23 Birds that nest on the ground in open areas, like Piping Plovers (*Charadrius melodus*) and interior  
24 Least Terns (*Sternula antillarum athalassos*), are exposed to high temperatures in thermally stressful  
25 environments. As a result, some ground-nesting avian species have adapted behavioral strategies to  
26 maintain thermal regulation of eggs and themselves. We assessed the impact of sand temperature on  
27 shorebird nesting behaviors by installing video cameras and thermocouples at 52 Least Tern and 55  
28 Piping Plover nests on the Missouri River in North Dakota during the 2014—2015 breeding seasons.  
29 Daily duration and frequency of shading behaviors exhibited a nonlinear relationship with  
30 temperature; therefore, we used segmented regressions to determine at what threshold temperature  
31 (mean temperature = 25.7°C for shading behavior daily frequency and mean temperature = 25.1°C for  
32 shading behavior daily duration) shorebird adults exhibited a behavioral response to rising sand  
33 temperatures. Daily nest attendance of both species decreased with increasing sand temperatures in our  
34 system. Frequency and duration of daily shading behaviors were positively correlated with sand  
35 temperatures above the temperature threshold. Piping Plovers exhibited more and longer shading  
36 behaviors above and below the temperature thresholds (below: frequency= $10.30 \pm 1.69$  se,  
37 duration= $7.29$  minutes  $\pm 2.35$  se; above: frequency= $59.27 \pm 6.87$  se) compared to Least Terns (below:  
38 frequency= $-1.37 \pm 1.98$  se, duration= $-0.73$  minutes  $\pm 1.51$  se; above: frequency= $31.32 \pm 7.29$  se). The  
39 effects of sand temperature on avian ground-nesting behavior will be critical to understand in order to  
40 adapt or develop recovery plans in response to climate change.

45

46

47 **1. Introduction**

48 It is well documented that many shorebird species, including interior Least Terns  
49 (*Sternula antillarum athalassos*; hereafter “Terns”) and Piping Plovers (*Charadrius melodus*;  
50 hereafter “Plovers”) on the Missouri River, avoid establishing nests in predominantly vegetated  
51 habitats to decrease predation risk by increasing their visual detection of predators (Götmark et  
52 al. 1995, Amat & Masero 2004a, Catlin et al. 2011, Saalfeld et al. 2012, Sherfy et al. 2012).  
53 However, the trade-off for increased visual range around the nest is prolonged exposure to  
54 extreme summer temperatures. Incubating shorebirds face two problems when nesting on the  
55 ground in open, hot environments: (1) overheating of the adult while on the nest and (2)  
56 maintaining egg temperatures below lethal levels. When exposed nests of ground-nesting birds  
57 are left unattended during high temperatures ( $> 42^{\circ}\text{C}$ ), even for short periods of time, the eggs  
58 are more vulnerable to hyperthermia, which results in lethal overheating of the embryos (Grant  
59 1982, Webb 1987, Brown & Downs 2003). Even at lower temperatures ( $32^{\circ}\text{C}$ ), Amat et al.  
60 (2017) reported the potential for unattended eggs to reach hyperthermic conditions for incubating  
61 Little Terns (*Sternula albifrons*). Therefore, incubating birds in hot climates must prevent  
62 themselves and their nests from overheating by cooling their body temperatures as well as the  
63 eggs.

64 Hyperthermia of incubating adults and eggs is primarily avoided or reduced by adaptive  
65 behaviors that facilitate heat reduction at the nest. Shorebirds that nest in climates characterized  
66 by extreme temperatures have developed several behavioral adaptations to manage thermal stress  
67 and egg thermoregulation during incubation such as bi-parental nest attendance, shading eggs,  
68 belly-soaking, gaping and panting (Purdue 1976, Grant 1982, Amat & Masero 2004b, Saalfeld et  
69 al. 2012). Bi-parental nest attendance (the sharing of adult attendance at the nest) facilitates

70 thermoregulation of the eggs by almost continuous control of egg temperature throughout  
71 incubation and thermal stress management by allowing the adults to leave when overheated  
72 (Grant 1982). Nest attendance of Snowy Plovers (*C. nivosus*), Wilson's Plovers (*C. wilsonia*)  
73 and Killdeer (*C. vociferous*) decreased during diurnal moderate temperatures (68%—76%) and  
74 increased to > 90% during the hottest times of the day (Purdue 1976, Grant 1982, Bergstrom  
75 1989). In response to rising ambient air temperatures, Lesser Black-winged Plovers (*Vanellus*  
76 *lugubris*) increased bi-parental nest attendance (Ward 1990). Kentish Plovers (*C. alexandrinus*)  
77 that incubated covered nests exhibited no behavior related to heat stress (Amat & Masero  
78 2004b). Conversely, Kentish Plover female incubation bouts decreased (primarily female  
79 uniparental incubation during the daytime) and bi-parental care of uncovered nests increased as  
80 temperatures rose. Overall, past research reported a positive relationship between parental nest  
81 attendance and temperature (Vincze et al. 2013)

