Abstract

Agricultural soils are a major source of atmospheric nitrous oxide (N₂O), a potent greenhouse gas (GHG). Because N₂O emissions strongly depend on soil type, climate, and crop manage-21 ment, their inventory requires the combination of biophysical and economic modeling, to simulate farmers' behavior. Here, we coupled a biophysical soil-crop model, CERES-EGC, with an 23 economic farm type supply model, AROPAj, at the regional scale in northern France. Response curves of N₂O emissions to fertilizer nitrogen (Nf) inputs were generated with CERES-EGC, and linearized to obtain emission factors. The latter ranged from 0.001 to 0.0225 kg N₂O-N kg⁻¹ Nf, depending on soil and crop type, compared to the fixed 0.0125 value of the IPCC guidelines. The modeled emission factors were fed into the economic model AROPAj which relates farm-28 level GHG emissions to production factors. This resulted in a N₂O efflux 20% lower than with the default IPCC method. The costs of abating GHG emissions from agriculture were calculated 30 using a first-best tax on GHG emissions, and a second-best tax on their presumed factors (live-31 stock size and fertilizer inputs). The first-best taxation was relatively efficient, achieving an 8% 32 reduction with a tax of 11 €/ t-CO₂-equivalent, compared to 68 €/t-CO₂ eq for the same target with the second-best scheme. **Keywords:** nitrous oxide, agro-ecosystem model, economic modeling, greenhouse gas, mitiga-35 tion measures Abbreviations: GHG - Greenhouse Gas; Nf - Fertilizer nitrogen; IPCC - Intergovernmental 37 Panel on Climate Change; CAP - Common Agricultural Policy; FADN - Farm Accountancy Data Network ; t-CO₂-eq - t DM-CO₂-equivalent ; LU - Livestock Unit; CERES-EGC: agro-39 ecosystem model simulating N₂O emissions; STICS: agro-ecosystem model simulating crop yields; AROPAj: economic farm model including GHG emissions; NOE: algorithm predicting N₂O emissions from soil drivers.

1 Introduction

44 1.1 N_2O emissions in agriculture

The global abundance of nitrous oxide (N_2O) in the atmosphere was 319.2 ppb in 2004, and had 45 been increasing at a rate of 0.74 ppb per year over the past decade WMO and WDCGG (2006). 46 Nitrous oxide is a potent greenhouse gas, with a global warming potential about 300 times higer 47 than the carbon dioxide (CO_2) . It is the third contributor to anthropogenic global warming, after 48 CO₂ and methane (CH₄). Nitrous oxide is naturally emitted from soils and oceans, but human ac-49 tivities also contribute a third of its overall release (WMO and WDCGG, 2006). Policy measures aiming at abating anthropogenic emissions of N₂O are thus being actively sought. At the country 51 level, the agricultural sector is generally the first anthropogenic source of N₂O. In France, its share was estimated at 76% in 2004 (CITEPA, 2008), when summing the emissions related to land-use and to the use of synthetic fertilizer nitrogen (Nf). Agricultural N₂O emissions are known to depend on Nf inputs of to a large extent (Houghton 55 et al., 1996). Besides, excessive use of fertilizer N is also responsible for the increase of ni-56 trate leaching (Beaudoin et al., 2005; Schnebelen et al., 2004) and ammonia (NH₃) emissions 57 (Herrmann et al., 2001). Nitrate pollution of groundwater is a well-known environmental prob-58 lem, particularly harmful for aquatic ecosystems, while NH₃ is a major atmospheric pollutant with impacts on atmospheric chemistry and on the stability and the biodiversity of terrestrial and aquatic ecosystems (Asman et al., 1998). However, the emission of these reactive N compounds 61 are not solely related to fertilizer inputs, inasmuch as they occur throughout the N cycle in the soil. Complex processes involving soil microbiology affect the dynamics of inorganic and organic forms of nitrogen in the soil, with the result that N losses by arable systems are tightly related to environmental conditions, and chiefly climatic sequence and soil type.

Coupling economic and biophysical models to assess N2O emissions 1.2

The Kyoto protocol (1997) is an agreement made under the United Nations Framework Convention on Climate Change. It requires signatory countries to inventory and report emissions for a set of greenhouse gases (GHG), including N₂O on an annual basis to monitor their time course. Guidelines were set up by the Intergovernmental Panel on Climate Change (IPCC) to help these 70 countries in their national inventories (Houghton et al., 1996), with a tiered approach. The simplest and most used methodology provided by the IPCC (Tier 1) relies on generic, fixed factors to convert national statistics on economic activities into GHG emissions. Because these factors 73 are default ones, they should not be considered as an exclusive standard. Caution is expressed in 74 the guidelines regarding "the default assumptions and data which are not always appropriate for specific national contexts". The development of alternative methodologies, as permitted under the Tiers 2 & 3 of the latest IPCC guidelines (IPCC, 2006), thus appears as a promising way to assess GHG emissions more accurately.

79

87

The major shortcoming of the IPCC default method lies in its ignoring the complexity of the 80 microbiological processes responsible for N₂O emissions (nitrification and denitrification; Fire-81 stone and Davidson 1989). Also, it is necessary to take into account the effects of soil charac-82 teristics, climate, crop management and land use in the assessment of the N₂O emissions (Granli 83 and Bockman, 1995; Smith et al., 1998; Ruser et al., 2001), and their variability in both space and time (Kaiser et al., 1998; Dobbie et al., 1999; Smith et al., 2004). 85 Contrary to the IPCC Tier 1 method, biophysical soil-crop models have the potential to deal with these drivers, and may be used to assess more accurately the amounts of N₂O emitted from agri-

the complexity of nitrogen cycles pathways in the soil-crop-atmosphere system, they are also

cultural soils, in relation to crop management (Neufeldt et al., 2006). As those models integrate

