimnion (Figure 7) and saline groundwater is also likely alkaline. The concentration of phosphorus generally increases with depth as shown on figure 1 due to the deposition of phytoplankton in deep waters. In figure 3, Iron exhibits a decrease in concentrations at about 100-meter-deep with increasing age of deep waters. In the intermediate zone, the concentration increases due to the remineralization of iron. After, iron is removed to the sediments and unable to mix back in the water leading to continuous depletion. Ammonia gets into water as runoff in farm lands due to fertilizers usage this could be the main reason for increasing it in the lake water (figure 5). Partial Pressure of CO₂ was calculated from Alkalinity, however, its accuracy is difficult to assess at this time. Calculation of CO₂ flux suggests that CO₂ moves upwards in the water column except in the deepest measurements where CO₂ is transported down from 340 m to 390 m, this process is unlikely (Figure 8).

There exists the variation with the data taken in June, 2018 and those taken in February, 2004 by Schmidt. Generally, the change is significant at greater depth.

Fig 12. PH produced in february2004 and June2018

The increased temperature or excess nutrients from farmland runoff and waste water streams influence the growth higher algal and plant growth which result in the increase of pH level of lake water. Downward, the pH decreases with increase in temperature and the presence of carbon dioxide causes the acidity increase leading to the decrease in pH

Fig 13.Sulfide concentrations(2004&2018)

The sulfide concentration infers to the decrease of phytoplanktons, temperature increase (Kotch & Erskine, 2001), increased sediment organic matter (Govers, et al., 2014), iron poor sediments(Marba et al., 2008 and deeper water with low oxygen content. From 2004 to 2018, the concentration of sulfide decreased caused by the decrease in sedimentation rate of organic matter due to control measures taken.

Figure 14. comparison of alkalinities

Figure 15. Comparison of silca content

Figure 16. comparison of phosphate concentration

The concentration of phosphate is decreasing overtime (figure 16). This is due to the controlled runoff, prevention livestock from entering water sources, and manure management plan.

When a huge volume of waste water from the residence and hospitals are directly discharged into the lake, it contributes chemicals to the chemical concentration of lake water body like phosphate and nitrates. Not only this but also agricultural runoff increase phosphate concentration in water from due to the use of fertilizers. Phosphate stimulates the productivity of plankton and aquatic plants which provide food for larger organisms, including zooplankton, fish, humans, and other mammals (Ricklefs & Schluter, 1993). The decrease in phosphate concentration overtime will have a great effect on the aquatic life that feed on the zooplankton and phytoplankton. Anytime later, some organisms will disappear.

Figure 17. Comparison of sulfate concentrations

5. conclusion

Water chemistry varies significantly across different depths in Lake Kivu, the boundary between the mixolimnion and monolimnion was identified at approximately 40 meters based on Temperature and PH data derived from the CTD. This is 20 meters closer to the surface than previous studies that were 60 meters. Increases in turbidity occur at key boundaries identified in the temperature and conductivity data. Wastewater from the residence, hospitals contribute some chemicals like nitrates, sulfates into Lake Kivu water. Additionally, farmlands through erosion and runoff increase the concentration of phosphates in the water. The rise of concentrations of chemicals stimulates the growth of planktons and other marine organisms that can lead to the eutrophication consuming the available oxygen affecting negatively the aquatic life. The water of the lake is permanently stratified just because of the high salinity in the bottom of water the Lake Kivu.