82         The thermoregulatory role of shading behaviors (elevation of tibiotarsi until the  
83 incubation patch is extended above the eggs by 2—3 cm) has been considered less frequently  
84 (Downs & Ward 1997). Shading eggs was first considered a thermoregulatory mechanism to  
85 cool egg temperature by convection (Dixon & Louw 1978, Bennett et al. 1981). However, more  
86 recent evidence indicates that the primary purpose of shading eggs is to prevent overheating of  
87 the incubating adult (Downs & Ward 1997, Brown & Downs 2003). Wilson's Plovers and  
88 Killdeer spent 27.6% and 28.1% of their time shading eggs at temperatures > 23—25°C at the  
89 Aransas National Wildlife Refuge in Texas (Bergstrom 1989). Amat and Masero (2004b)  
90 reported that female Kentish Plovers exhibited shading behaviors for 10.4% ± 12.8 se of their  
91 time at a mean ambient temperature of ≥ 31°C. There is a general consensus from past research  
92 that the occurrence of shading behaviors increases with higher temperatures.

93 Indirect (e.g. determination of nesting behaviors using temperature data loggers) or  
94 abbreviated (e.g. observations at a distance by personnel using scopes or binoculars) behavior  
95 measurements were a common shortcoming of most past research that attempted to quantify  
96 shorebird responses to thermal stress. In addition, the use of personnel to directly observe nests  
97 to measure nesting behaviors was another limitation that decreased sample sizes for analyses. An  
98 alternative approach to direct field observations of nest attendance is indirect measurements via  
99 probes placed in the nest. Saalfeld et al. (2012) used iButtons placed in and around Snowy Plover  
100 nests in the Texas panhandle to indirectly measure and correlate nest attendance to temperature  
101 and habitat selection. The use of thermocouples to indirectly calculate nest attendance increased  
102 sample size (n=104 nests) in the preceding study (Saalfeld et al. 2012), but may reduce precision  
103 of nest attendance measurements according to Schneider and McWilliams (2007), who reported  
104 that temperature data loggers were unsuccessful in determining nest attendance of Plovers at  
105 Cape Cod National Seashore.

106 One method that would improve research focused on the relationship between  
107 temperature and nesting behaviors is the combination of video cameras with temperature data  
108 loggers placed at or near the nest. The integration of video cameras to quantify behaviors allows  
109 direct measurement of responses to temperatures and increases sample sizes for analyses. Terns  
110 and Plovers that nest along the Missouri River system are perfectly suited to study the influences  
111 of temperature on nesting behaviors for several reasons including: (1) both species nest on the  
112 ground in the open with full exposure to the sun, (2) both species have known adaptive behaviors  
113 to cope with thermal stress and (3) sand temperatures range on a daily basis from 4.4°C to 50°C.  
114 Our primary objective was to assess the potential impact of sand temperatures on shorebird nest  
115 behavior patterns. We expected adult Terns and Plovers would exhibit more behaviors associated

116 with thermal stress, such as increased nest attendance and shading eggs, with increasing sand  
117 temperatures. Since both species exhibit bi-parental care of the clutch and previous research  
118 demonstrated high daily nest attendance rates (> 90% of time/day), we expected a steady  
119 increase in daily nest attendance in response to rising sand temperatures (Andes 2018).  
120 Conversely, we expected little to no use of shading behaviors by the adults until sand  
121 temperatures reached a threshold, corresponding to a sharp increase in the frequency and  
122 duration of shading behaviors.

## 123 **2. METHODS**

### 124 **2.1. Study Area and Species**

125 This study was conducted on the Garrison Reach of the Missouri River in North Dakota,  
126 from the dam at Riverdale south to Bismarck, previously described by Shaffer et al. (2013),  
127 during May through August from 2014 to 2015. Both Terns and Plovers are small, ground-  
128 nesting shorebirds that select open, sparsely vegetated sand habitat with pebbles or gravel, such  
129 as coastal and riverine shorelines, temporary sandbars and permanent islands (Anteau et al. 2012,  
130 Sherfy et al. 2012, Stucker et al. 2013). Female Terns lay 2—3 eggs in a clutch, one every day,  
131 that are oval, beige in color and speckled (Kirsch 1996, Thompson et al. 1997). Incubation  
132 begins at the start of the egg-laying stage and lasts approximately 19—25 days (Thompson et al.  
133 1997). Unless the nest is depredated or destroyed, pairs only breed once a season (Thompson et  
134 al. 1997). Both adults share parental responsibilities; however, the female parent contributes the  
135 most time to incubation and chick-rearing duties (Keane 1987).