NO₃, NH₃ and NO). However, while there exist spatially-explicit maps for the biophysical input parameters of these models (including soil properties and climatic data), information on crop management on the same mapping units proves much more challenging to infer because of the 93 variety of agricultural production systems present within a given geographical zone. Such data are usually obtained through field surveys, regional statistics or farm accountancy data, but their scales do not match that of the spatial units relevant to the biophysical processes at stake (Leip et al., 2008). Intersecting the two levels practically implies the use of agricultural fields as ele-97 mentary objects. Economic models at the farm level provide a unique means of predicting and 98 scaling down management data from aggregated statistics. Coupling economic and biophysical 99 models has therefore emerged as a promising route to address the environmental impacts of agri-100 culture and their regulation (Vatn et al., 1999; Godard et al., 2008), tackling the issue of spatial 101 and temporal variability in environmental losses. However, because economic and biophysical 102 models do not operate at the same level, disaggregation techniques are required to generate man-103 agement information at the scale relevant to biophysical processes. These include econometrics, 104 Bayesian inference of spatial distribution parameters based on physical co-variables (Leip et al., 105 2008), and expert knowledge (Godard et al., 2008; Godard, 2005). 106

Recent work has underlined the usefulness of such coupling in the estimation of GHG emissions from agriculture at regional (Neufeldt et al., 2006) to continental (Leip et al., 2008) level. The latter authors fed outputs from economic modeling of agricultural activities at farm or regional level to a biophysical model, DNDC (Li et al., 1992), to predict the GHG balances of statistically representative farms or homogeneous simulation units. They highlighted the large variability of N₂O emissions across landscape, soil, climate characteristics and farming systems. However, they did not address the effects of taking this variability into account when designing policies to regulate GHG emissions from agriculture, which is the focus of this paper. In principle, it should

107

allow more accurate studies on the effects of public policies, because agro-ecosystem models
can deal with heterogeneities occuring at finer scales.

1.3 Modeling the efficiency of mitigation measures for greenhouse gas emissions from agriculture

For countries having ratified the Kyoto Protocol, there is a need to investigate the efficiency of GHG mitigation measures, including their economic costs. Economic models have a capacity to 121 simulate the impact of various policy scenarios of the agricultural sector, in our case. Coupling 122 them with biophysical agro-ecosystem models is thus a promising way to appraise the efficiency 123 of pollution mitigation policies, and of GHG emissions in particular. Economic regulation aim-124 ing at mitigating environmental damage leads to consider two standardized taxing schemes: a 125 first-best scheme levying a tax on the direct damage, such as the quantity of pollutants dumped 126 into the environment; and a second-best scheme taxing the presumed factors of the damages incurred (Henry, 1989; De Cara and Jayet, 2000b). First-best taxing allows a very tight linkage 128 with damages, and thereby theoretically the best economic efficiency in its abatement. It usu-129 ally refers to an ideal world where information is fully accessible and transaction costs are as 130 small as possible. Although the underlying assumptions are never satisfied in the real world, the 131 first-best option provides the 'best possible world' reference. Namely, in our case, this situation 132 refers to a world where farmers do actually optimize their N fertilizing level to maximize their 133 profit, based on their knowledge of the relationships between yield and GHG emissions and Nf 134 rates. It implies they would make the most of the information currently provided to AROPAj 135 by the biophysical models. This reference corresponds to what could be expected in terms of welfare, including environmental economics, when the best options are implemented into the 137 system. However, it requires a detailed knowledge of the actual damage, an information which 138 is very costly if not impossible to obtain. In practice, it is thus more convenient to consider the 139

production factors presumed to be responsible for the damage, which may be better-known and measurable. This leads to the implementation of a second-best taxation, which usually results in a loss in the efficiency of the mitigation measure ¹. Second best options are obviously more relevant for policy makers, and incur a loss of welfare which is interesting to assess. Here, we investigated two possible measures for the reduction of GHG emissions from agriculture, using either a first-best tax on the GHG emissions or a second-best tax on their presumed management factors.

147

Godard et al. (Godard et al., 2008; Godard, 2005) coupled the biophysical crop-model STICS 148 (Brisson et al., 1998) and the economic farm type model AROPAj (De Cara and Jayet, 2000a), 149 which is based on the European data of the Farm Accountancy Data Network (FADN; see section 150 2.2 for a detailed presentation). This linkage made it possible to simulate the response of crop 151 yields to fertilizer nitrogen (Nf), in various regions of the European Union (EU), and thereby 152 predict the effect of various GHG emissions taxation scenarios on farmers' crop management 153 practices. Currently, with the AROPAj model, the consequences in terms of GHG emissions at 154 the farm type level were estimated using the optimized Nf doses and the IPCC default emission 155 factor of 1.25% for N_2O (whereby 1.25% of applied Nf is evolved as N_2O). 156

157

Here, we set out to further the analysis by using a biophysical crop model to predict the N_2O emissions, instead of the fixed emission factor of the IPCC Tier 1 methodology. Such an approach allows for improved relationships between farming activities and N pollution, and should benefit the economic analysis of GHG emissions and mitigation. This is especially relevant since agriculture is a major contributor to N_2O emissions. This paper thus focuses on the derivation of N_2O emission functions and on the impact of their implementation in an agricultural economic model, regarding GHG emissions and the efficiency of two GHG taxation schemes. Ideally, the

same biophysical model could have have been used to simulate both the response of crop yields 165 to Nf and the emissions of N₂O. However, because the STICS model does not simulate N₂O 166 emissions as yet, we had to use another one for N₂O. We selected the CERES-EGC crop model 167 (Gabrielle et al., 2006a) for the coupling, as it struck a good balance between process description level and ease of use. 169 The objectives of this work were thus three-fold: i/ to build response curves relating N₂O emis-170 sions from cropland to fertilizer N application rates using the CERES-EGC model, ii/ to input 171 these results to the economic model AROPAj to assess the regional N₂O emissions from agricul-172 ture, and iii/ to investigate the effects of various mitigation measures. We focused on the Picardie 173 region in Northern France, but the following methodology could easily be extrapolated to any 174 FADN region within the EU.

176 2 Materials and Methods

77 2.1 The biophysical model CERES-EGC

CERES-EGC was adapted from the CERES family of soil-crop models, which have been extensively tested worldwide for more than 20 years (see Jones et al. (2005) for a review). This particular version focuses on environmental outputs (nitrate leaching, gaseous emissions of N₂O, 180 ammonia and nitrogen oxides). It comprises sub-models that simulate the major processes gov-181 erning the cycles of water, carbon and nitrogen in soil-crop systems, on a daily time step. A 182 physical module simulates the transfer of heat, water and nitrate down the soil profile, as well 183 as soil evaporation, plant water uptake and transpiration in relation to climatic demand. Water 184 infiltrates down the soil profile following a tipping-bucket approach, and may be redistributed 185 upwards after evapo-transpiration has dried some soil layers. In both of these equations, the 186 generalized Darcy's law has subsequently been introduced in order to better simulate water dynamics in fine-textured soils. A microbiological module simulates the turnover of organic matter in the plough layer, involving both mineralization and immobilization of inorganic N (Gabrielle and Kengni, 1996). Ammonia volatilization is calculated using a classical resistance model for turbulent transport between the soil surface and the atmosphere, and physico-chemical equilibriums in the liquid and gaseous phases of the topsoil, as a function of soil pH and ammonium concentration. The model is available for a wide range of crops, and was tested against experimental data for a broad range of agronomic and pedoclimatic situations, mostly in France and in Europe, for the simulation of crop yields, soil water and N dynamics, nitrate leaching, or gaseous losses (Gabrielle and Kengni, 1996; Gabrielle et al., 2002; Rolland et al., 2008). In particular, it was used to simulate N₂O emissions from wheat crops at the field and regional scales (Gabrielle et al., 2006a,b; Gabrielle and Gagnaire, 2007), using a large database of field-scale observations over Northern France (Lehuger et al., 2008). Figure 1 presents a general schematic of the model, with the various modules involved.

[Figure 1 about here.]

NOE is the semi-empirical sub-model used in CERES-EGC to simulate the production and re-duction of N₂O in agricultural soils (Hénault et al., 2005). NOE simulates N₂O release through the denitrification and nitrification pathways. The total denitrification of soil NO₃⁻ is calculated as the product of a soil-specific potential rate with three unit-less factors related to soil water content, nitrate content and temperature. The fraction of denitrified nitrate that evolves as N₂O is then considered as constant for a given soil type. Nitrification is modeled as a Michaëlis-Menten reaction, with NH_4^+ as substrate. The corresponding rate is multiplied by unit-less modifiers related to soil water content and temperature. A soil-specific proportion of total nitrification evolves as N2O.

2.2 The AROPAj economic farm-type model

AROPAj is a linear programming model which simulates the agricultural supply of the European Union regions (De Cara and Jayet, 2000a; Godard et al., 2008). For a given economic situation (i.e. a set of prices, taxes and policy measures), it provides an assessment of the type and amount of the agricultural products delivered on the markets. This model is mostly used to study the successive reforms of the Common Agricultural Policy (CAP) of the European Union (Jayet and Labonne, 2005), but it has been used also to address global agro-environmental problems such as agricultural GHG emissions (De Cara et al., 2005).

221

AROPAj is built as a set of independent sub-models, each of them simulating the behavior of a category of producers as related to a 'farm-type' (Chakir et al., 2005). The farm types result 223 from the clustering of individual farms described in the Farm Accounting Data Network (FADN), 224 using (i) FADN normalized farm types, (ii) elevation class, and (iii) normalized economic size. 225 Clustering is done at the FADN-Region level. Farm types are weighted by a parameter estimated 226 through the individual weights provided by the FADN. These farm types are statistically repre-227 sentative of actual production systems at the regional level, and reflect the behavior of the farmers 228 assuming that they optimize their gross margin. A detailed presentation of the AROPAj model 229 is available in (Chakir et al., 2005; De Cara and Jayet, 2000a), while additional information is also provided by deliverables from the GENEDEC project¹. In the version of the AROPAj model 231 used in this study, French agriculture is divided into 131 farm types, among which 4 are located 232 in the Picardie Region. 233

Figure 2 presents a schematic of the AROPAj model, deatailing its input parameters, constraints, and outputs. The variables taken into account in AROPAj include the area of each crop (among a total of 32 crop activities), the livestock size per animal type (with 31 pre-defined classes),

¹http://www.grignon.inra.fr/economie-publique/genedec/eng/enpub.htm

the quantity of meat, milk, grains or other crop types produced, the quantity of animal feed purchased, and the opportunity cost of land.

239

240

241

[Figure 2 about here.]

AROPAj includes a GHG calculation module inventorying around 20 sources of CH₄ and N₂O 242 from livestock and arable farming, based on the IPCC Tier 1 guidelines. Methane is produced 243 by enteric fermentation of mono-gastric livestock, manure management, and rice cultivation. Ni-244 trous oxide is mostly produced by agricultural soils as a result of mineral Nf application, manure 245 application as well as soil incorporation of crop residues. The model assumes that the most im-246 portant factors behind GHG emissions may be assumed to be livestock size (for CH₄ and N₂O), 247 and nitrogen fertilizer use (for N₂O) (De Cara et al., 2005). By default, N₂O emissions from soils are assumed proportional to Nf inputs (Bouwman, 1996), ignoring the background emissions (considered non-anthropogenic). Thus, N₂O emissions represent a fixed fraction of the 250 inputs. This fraction, referred to as the emission factor, is set to 1.25% by default in the Tier 1 251 methodology (Houghton et al., 1996). However, the emission factor may be varied in AROPAj, 252 in order to explore alternative estimation methods. 253

254

255

257

258

In the implementation of AROPAj we used, it is important to note that the utilized arable area for each farm-type is constant. Also, cattle farmers have the possibility to adjust their livestock within a range from 85% up to 115% of their initial size. Within AROPAj it is possible to introduce various mitigation measures, such as taxes on GHG emissions, on animals or on the fertilizer N use, and to examine their effects on the model outputs.