136 Double-brooding by Plovers is rare (Hunt et al. 2015). First attempt clutches typically  
137 contain four eggs, laid every other day, that are oval, sand colored with evenly distributed spots  
138 (Cairns 1982, Elliott-Smith & Haig 2004). Multiple re-nests are possible if the previous attempts

139 fail; however, clutch size for re-nests decreases with attempts (Bottitta et al. 1997, Elliott-Smith  
140 & Haig 2004). Full incubation begins after the last egg is laid. However, there are reported  
141 instances when short incubation periods were observed during the egg-laying period (Cairns  
142 1977, Whyte 1985). Both sexes incubate the nest, which lasts 25 to 28 days (Wilcox 1959,  
143 Cairns 1977, Whyte 1985, Haig & Oring 1988).

## 144 **2.2. Field Methods**

145 We used systematic grid and behavioral searches to locate and monitor Tern and Plover  
146 nests throughout the 2014 and 2015 breeding seasons (refer to Shaffer et al. (2013) for a detailed  
147 description of the monitoring methodologies). Clutch age was calculated by egg flotation at the  
148 initial nest visit (Mabee et al. 2006, Shaffer et al. 2013). Egg flotation allowed researchers to  
149 determine incubation stage as well as estimate initiation (date first egg was laid) and hatching  
150 dates for nests of both species (assuming 18- and 25-day incubation periods for Terns and  
151 Plovers (Shaffer et al. 2013)). Clutch size was recorded at the onset of incubation. Nests were  
152 monitored on a 3-day schedule until the estimated hatch date approached (< 3 days) when visits  
153 were increased to daily. Monitoring continued until nest completion when the fate was  
154 determined as either successful (hatched with at least one chick observed in the nest bowl),  
155 probable successful (evidence of hatching but no chicks present in the nest bowl), failed (nest  
156 could not have hatched based on estimated hatch date or evidence suggested infertile eggs,  
157 depredation, abandonment, destruction by weather or livestock) or unknown (Shaffer et al. 2013,  
158 Andes et al. 2019).

159 To observe nesting behaviors, video camera systems (miniature infrared surveillance  
160 cameras equipped with 24 LEDs and 4.3-mm lenses (Jet Security USA, Buena Park, CA) were  
161 installed at a subset of nests after incubation reached a minimum of two days and were not

162 removed until a nest outcome was confirmed by field personnel (refer to Andes et al. (2019) for a  
163 detailed description of the camera system design and installation). The camera was installed  $\geq 1$   
164 meter away from the nests at a height of 15—25 cm. The 12-V, 35-Amp-hour batteries and 32-  
165 GB SD cards housed in a weatherproof case (SEAHORSE Protective Equipment Cases, Fuertes  
166 Cases, La Mesa, CA) were buried in the sand at least 25—30 meters away from the nest and  
167 exchanged every 3—4 days to ensure continuous recording of the nests. We used video and not  
168 thermal cameras to increase sample sizes of shorebird nesting behaviors. Furthermore, the video  
169 camera system utilized in this study was more versatile to address a wide range of behavioral and  
170 predator-specific questions (Andes et al. 2019). Terns and Plovers are both federally protected  
171 under the Endangered Species Act (U.S. Fish and Wildlife Service 1985a, U.S. Fish and Wildlife  
172 Service 1985b), and the permit authorizing this research prohibited the placement of data loggers  
173 near the nest bowl. Alternatively, we measured sand temperature with thermocouples (Onset  
174 Computer Corporation, Cape Cod, MA; hereafter “HOBO”) installed  $> 1$  meter away from the  
175 weatherproof case and battery (which were  $\geq 25$  meters away from the nest). We installed the  
176 thermocouples in substrate (sand, gravel, pebble or mud) similar to the surrounding nest bowl  
177 habitat because various surfaces may have different thermal capacities, which in some cases can  
178 significantly affect heating rates of eggs (Mayer et al. 2009, Gomez et al. 2019). Our intent was  
179 to reduce or minimize the differences between the nesting substrate and the thermocouples  
180 surface locations. The thermocouples were pushed into the ground, at a depth of 5—8 cm, until  
181 the temperature sensor at the top was level with the sand surface. Sand temperatures were  
182 recorded on a 30-minute interval starting at camera installation until removal after nest outcome.  
183 Both the camera system and thermocouple were removed after the brood vacated the nesting area  
184 or a nest fate was assigned in the field by researchers. We assumed that both sand and ambient

185 temperatures were highly correlated. It is well documented that ambient temperature influences  
186 shorebird nest attendance and shading behaviors (Downs & Ward 1997, Browns & Down 2003,  
187 Amat & Masero 2004b, Amat et al. 2012, Vincze et al. 2013, Clauser & McRae 2016, Gómez et  
188 al. 2016, Amat et al. 2017). However, sand temperature was recorded because heat absorption by  
189 conduction may also influence shorebird nesting behaviors as well as both incubated and  
190 unattended eggs.