Coupling CERES-EGC and AROPAi 2.3

2.3.1 Principles of the coupling: Nf-response curves

The coupling is based on the introduction in AROPAj of two mathematical relationships, relating Nf rates to crop yields and N₂O emissions, respectively. The former were generated with the methodology developed by Godard et al. (2008), by running the STICS model over a range of Nf rates for various possible combinations of other crop production factors (soil type, crop management practices, climate) specific to each farm type. The methodology to determine those factors and the input data is detailed in Godard et al. (2008). Thus, a series of points (Nf rate and crop yield) were obtained for each crop in all farm types, and an exponential function was fitted to these series. Such a form of function met economic requirements for the estimation of a mathematical optimum (ie, a concave shape with 1st derivative greater than 0), being altogether consistent with the expected agronomic response (Godard et al., 2008). Hence, the following function was selected:

$$Y(Nf) = Ymax - (Ymax - Ymin) \times e^{-\tau Nf}$$
(1)

where Y(Nf) is the crop yield (in t ha⁻¹), Nf is the fertilizer N rate (kg N ha⁻¹), τ the rate of 262 increase (curvature) of the yield function, and Ymin and Ymax are the minimum and maximum (asymptotic) yields, respectively. This relationship was derived by running the STICS model 264 with the same input data and adjustment procedure as Godard et al. (2008). 265

The relationship between N₂O emissions and Nf was generated by running the CERES-EGC models in the same conditions as with the yield response curve, namely the same biophysical 268 inputs and Nf range for each crop in all farm types. The resulting yearly N₂O emissions curves 269 were regressed against Nf assuming a straight-line, following the 'emission factor' approach of 270

the IPCC Tier 1 methodology.

266

267

2.3.2 Simulation scenarios with the coupled models AROPAj and CERES-EGC

The two relationships Nf-yield response curve and N₂O emission factor were fed into the AROPAj 273 model. The yield response curves were input in the form of the exponential function given in eq. 1, specific for each crop of each farm type, as were with the N₂O emission factors generated 275 with the CERES-EGC simulations. An exception was made for the crops not simulated with 276 CERES-EGC, in which case the IPCC default value of 1.25% was used. The CAP agenda 2000 277 scenario (De Cara et al., 2005) was implemented in the economic model that was also run under 278 a set of taxation rules, in which case the farmers could be expected to adjust their fertilizer doses 279 taking into account these new economic environment. The objective of this paper was to study 280 the variation of N₂O emissions and the effect on them of various taxation scenarios, under vari-281 ous modeling assumptions relating the biophysical model CERES-EGC and the economic model 282 AROPAj. After having checked the consistency of the yield-Nf response curves obtained with 283 the CERES-EGC and the STICS models, the N2O emissions factors were computed from the 284 CERES-EGC simulations. Two simulation scenarios for crop yields and two simulation scenar-285 ios for N₂O emission factors were tested. In the first variant for yields (referred to as EXOG in 286 the following), the yields were considered constant and fixed at the values given in the FADN for 287 each crop and farm type. The total nitrogen fertilizer inputs were estimated based on the costs of 288 each crop and farm type, as extracted from the FADN data. In the second variant for crop yields 289 (noted ENDOG), the yields and the fertilizers rates were calculated by optimizing the field's gross margins based on the response curves. This led to solve simple mathematical programs of 291 the type ' $max_N f [p Y(Nf) - w Nf]$ subject to $Nf \ge 0$ ', where Nf is fertilizer N input rate, p 292 is the crop selling price, Y(Nf) is the crop yield, and w is the market price of fertilizer N. Within 293 this "ENDOG" scenario, changes in fertilizer costs due to taxes on this commodity are expected 294 to alter the optimum Nf rate. For comparison with the IPCC method, the N₂O emissions of the 295 farm types were assessed with AROPAj either with the default emission factor (noted IPCC) or

with the CERES-EGC derived emission factors (noted CERES). Table 1 summarizes the four simulation scenarios tested with the AROPAj micro-economic model.

[Table 1 about here.]

2.4 Crop simulations at the regional level

299

319

Since this work directly follows that of Godard et al., and involves comparison with her results, 301 we chose the same simulation conditions. We focused on the Picardie region (northern France), 302 which is characterized by an important agricultural activity based on intensive cereal, sugar beet, 303 potato, oil and protein-producing crops. Its climate is temperate and mild, with marine influence. 304 The annual rainfall is 630 mm, and the mean annual air temperature is 10.6 °C. In the AROPAj 305 model, the Picardie region is represented by four farm types (CrPi1, CrPi2, CaPi1, and CaPi2) 306 representing, respectively, 2819, 4786, 2116, and 1002 real farms. They involve both arable and 307 arable-livestock farming. The harvest year of the simulations is 1997 because the economic data 308 used by AROPAj are derived from the FADN data for this particular year. Since all farm types belong to the same AROPAj altitude class (namely, less than 300 meters above sea level), we 310 considered only one set of daily weather data for the whole Picardie region (Godard et al., 2008). 311 We used weather data for the years 1995 through 1997, to take into account the preceding crop. 312 The main data sources and methods to estimate inputs for the biophysical models are listed in 313 Table 2. Readers are referred to Godard et al. (2008) for a full description of these databases. The 314 characteristics of the cases studied in Picardie are presented in Tables 3 (for the farm types and 315 crops) and 4 for soils' properties. CERES-EGC uses the same soil parameters as STICS with 316 the exception of specific additional parameters needed by the nitrification and denitrification routines. Those were obtained from references involving similar soil types, as listed in Table 4. 318

[Table 2 about here.]

14

Simulations with the CERES-EGC model for the studied cases for yield and N_2O Nf-response curves were carried out with yearly Nf rates varying from 0 to 400 kg N ha⁻¹, in 20 kg N ha⁻¹ increments.

[Table 3 about here.]

323

324

325

[Table 4 about here.]

The variation in the earliness implies a variation in the dates of the phenological stages of the

crops, and thus in the fertilizers application dates (Godard, 2005). We started the simulations 326 upon sowing of the preceding crop in order to smooth out the effects of initial soil conditions 327 setting. The preceding crop was either a non-fertilized pea or a fertilized soft wheat. Since we 328 focused on N-losses in relation to Nf application, and because the processes in the nitrogen cycle 329 responsible for the various N-losses do not instantly respond to Nf inputs, it may be relevant 330 to include the N losses occurring over the next few years of the crop rotation. However, as the 331 economic model only takes into account the year of the FADN data (1997, in this case), we only 332 used the N-loss estimates for this year. 333 Not all crops grown in Picardie could be simulated by the CERES-EGC model: such was the case 334 for potato and sunflower, which have not yet been implemented in the model. However, as shown 335 in Table 5, we worked with the major crops present in Picardie: wheat, barley, maize, rapeseed 336 and sugar beet cultivation made up 74% of the total arable area of the region in 1997 (AGRESTE, 337 1997). For the crops that were not simulated with CERES-EGC, we kept the default yield and Nf 338 values, i.e. the ones from the FADN of the year 1997. Since there was some livestock farming 339 in the region, manure N was taken into account in the yield response curves simulated by STICS (Godard et al., 2008). Emissions of GHG from manure handling and spreading are included 341 in AROPAj, based on IPCC guidelines and regional coefficients. Since CERES-EGC was not 342 used to simulate the direct emissions of N₂O resulting from manure application, there were no modeled emission factors for manure N input and we used the IPCC Tier 1 emission factor of $0.0125 \text{ kg N-N}_2\text{O kg}^{-1} \text{ Nf}.$

350

3.1 Response of N_2O emissions to nitrogen fertilizer inputs

3.1.1 Simulation of N_2O emissions across crops and farm types

[Figure 3 about here.]

Figure 3 presents the N₂O emissions simulated with the CERES-EGC crop-model, for Nf rates varying from 0 to 400 kg N ha⁻¹, in the various regional cases. Generally, N₂O emissions in-352 creased as Nf increased. Strong differences occurred between the cases in the magnitude of 353 the N₂O emissions. For a 400 kg N ha⁻¹ fertilizer input, N₂O emissions reached as much as 354 $3.5 \text{ kg N}_2\text{O-N ha}^{-1}$ for soft wheat, and nearly $11 \text{ kg N}_2\text{O-N ha}^{-1}$ for sugar beet. In the medium 355 range of Nf (around 200 kg N ha⁻¹) corresponding to the actual application rates determined 356 with the Nf yield response curves (Godard et al., 2008), the emissions rates ranged from 0.60 357 for winter barley to 7.61 kg N₂O-N ha⁻¹, and averaged about 2.94 kg N₂O-N ha⁻¹ across the 358 various cases. This value is very close to the average flux of 2.7 kg N₂O-N ha⁻¹ reported by 359 (Leip et al., 2008) for the whole of France with a similar mean application rate (201 kg N ha⁻¹), 360 and to the 1.94-2.53 kg N₂O-N ha⁻¹ range by (Neufeldt et al., 2006) for the Baden-Wurtemberg region of Germany. 362 There was a stark contrast between winter- and spring-sown crops, with emissions being higher 363 by a factor of 2 for the latter compared to the former. This may be explained by the fact that Nf 364 application occurred later in the season for spring crops, when temperature conditions are more 365 conducive for nitrification and denitrification. These processes may also be enhanced because 366

of the build-up of inorganic N from spring mineralization of soil organic matter under the bare 367 soil preceding the planting of spring crops. However, this may be a specific to the environmental 368 conditions of Picardie. In Baden-Wurtemberg, an opposite trend was noted with winter cereals 369 emitting slightly more N₂O than spring types (Neufeldt et al., 2006). This highlights the interplay 370 between climate, soil conditions and crop management which may produce different outcomes 371 depending on their respective dynamics. 372 Besides, the response pattern to the Nf input differed significantly between cases, to the extent 373 that in a 2 cases out of 12 (involving soft wheat crops) the model simulated a decrease of N₂O 374 emissions when Nf increased. This may be seen for case 6 on Figure 3, and was actually due to 375 the fractionation scheme for fertilizer application, which changed around that rate. Under a total 376 dose of 80 kg N ha⁻¹, fertilizer was applied all at once in mid-April, whereas it was split into 2 377 applications (early March and mid-April) above. This split resulted in a higher growth potential 378 for the wheat in early spring, and a higher N use efficiency (and hence lower emissions) following 379 subsequent Nf inputs. This feedback leading to counter-intuitive results may still be an artefact 380 of the model simulations, but nevertheless reflects the long-established agronomic principle that 381 split applications increase Nf use efficiency. The resulting regression curve was somewhat sen-382 sitive to the 4 first data points, since shifting them down to force a monotonic response increased 383 its slope from 0.58% to 0.70%. This slight variation would have had limited consequences in the 384 economic modeling, and we kept the original simulation curves to maintain the consistency of the models' coupling. Note that the economic model uses the regression coefficients (and not the jagged simulation line itself). Other than that, the response curves obtained with CERES-EGC 387 for the different cases varied according to of one or several of their specific parameters: soil and 388

390

389

crop types, sowing date, and previous crop.