### 191 **2.3. Recording Nesting Behaviors**

192 We were interested in documenting behaviors that are impacted by temperature such as  
193 nest attendance and shading behaviors. Nest attendance was defined as the adult (we were unable  
194 to distinguish between male and female individuals) attending or “on” the nest, which included  
195 sitting on or standing over at least one egg in the nest. We defined shading behaviors as the  
196 adults visibly standing over at least one egg in the nest for a period > 3 seconds (see Multimedia  
197 video clip “PipingPloverShadingBehavior.mp4” for an example of shorebird shading behavior).  
198 We started recording shading behaviors when an adult first arrived to attend the nest and stood  
199 over the eggs or stood up during incubation. We recorded start and stop times for all  
200 observations when adults were attending the nest or shading eggs. All behavioral observations  
201 were recorded within one calendar day (24-hour period) from 00:00:00 in the morning till  
202 23:59:59 at night. Because nest attendance was lower when researchers were present (Andes  
203 2018), we only included days with no research activities at the nest or within the nesting area for  
204 analyses.

205 We were unable to watch all of the video collected from the 107 camera nests; therefore,  
206 a subsample of those nests was selected to review based on the spatial and temporal distribution  
207 of cameras on the Missouri River to ensure independence between nests. In other words, camera

208 nests were selected from each segment (lower, middle and upper) of the Missouri River as well  
209 as across the breeding season (early, middle and late initiation dates). Within individual-sampled  
210 camera nests, days were selected to ensure equal representation of incubation stage (early,  
211 middle and late) as well as seasonal temperature variation (early, middle and late breeding  
212 season dates). We recorded the total duration in minutes per day of nest attendance and shading  
213 behaviors as well as the total frequency per day of shading behaviors for analyses.

#### 214 **2.4. Data Analysis**

215 Sand temperature measurements were summarized as daily minimum, maximum and  
216 mean by year, nest and date. We graphically explored the relationships between temperature and  
217 shorebird daily nesting behaviors to determine the appropriate statistical method to analyze the  
218 data. If shorebird adults only exhibited shading behaviors after a critical sand temperature was  
219 reached, then we performed a segmented regression using the “segmented” package (Muggeo  
220 2008) in R 3.5.2 (R Core Team 2018) to determine that threshold. Adult shading behaviors were  
221 analyzed as linear relationships above and below the threshold temperature determined by  
222 segmented regression. We conducted generalized linear mixed models (GLMM) using the  
223 procedure PROC GLIMMIX (SAS 9.4; SAS Institute, Cary, NC) for all linear statistical  
224 analyses. The response variables included daily nest attendance duration as well as daily  
225 frequency and duration of shading behaviors. Daily nest attendance was defined as the total  
226 minutes the adults attended at least one egg in the nest. Daily duration of shading behaviors was  
227 defined as the total minutes the adults spent standing over at least one egg in the nest. Daily  
228 frequency of shading behaviors was defined as the total number of occurrences. Year, categorical  
229 nest and habitat identifications on the Missouri River were included as hierarchical random  
230 effects to account for repeated measures (multiple days/nest and multiple nests/location/year on

231 the Missouri River). We modeled the response variables (daily nest attendance and shading  
232 behaviors) in relation to daily minimum (MIN), mean (MEAN) and maximum (MAX) sand  
233 temperatures. Each model contained only one temperature covariate to avoid issues with  
234 collinearity. Additionally, the covariates Species (Least Tern or Piping Plover), Date (ordinal day  
235 of the breeding season) and Clutch Age (age of the nest) were included as predictor variables in  
236 all GLMM analyses because previous research determined that they may influence nesting  
237 behaviors (Smith & Wilson 2010). We adopted an information-theoretic approach to model  
238 selection and ranked models based on their Akaike's Information Criterion corrected for small  
239 sample sizes ( $AIC_c$ ), model weight ( $w_i$ ) and model goodness-of-fit (-2ll) (Burnham & Anderson  
240 2002). We conducted model selection on a set of 16 *a priori* models for daily nest attendance and  
241 shading behavior response variables. Models that best described the impact of temperature on  
242 nesting behaviors had the lowest  $AIC_c$  scores and the largest model weights,  $w_i$  (Burnham &  
243 Anderson 2002). Estimates and 85% confidence intervals (CI) were derived from the top  
244 model(s) (Arnold 2010). We used 85% confidence intervals to distinguish between  
245 uninformative and informative parameters because the more commonly used 95 % CI often  
246 excludes variables from top models that are supported by lower AIC scores (Arnold 2010). We  
247 considered models with a  $\Delta AIC_c > 2$  as noncompetitive.