The straight lines (noted *Bouwman assessment*) on Figure 3 represent the N₂O emissions as-

sessments according to the equation $E_{N_2O}=1+0.0125*Nf$, with E_{N_2O} is the annual direct 392 emission of N₂O (kg N-N₂O ha⁻¹) and Nf the fertilizer N rate (kg Nf ha⁻¹) (Bouwman, 1996). 393 This linear model is used as the default IPCC methodology (Tier 1) (Houghton et al., 1996), 394 and represents the current calculation of the N₂O emissions in the AROPAj economic model, with the difference that the background emissions (in the absence Nf inputs) are not taken into 396 account. The Bouwman equation and the CERES-EGC response curves never matched, whether 397 regarding the background emission rates or the slope of the curves. Depending on the cases, the 398 former led to either lower of higher estimates than those resulting from the biophysical modeling. 399 Such discrepancies were also noted in a study on N₂O emissions from winter wheat crops in a 400 neighboring region, where the modeled N₂O emissions were 40% to 80% lower than estimated 401 with the Tier 1 emission factor (Gabrielle et al., 2006b). When compared with observations at the 402 field-scale, the CERES-EGC model had a mean deviation typically ranging (in absolute values) 403 from less than 1 to 5 g $N-N_2O$ ha⁻¹ d⁻¹ (Gabrielle et al., 2006a,b), which may be considered as 404 resulting in unbiased predictions at the yearly scale given the high temporal variability of these 405 fluxes (Hénault et al., 2005). These gaps between the two estimation methods also stress the im-406 portance of a finer assessment of the N₂O emissions with a biophysical model that can take into 407 account regional variations in soil and climate conditions, along with crop management practices. 408

409

413

414

415

While CERES-EGC model was only applied to one year, the inter-annual variability of climate was likely to affect its simulation of N₂O emissions in the long run. In a study on GHG emissions from arable crops in the same region, Gabrielle and Gagnaire (2007) found coefficients of variations of up to 80% across the years when running the same model on a 30-yr series of past weather data. However, the differences between crops were persistent over the years, as did the discrepancies between the IPCC Tier 1 estimates and the modeled emissions. Thus, inter-annual variability should not undermine the tendency obtained with the particular year we used here

when comparing our biophysical/economic modeling with approaches that fully ignore soil and climate variability. From a quantitative point of view, and to put our particular simulation year into prospective, it should lastly be mentioned that it led to N_2O emission levels 30% lower than the 30-yr average for the cases simulated here. Thus, the discrepancies with the IPCC Tier 1 estimates were probably slightly over-emphasized.

3.1.2 Regression analysis and link with economic model

430

The N_2O response curves simulated by CERES-EGC for the various cases were input to the economic model AROPAj in the form of linear regression coefficients. Note that the rather variable levels of background emissions, in the absence of fertilizer inputs (ranging from 0.37 to 3.67 kg N_2O-N ha⁻¹), were not input to AROPAj, since they were deemed natural and not anthropogenic. However, the fact that they varied across crops (contrary to the Bouwman (1996) equation) underlines the arbitraty limitation of this convention. Table 6 presents the characteristics of the linear regressions of N_2O emissions against Nf inputs.

[Table 6 about here.]

The linear regressions fitted the N₂O emission response curves rather well, with R-squared values 431 ranging above 0.80 in 8 cases out of 12. Such pattern was also reported by Neufeldt et al. (2006) 432 with the biophysical model DNDC in the Baden-Wurtemberg region of Germany, with an \mathbb{R}^2 433 of 0.79 for the same types of crops and Nf rates ranging from 40 to 250 kg N ha⁻¹. However, 434 for two cases involving soft wheat, the N₂O emissions curves presented an important dip (see 435 case 6 on Figure 3). This particular pattern in the response curve was ignored by the linear 436 regression, and resulted in poorer R² values. Non-linear models were also tested, including an exponential model, which achieved a better fit and a lower residual standard error. However, 438 the latter remained relatively low and acceptable with the linear models, being for instance of 439 only 0.13 kg N_2O -N ha^{-1} for the wheat crops, i.e. less than 10% of the annual total for the optimal fertilizer rate. We reverted to the liner model, considering it sufficient to address the first-order effect of our approach, which stems from the slope of the regression curve being in sharp contrast with the Tier 1 IPCC emission factor. Deviations from the linear response curves are a second-order effect, which would be worth tackling in future work.

445 3.2 Impacts of response functions to nitrogen input in economic modeling.

3.2.1 Regional GHG emissions and economic margins

447

448

[Figure 4 about here.]

[Figure 5 about here.]

Figures 4 and 5 present the AROPAj results for the N₂O emissions and the global GHG emis-449 sions for the whole Picardie region. The emission factors obtained with CERES-EGC led to a 450 reduced estimate of N₂O emissions, whether with the exogenous or endogenous yields, with a 451 20% decrease compared to the IPCC estimate. Whatever the emission factors, the emissions of N₂O were also 30% lower with the endogenous yields than with the exogenous ones. This could 453 be expected, since the use of yield response curves allowed a higher efficiency of fertilizer use 454 by crops, and thus led to an overall reduction in fertilizer consumption by farmers. With the en-455 dogenous yields, the model was also more reactive to the CAP 'Agenda 2000' scenario, resulting 456 in changes in the management of each farm type: the areas allocated to each crop were slightly 457 modified, as well as crop yields, so were the GHG emissions. 458 Total GHG emissions followed the same pattern as the N₂O emissions across the simulation sce-459 narios (Figure 5), being lower with the CERES-EGC emission factors compared to the IPCC 460 one, and lowest with the endogenous yields. Obviously, GHG emissions from animals were not affected by the choice of the N₂O emission factors. On the one hand, as was expected, the gross 462 margins, crop areas and crop productivity levels calculated by AROPAj were not impacted by 463 the changes in N₂O emissions' estimates (IPCC vs CERES). On the other hand, changes in the yield assessment method in AROPAj (EXOG vs ENDOG) strongly affected the AROPAj results.

The total gross margin increased by 5% with the endogenous method compared to the exogenous one, reflecting the higher efficiency of Nf inputs and marketable yield levels permitted by the yield response curves. This increase was higher for the arable crops specialized farm types (CrPi1 and CrPi2), and lower for the livestock-oriented farm types. The total arable area of the farm types was not modified because the AROPAj model considers them as constant. Nevertheless, the breakdown of arable area among crops was modified: there was a slight increase in cereal crops, industrial crops and pea, and a decrease in fodder crops.