### 248 **3. RESULTS**

249 We installed video cameras and thermocouples at 52 Tern and 55 Plover nests on the  
250 Missouri River in North Dakota during the 2014—2015 breeding seasons. Of the 107 nests with  
251 cameras and thermocouples, a subset of 42 were included in the GLMM analyses (Tern nests  
252 =22, Plover nests=20). Data for 157 days were included in the analysis of temperature influences  
253 on nest attendance and shading behaviors. There was continuous variation in daily minimum,

254 mean and maximum temperatures throughout both nesting seasons (2014—2015) during the  
255 duration of this study (Fig. 1). Average daily mean and maximum temperatures were slightly  
256 higher in 2015 (mean=24.6°C, maximum=42°C) compared to 2014 (mean=23.6°C,  
257 maximum=39°C), while the minimum was similar for both years (2014=13.9°C, 2015=13.6°C).  
258 Daily maximum temperature had a small negative influence on shorebird daily nest attendance;  
259 days with hotter temperatures corresponded to a small decline in shorebird daily nest attendance  
260 (Fig. 2). The time spent (duration in minutes) and frequency of shading behaviors for both  
261 species were higher for hotter temperatures, with the sharpest increase of these activities at daily  
262 mean  $\geq 25^\circ\text{C}$  (Fig. 3).

### 263 **3.1. Daily Nest Attendance**

264 The variation in shorebird daily nest attendance was best explained by four top models,  
265 accounting for 52.9% of the model weight. The top three models explaining variation in daily  
266 nest attendance included: 1) MAX, 2) Intercept, and 3) Date (Table 1). We considered the fourth  
267 ranked model, MAX + Species, as uninformative because it was nested within the top model (the  
268 addition of an uninformative parameter) but did not improve model fit (Burnham and Anderson  
269 2002). There was a negative relationship between daily nest attendance and sand temperature  
270 (Table 1). Confidence intervals for parameter estimates for both MAX and Date covariates  
271 excluded zero (Table 1). Daily nest attendance was similar between species (Tern= 1,365.1  
272 minutes  $\pm$  10.1 se, Plover= 1,375.4 minutes  $\pm$  6.7 se).

### 273 **3.2. Shading Behaviors < 25°C**

274 Graphical representation of shorebird daily shading behaviors revealed a nonlinear  
275 relationship between frequency and duration of these behaviors with daily mean temperature  
276 (Fig. 3). The breakpoints in temperature were estimated to range between 24-27°C for both daily

277 duration (Tern= $25.4^{\circ}\text{C} \pm 0.53$  se, Plover= $24.8^{\circ}\text{C} \pm 0.45$  se, both species= $25.1^{\circ}\text{C} \pm 0.34$  se) and  
278 frequency of shading behaviors (Tern= $27.9^{\circ}\text{C} \pm 0.27$  se, Plover= $24.4^{\circ}\text{C} \pm 0.58$  se, both  
279 species= $25.7^{\circ}\text{C} \pm 0.32$  se). Therefore, we divided GLMM analyses for both species combined at  
280  $25.7^{\circ}\text{C}$  for frequency and  $25.1^{\circ}\text{C}$  for duration of daily shading behaviors. For the frequency of  
281 daily shading behaviors  $< 25.7^{\circ}\text{C}$ , there were two top models that accounted for 83.2% of the  
282 model weight. Both top models included Species and Clutch Age as covariates (Table 2). Date  
283 and MEAN were also covariates included in the best and second-ranked models respectively. We  
284 derived and interpreted estimates for Species, Clutch Age and Date parameters from the top  
285 model. The parameter estimate for MEAN temperature was derived and interpreted from the  
286 second-ranked model. There was a positive relationship between the frequency of daily shading  
287 behaviors  $< 25.7^{\circ}\text{C}$  and MEAN temperature (Table 3). Confidence intervals for parameter  
288 estimates of Species, Date, and MEAN covariates excluded zero. Below the temperature  
289 breakpoint, Plovers exhibited a higher frequency of daily shading behaviors compared to Terns  
290 (Table 4).