473 **3.2.2** Mitigation measures and taxation schemes

Various tax policies may be implemented within AROPAj, using different parameter sets. In order to mitigate the total GHG emissions, and thereby the emissions of N_2O , we enforced two taxation schemes: a first-best scheme directly taxing the GHG emissions; and a second-best scheme taxing the presumed factors behind the GHG emissions.

478 Direct taxation of GHG emissions

479

[Figure 6 about here.]

We studied for each of the simulation scenarios presented in Table 1 the effects of an increasing tax on the GHG emissions, ranging from 0 to 100 € per t-CO₂-eq. Figure 6 presents the results for the Picardie region regarding the total GHG emissions and their abatement. As expected, the GHG emissions decreased as the tax level increased, for all simulation scenarios. The major difference between the scenarios was due to the yield assessment method: GHG emissions were significantly higher with the exogenous method than with the endogenous one. This could be expected since farmers have more degrees of freedom avaiable with the endogenous yield determination to maximize N use efficiency and abate GHG emissions than with the fixed, exogenous

yields. The rate of abatement was also higher with the endogenous yields. However, these pat-488 terns were affected by the N₂O emission factors, which drastically changed the magnitude of the 489 emissions, and to a minor extent the abatement rates. Examination of the level of tax needed to 490 achieve a given target of GHG mitigation corroborates this analysis. The three horizontal lines 491 on Figure 6 present three mitigation targets of 4, 8 and 12% compared to the baseline emissions 492 (ie in the absence of GHG-related taxes). Their intersection with the GHG emission curves ob-493 tained with the four simulation scenarios provide an estimate of the tax level required to meet 494 these targets, which are quantified in Table 7. 495

[Table 7 about here.]

Higher taxes on GHG emissions were necessary to reach a given mitigation target with the exogenous yield assessment compared to the endogenous one. This gap widened as the mitigation
target increased: taxes with the exogenous yields were twice higher than with the endogenous
yields for the 4% mitigation target, and 3 to 4 times higher for the 8% target. Differences between
the N₂O assessment methods were also evidenced. Generally, the tax level needed to achieve a
given mitigation target was slightly higher when using the CERES-EGC emission factors than
the IPCC one, and this gap widened as the mitigation target increased.

504 505

506

508

509

510

511

496

[Figure 7 about here.]

The same tendencies were observed with the total gross margin for the whole Picardie region and its response to increasing tax on GHG emissions (Figure 7). There was a notable difference between the two yield assessment methods, with a higher gross margin with the endogenous yields. In addition, the reduction in the gross margin as the tax increased was significantly lower with the endogenous method than with the exogenous one. Indeed, the former allows a better

reactivity of the farmer to changes in crop prices, and thereby to political measures. These gross margin results also evidence small differences due to the use of the CERES-EGC emission factor, which became more pronounced as the tax level increased.

This first-best tax on GHG emissions allows the public regulator to reach ambitious target of environmental damage abatement. However, such taxation is very costly to implement because each farmer's GHG emissions must be precisely known. Economically and practically speaking, it is unfeasible to measure these GHG emissions on each arable field. That is why we also compared that first-best scheme with its alternative, a second-best scheme taxing the presumed factors of the environmental damage.

Taxing the presumed factors of the GHG emissions

AROPAj calculates the emissions of two GHG: methane (CH₄) and N₂O. Because farming activ-522 ities are globally affected by any change in the economic environment, changes in land allocation 523 between marketed crops, fodder crops and pastures (linked to livestock farming) have to be im-524 plemented in our framework. We thus included the methane emissions and livestock activities in the below results. As livestock or nitrogen fertilizer consumption are easily observable factors (through the CAP or the markets), they may serve as a basis for a second-best GHG mitigation 527 policy. It would lead to tax the livestock population and the fertilizer use of each farm type. We 528 thus implemented such a scheme in the AROPAj model, and its effects on GHG emissions using 529 the four simulation scenarios of Table 1. 530

531

532

[Figure 8 about here.]

Figure 8 presents the results of AROPAj simulations with a combination of two taxes: one on
Livestock Units ² (in €/LU) and one on nitrogen fertilizer input (in €/t Nf). The curves present
the combined tax needed to reach a certain level of reduction (2 to 12% reduction of the total

GHG emissions - in relation to the baseline level of emissions). Similar to the first-best taxation, important differences occurred between the exogenous and endogenous yield assessment 537 methods. With the exogenous yields, reasonable mitigation targets were harder to reach: a 2% 538 or higher reduction in GHG emissions required both taxes on LU and Nf to be higher than 200 €(per LU or t Nf). With the endogenous yields, such tax levels make it possible to abate 540 the emissions by more than 10%. It is important to note that in the current implementation of 541 AROPAj, contrary to crop yields, animal productions are not optimized against their production 542 factors. The production levels of meat or milk are not related to the levels of animal feed sup-543 ply. Obviously, such assessment would confer more reactivity to the model, and a more realistic 544 response to the second-best taxation. The graphs also show an effect of the method used for the 545 assessment of N₂O emissions. Overall, the taxes were higher with the CERES-EGC emission factors than with the IPCC one for the same reduction target. Using the endogenous yields, a 12% reduction of the GHG emissions was attained with a tax on fertilizer N ranging from 180 548 to 250 €/t N with the IPCC emission factor, compared to a 240 to 250 €/t N range with the 549 CERES-EGC emission factors. 550

551

Second-best taxes should be quite high to reach a given target of GHG emission abatement, 552 much higher than the first-best tax when expressed in €/t-CO₂ eq abated through the physical 553 relationship between the factor and the emission. For an 8% reduction in GHG emissions, the first-best tax was around 11 €/t-CO₂ eq, whereas the second-best tax could reach as high as 125 €/t N and 110 €/LU. Considering that 1 t of Nf produces about 4 t-CO₂ eq, and that 1 LU 556 produces 3 t-CO₂ eq, the equivalent tax on GHG emissions for the second-best taxation would be 557 68 €/t-CO₂ eq, i.e. 6 times higher than the first-best tax. Moreover, the relative efficiency of the 558 second best tax scheme compared to first-best one may be highly dependent on the abatement 559 target. Therefore, an analysis of costs and profits of the various taxation policies needs to be 560

done in order to compare the efficiency of the 2 taxes more rigorously.