291         There was one top model that accounted for 96.7 % of the variation in daily duration of  
292 shading behaviors  $< 25.1^{\circ}\text{C}$  (Table 2). We derived and interpreted the estimates for Species,  
293 Clutch Age and Date from the top model. Parameter estimates derived and interpreted from the  
294 top models displayed a similar effect for daily duration of shading behavior compared to  
295 frequency (Table 3). Confidence intervals for the estimates included in the top model all  
296 excluded zero (Table 3). Below the temperature breakpoint, Plovers exhibited a higher duration  
297 of daily shading behaviors compared to Terns (Table 4).

### 298 **3.3. Shading Behaviors $> 25^{\circ}\text{C}$**

299 For the frequency of daily shading behaviors  $> 25^{\circ}\text{C}$ , there were two top models that  
300 accounted for approximately 66.2% of the model weight, which included MEAN, MAX and  
301 Species (Table 2). We considered the third-ranked model as uninformative, increasing the  
302 combined model weight of the top two to 76.4%. We derived and interpreted parameter estimates  
303 for MEAN and Species from the top model. The MAX parameter estimate was derived and  
304 interpreted from the second-ranked model. Each increase of one degree in MEAN and MAX  
305 daily temperature  $> 25.7^{\circ}\text{C}$  resulted in the increase of daily frequency and duration of shading  
306 behaviors by  $13.18 \pm 1.91$  se and  $5.58 \pm 0.78$  respectively (Table 3). Confidence intervals for the  
307 estimates included in the top models all excluded zero (Table 3). Additionally, Plovers exhibited  
308 a higher daily frequency of shading behaviors  $> 25.7^{\circ}\text{C}$  compared to Terns (Table 4).

309 There were two top models that accounted for 59.0 % of the variation in duration of  
310 shading behaviors  $> 25.1^{\circ}\text{C}$ , which included MEAN and MAX as covariates (Table 2). We  
311 considered models 3-4 as uninformative, increasing the combined model weight of the top two to  
312 77.7 %. The MEAN and MAX parameter estimates exhibited a similar effect on daily duration of  
313 shading behavior compared to frequency  $> 25.1^{\circ}\text{C}$  (Table 3). The confidence intervals for both  
314 MEAN and MAX parameter estimates excluded zero (Table 3). Daily duration of shading  
315 behaviors increased by  $35.52$  minutes  $\pm 5.22$  se and  $15.00 \pm 2.20$  with every increase of one  
316 degree in MEAN and MAX temperatures  $> 25.1^{\circ}\text{C}$  respectively (Table 4).

#### 317 **4. Discussion**

318 Terns and Plovers expressed behaviors related to thermoregulation while nesting on the  
319 Missouri River in North Dakota with sand temperatures that reached  $54.7^{\circ}\text{C}$  during the two-year  
320 study. Appropriately, these shorebirds exhibited plasticity in their nesting behaviors in response  
321 to rising temperatures. Adults drastically increased the frequency and duration of daily shading

322 behaviors at sand temperatures above a mean daily temperature of 25°C. Our results were similar  
323 to those reported from a video camera study conducted on King Rails (*Rallus elegans*) at the  
324 Mackay Island National Wildlife Refuge (Clauser & McRae 2016). King Rails spent  
325 significantly less time incubating and more time exhibiting shading behaviors as ambient  
326 temperature increased (Clauser & McRae 2016). However, we observed only a modest response  
327 of shorebird thermal behaviors in response to higher temperatures compared to most past studies  
328 conducted on shorebirds (Purdue 1976, Grant 1982, Bergstrom 1989, Ward 1990, Amat &  
329 Masero 2004).

330         Daily Plover and Tern nest attendance decreased with a corresponding increase in  
331 temperature, which conflicts with results reported from past research (Purdue 1976, Grant 1982,  
332 Bergstrom 1989, Ward 1990, Amat & Masero 2004). We expected a positive relationship  
333 between daily nest attendance behaviors and sand temperature, which was not supported by our  
334 results. Sand temperatures in this system only briefly (approximately 2—3 hours/day) increased  
335 to ranges when thermal behaviors were exhibited. During days with prolonged warmer  
336 temperatures there may be time periods (e.g. mid-morning) when eggs do not require continuous  
337 nest attendance by adults to maintain optimal temperatures for embryo development. Heat  
338 absorbed by unattended eggs during exposure to solar radiation during these time periods may be  
339 adequate for embryogenesis (Amat et al. 2012). It is likely sand temperatures were not high  
340 enough to require prolonged expenditure of thermally adapted behaviors for Terns and Plovers in  
341 the Missouri River system.

342         There was a distinct pattern in the shading behaviors between Terns and Plovers in  
343 response to increased temperatures. At a given sand temperature, Plovers exhibited more  
344 frequent and longer shading behaviors compared to Terns. Potential reasons for this behavioral

345 difference between species may be clutch as well as egg volume and coloration. Because Plovers  
346 lay larger clutches (3—4 eggs) with higher average egg volumes (17,092.9 mm<sup>3</sup> reviewed by  
347 Elliot-Smith and Haig (2004)), they may expend more energy to regulate egg temperatures  
348 compared to Terns (2—3 eggs, 16,134.5 mm<sup>3</sup> average egg volume reviewed in Thompson et al.  
349 (1997)). This increased energy expenditure by Plovers may increase their core temperatures  
350 faster, resulting in overheating more quickly, when the adults responded by exhibiting more and  
351 longer shading behaviors. Eggshell coloration may also influence egg thermoregulation. Tern  
352 eggs with paler eggshells may absorb less heat than those of plovers (Gómez et al. 2016),  
353 resulting in plover adults overheating more quickly. Some of our observations of individual Tern  
354 shading behaviors may be conservative due to observational challenges from watching video.  
355 For example, a combination of camera angle, poor video quality and lighting, nest obstruction by  
356 debris as well as much shorter legs made it difficult to distinguish shading behaviors for some  
357 and not all nesting adult Terns. These conservative observations were the exception and their  
358 potential impact was minimal on the overall estimate of frequency and duration of Tern shading  
359 behaviors. Even if the overall estimate of Tern shading behaviors may be marginally  
360 conservative, past research reported that clutch size did not influence mean clutch temperatures  
361 (Clauser & McRae 2016), which provides support that Plovers may have overheated faster to  
362 maintain incubation temperatures of more eggs, resulting in increased shading behaviors.

363         There are two primary hypotheses for plasticity of shading responses to temperature  
364 fluctuations at the nest: (1) to cool egg temperatures within a nonlethal range (DuRant et al.  
365 2013) and (2) to prevent overheating of adults while incubating (Downs & Ward 1997, Brown &  
366 Downs 2003). Temperatures of nesting Crowned Plovers (*Vanellus coronatus*) were always  
367 lower during shading behaviors compared to incubation time periods, while egg temperatures

368 were always higher during shading rather than when incubated (Brown & Downs 2003). This  
369 may suggest that the heat gained by eggs due to conduction from the nest bowl substrate during  
370 shading behaviors may increase the risk of egg hyperthermia compared to incubation. Since both  
371 Plovers and Terns are federally protected, we were unable to measure egg or adult temperatures  
372 to definitively determine the role of shading behaviors. However, the thermal breakpoints when  
373 both daily duration and frequency of shading behaviors sharply increased were well below the  
374 optimal temperature threshold for normal embryo development (35—38°C, Webb 1987),  
375 suggesting that the birds may be regulating their body temperature and not egg temperature. If  
376 the purpose of shorebird nesting behaviors in this system was to maintain egg temperatures, nest  
377 attendance should increase with the rise in temperature (Browns & Down 2003). Instead, daily  
378 nest attendance decreased while shading behaviors increased, which may indicate that the  
379 purpose of the behaviors was to prevent overheating of the adults and not the eggs in this system.

380         It is crucial that breeding shorebirds be able to cope with fluctuating temperatures in  
381 response to climate change. Increased temperature fluctuations may result in breeding pairs of  
382 shorebirds that may not be able to cope with high levels of thermal stress during incubation,  
383 which may decrease egg survival. The results of this study add to mounting evidence that  
384 ground-nesting avian species adapt their nesting behaviors appropriately to temperature variation  
385 (Grant 1982, Bergstrom 1989, Ward 1990, Amat & Masero 2004b, Saalfeld et al. 2012, Clauser  
386 & McRae 2016, Vincze et al. 2017). The occurrence of thermally-related behaviors in Plovers  
387 and Terns suggests that these populations may be able to adapt to future temperature fluctuations  
388 due to climate change.

389         Care should be taken to develop monitoring programs that do not disrupt nesting  
390 behaviors during extreme temperatures, especially for protected species such as Terns and