4 Conclusion

The IPCC Tier 1 methodology is currently widely used to assess greenhouse gas emissions - and in particular N₂O emissions from agriculture. However, this methodology is relatively imprecise 564 when used at the regional scale as it ignores the effect of the local environment. This paper 565 explored an alternative methodology to assess the N₂O emissions by coupling a biophysical soil-566 crop model to a micro-economic farm model. The biophysical model CERES-EGC enabled a 567 fine assessment of N₂O emissions, as related to local environmental conditions, and the eco-568 nomic model AROPAj enabled the generalization of the N₂O results at the level of farm types 569 representative of actual farms. The paper also studied possible policy measures to mitigate GHG 570 emissions. 571

572

A series of cases representing different soil and crop management characteristics was set up in the Picardie region, based on an analysis of various comprehensive databases. Response curves 574 of N₂O emissions to Nf inputs were built for these cases, and fitted with a a linear regression 575 function. The slopes of these regressions ranged from 0.10% to 2.25% depending on the cases, 576 whereas the IPCC default method considered a constant 1.25% emission factor. These slopes 577 were input to the economic model AROPAj as new emission factors depending on crop type and 578 farm type. Four simulation scenarios were run with AROPAj: crop yields were either exogenous 579 or endogenous using yield response curves to nitrogen input, and the N₂O emission factors were either obtained from the biophysical model or set at the IPCC value. The use of the modeled emission factors resulted in a 20% decrease in the magnitude of N₂O emissions compared to 582 the IPCC estimate. Thus, taking into account the yield response functions to Nf inputs appeared 583 beneficial to the economic modeling.

585

AROPAj allowed us to study two different greenhouse gas mitigation measures: a first-best 586 tax on GHG emissions, and a second-best tax on the presumed factors of the GHG emissions 587 (livestock and Nf inputs). Interestingly, the simulation variants (using exogenous or endogenous yields, and IPCC or CERES-EGC N₂O emission factors) had a marked influence in the response 589 to taxes, and thereby in the conclusions that could be drawn on the efficiency of the mitigation 590 policies. With the first-best scheme, the discrepancies between the scenarios led to a tax range 591 of 11 to 53 €/t-CO₂ eq for an 8% reduction of the GHG emissions. The gap was firstly due to 592 the yield assessment method: the reduction of the GHG emissions was more pronounced with 593 the endogenous yields as the tax increased. For high level of taxes (up to 50 €/t-CO₂ eq), dif-594 ferences due to the N₂O emission factors started to appear. A similar pattern was observed with 595 the second-best taxation scheme. Endogenous yields conferred a higher reactivity to the model, and mitigation targets were easier to reach than with the exogenous yields. However, the taxes 597 were higher than with the first-best taxation: an 8% abatement of GHG emissions required, for 598 instance, a tax of 110 € per livestock unit and a tax of 125 € per ton of fertilizer N. However, a 599 detailed analysis of the costs and profits of each taxation scheme should be undertaken to com-600 pare the 2 types of taxation, and measure their respective efficiency. 601

602

605

606

607

608

609

The method we proposed here needs to be extended to a wider set of EU regions and crop types to improve its operational status. It also has the potential to address environmental impacts, such as related to the emissions of NH_3 and NO_3^- , which could be easily introduced into the economic analysis. It could also be interesting to use the best-fit model (which is not necessarily linear) to describe the response of N losses to Nf inputs, and introduce these functions in AROPAj. Implementing response functions of animal production (meat and milk) to animal feed supply levels in AROPAj is also an important issue, allowing a more realistic response of farmers to GHG

610 taxation schemes.

611 Notes

- ¹The theoretical economic second-best world is quite large and complex. In the wide body of literature on the subject, we refer readers to Henry (1989) for a review.
- ²Livestock Unit (LU) is a unit used in order to compare livestock size of different species or category of animals.

 It is based on the feeding demand of the animals.

12	Winter Barley	CaPi1	1974	RA	31 Oct. 1996	Pea

^{1:} Earliness is a characteristic of a crop cultivar defining its maturity date. It determines the dates of the various management intervention during the crop growing cycle. Cultivars belonging to 'earliness group 1' have an earlier maturity than those of 'earliness group 2'.

Table 3: Characteristics of the various simulation cases in Picardie. Farm types CrPi1 and SCrPi2 specialize in arable crops, whereas farm types CaPi1 and CaPi2 are mixed livestock-arable farms. Soil characteristics are given in Table 4.

^{2:} The preceding crop 'Pea' is not fertilized whereas 'Wheat' is fertilized with 200 kg N ha⁻¹.

^{3:} RA: regional average.

Soil	FAO		pН	Organic	CaCO ₃	PDR^3
code	Classification ¹	PAW 2	value	carbon	content	
		mm		$\rm g~kg^{-1}$	${ m g~kg^{-1}}$	$kg N ha^{-1} d^{-1}$
1042	Eutric Fluvisol	150.6	6.5	10	10	8.0
1792	Calcic Cambisol	118.4	8.0	18	50	3.4
1969	Orthic Luvisol	189.6	6.5	10	0	16.0
1974	Calcaric Eutric Cambisol	114	7.0	10	20	6.0

Table 4: Codes and selected characteristics of the soils used in the Picardie simulations.

 ¹: FAO-UNESCO (1974)