391 Plovers (Andes 2018). The examination of possible effects that temperatures of nesting  
392 substrates inflict on avian ground-nesting behavior will be critical to understanding how to adapt  
393 or develop monitoring programs in response to climate change. For Terns and Plovers, daily nest  
394 attendance decreased and shading behaviors increased at mean sand temperatures  $\geq 25^{\circ}\text{C}$ .  
395 Unattended shorebird eggs at the Salton Sea in California, exposed to a similar range of  
396 temperatures observed at the Missouri River, overheated and caused embryo death within two  
397 minutes (Grant 1982). Therefore, research activities should be conducted at sand temperatures  
398 that are within the thermal zone for normal embryo development to prevent prolonged exposure  
399 of eggs from unattended nests (Grant 1982). Likewise, extended adult absences from the nest due  
400 to researcher presence should be minimized. In the Missouri River system, research activities  
401 were prohibited once the ambient temperature exceeded  $32.2^{\circ}\text{C}$ . Additionally, research and  
402 monitoring should be designed to minimize disturbance to normal nesting behaviors (Andes et al.  
403 2019). Once a nest is located and then subsequently monitored, personnel should move far  
404 enough away from the nest to allow normal nesting behaviors to resume while data are recorded.  
405 Little Terns and Malaysian Plovers (*C. peronei*) were reported to reduce return times to the nest  
406 after a researcher visit during times of hotter ambient temperatures (Yasué and Dearden 2006,  
407 Amat et al. 2017). Since accuracy of nest fate determination decreases as clutch age increases (it  
408 is easier to determine fates for nests that fail during early incubation stages), nest monitoring can  
409 be minimized until the approach of the estimated hatch date (Andes et al. 2019).

## 410 **5. Acknowledgments**

411 We would like to acknowledge the contributions of Kasen Christiansen, Emily Foden,  
412 Anna Mattson, John McClinton, Devynarae Meeder, Melissa Murillo, Jessica Perkins, Mike  
413 Thiel, Dustin Toy and all of the USGS technicians for their assistance with camera setup and

414 maintenance. Thank you to Colin Dovichin for his help to initiate and develop this project. This  
415 work was supported by the U.S. Geological Survey 20098905-UND CESU G13AC00144; the  
416 Wheeler Foundation through the Department of Biology at the University of North Dakota; and  
417 the National Science Foundation under NSF EPSCoR Track-1 Women in Science and  
418 Engineering (WISE) Program OIA-1355466. Our field protocols were approved by the USGS  
419 Northern Prairie Wildlife Research Center Animal Care and Use Committee. All applicable  
420 ethical guidelines for the use of birds in research have been followed, including those presented  
421 in the Ornithological Council's "Guidelines to the Use of Wild Birds in Research." The data  
422 analyzed for this paper were collected under permits provided by the U.S. Fish and Wildlife  
423 Service (TE121914-0) and IACUC (#A3917-01, Protocol 1304-5). Any use of trade, firm or  
424 product names is for descriptive purposes only and does not imply endorsement by the U.S.  
425 Government. The dataset analyzed for this paper can be found at  
426 <https://doi.org/10.5066/P9ULK0ST>.

566

567

568

569 **Figure 1.** Daily minimum, maximum and mean sand temperatures at sites representative of  
570 interior Least Tern (*Sternula antillarum athalassos*) and Piping Plover (*Charadrius melodus*)  
571 nests on the Garrison Reach of the Missouri River, ND in a) 2014 and b) 2015.

572

573 **Figure 2.** Interior Least Tern (*Sternula antillarum athalassos*) and Piping Plover (*Charadrius*  
574 *melodus*) daily nest attendance (daily number of minutes spent sitting on or standing over at least  
575 one egg in the nest) in relation to daily maximum sand temperature on the Missouri River, ND  
576 during 2014—2015. Each dot represents the nest attendance at a single nest during one day (total  
577 days=157, Least Tern nests=22, Piping Plover nests=20).

578 **Figure 3.** Segmented linear models with 95% confidence intervals for duration (a) and  
579 frequency (b) of shading behaviors in relation to mean daily sand temperature exhibited by  
580 interior Least Terns (*Sternula antillarum athalassos*) (left), Piping Plovers (*Charadrius melodus*)  
581 (middle) and both species combined (right) on the Missouri River in North Dakota from 2014—  
582 2015. The dashed vertical lines indicate the estimated breakpoints where there is a change in the  
583 slope of the linear relationships between duration, frequency and mean temperature. The solid  
584 vertical lines represent the standard error of the estimated breakpoints.

585 **Table 1.** A subset of model-selection results with parameter estimates, standard errors and 85% confidence intervals (CI, Arnold  
586 2010) for the top 5 generalized linear mixed models (normal distribution) of interior Least Tern (*Sternula antillarum athalassos*) and  
587 Piping Plover (*Charadrius melodus*) nest attendance on the Missouri River, ND during 2014—2015. Daily nest attendance (total  
588 minutes spent sitting on or standing over at least one egg in the nest) was modeled in relation to the covariates: Species (Least Tern or  
589 Piping Plover), Clutch Age (age of the nest), Date (ordinal day of the breeding season), MAX (maximum sand temperature), MEAN  
590 (mean sand temperature) and MIN (minimum sand temperature).
