22 **Abstract**

23   Successful development of protein therapeutics depends critically on achieving stability

24   under a range of conditions, while retaining their specific mode of action. Gaining a deeper

25   understanding of the drivers of instability across different stress conditions, will potentially enable

26   the engineering of protein scaffolds that are inherently manufacturable and stable. Here, we

27   compared the structural robustness of a humanized antibody fragment (Fab) A33 using atomistic

28   molecular dynamics simulations under two different stresses of low pH and high temperature.

29   RMSD calculations, structural alignments and contact analysis revealed that low pH unfolding

30   was initiated through loss of contacts at the constant domain interface (C_L-C_H1), prior to C_L domain

31   unfolding. By contrast, thermal unfolding began with loss of contacts in both the C_L-C_H1 and

32   variable domain interface (V_L-V_H), followed by domain unfolding of C_L and also of V_H, thus

33   revealing divergent unfolding pathways. FoldX and Rosetta both agreed that mutations at the C_L-

34   C_H1 interface have the greatest potential for increasing the stability of Fab A33. Additionally,

35   packing density calculations found these residues to be under-packed relative to other inter-

36   domain residues. Two salt bridges were identified that possibly drive the conformational change

37   at low pH, while at high temperature, salt bridges were lost and reformed quickly, and not always

38   with the same partner, thus contributing to an overall destabilization. Sequence entropy analysis

39   of existing Fab sequences revealed considerable scope for further engineering, where certain

40   natural mutations agreed with FoldX and Rosetta predictions. Lastly, the unfolding events at the

41   two stress conditions exposed different predicted aggregation-prone regions (APR), which would

42   potentially lead to different aggregation mechanisms. Overall, our results identified the early

43   stages of unfolding and stability-limiting regions of Fab A33, which provide interesting targets for

44   future protein engineering work aimed at stabilizing to both thermal and pH-stresses

45   simultaneously.

46

47 **Author Summary**

48

49   Currently, antibody-based products are the most rapidly growing class of pharmaceuticals

50 due to their high specificity towards their targets, such as biomarkers on the surface of cancer

51 cells. However, they tend to aggregate at all stages of product development, which leads to

52 decreased efficiency and could elicit an immunological response. Improvements in the stability of

53 therapeutic antibodies are generally made during the development phase, by trial and error of the

54 composition of the formulated product, which is both costly and time consuming. There is great

55 demand and potential for identifying the drivers of instability across different stress conditions,

56 early in the discovery phase, which will enable the rational engineering of protein scaffolds. This

57 work elucidated the stability-limiting regions of the antibody fragment Fab A33 using several

58 computational tools: atomistic molecular dynamics simulations, *in-silico* mutational analysis by

59 FoldX and Rosetta, packing density calculators, analysis of existing Fab sequences and

60 predictors of aggregation-prone regions. Results identified particular regions in which

61 mutagenesis has the potential to stabilize Fab against both thermal and pH-stresses

62 simultaneously. Overall, the methodology used here could improve the developability screening

63 of candidate antibody products for many diseases, such as cancer, chronic inflammatory diseases

64 and infectious diseases.

Introduction

In the last 30 years, monoclonal antibody products have become the main drug class for new approvals in the pharmaceutical industry [1]. To date, over 60 antibody-based drugs are on the market, representing half of the total sales, with over 550 further antibodies in clinical development [2]. They are used as therapeutic drugs to treat human diseases, mainly in oncology, auto-immune diseases and cardiovascular diseases. The use of antibody fragments, such as the antigen-binding antibody fragment (Fab) studied here, brings additional advantages, including deeper tissue penetration due to their smaller size, which has proven beneficial to treat tumors [3]. In addition, Fab fragments lack the Fc domain, and thus are not glycosylated which allows simpler and less costly manufacture due to their expression in prokaryotic systems [4]. However, the lack of the Fc domain leads to their more rapid clearance in humans than for full antibodies.

The stabilization of therapeutic proteins against aggregation remains one of the biggest challenges facing approvals as biopharmaceutical products [5–7]. Thus, not only their mode of action, but protein stability is a crucial factor to their becoming successful products. Novel antibody products such as Fabs, single-chain variable fragments (ScFvs) and bi-specifics are currently being developed and their properties remain largely unknown. Knowledge about the stability of these pharmaceutical products, especially in the early development stages, would aid in their engineering and the design of antibody fragments that are more aggregation resistant.

Native protein conformations are only marginally stable, and are highly dynamic, hence they are more realistically described as a native ensemble. There is increasing evidence to suggest that under native conditions, aggregation takes place primarily from partially unfolded native-like states [8–12]. However, little is known about the structures of native conformers that initiate aggregation, or how these are affected by different stress conditions. Local unfolding of proteins can expose aggregation prone-regions (APR), that have the potential to trigger aggregation [13,14]. APRs are the regions in the protein most likely to form and stabilize the cross-

4

96   β structures that are characteristic of many aggregates, notably hydrophobic sequences with low

97   net charge and a strong β-sheet forming propensity. Generally, APRs are located in the protein

98   core, protected from the solvent, and thus blocked from forming cross-β structure. Under certain

99   stresses, such as an increase in temperature, a change in pH, addition of denaturants, or elevated

100   shear force, structural regions in the protein may destabilize and partially unfold to expose any

101   underlying APRs [15]. Each structural region of the protein can respond differently to stress, and

102   so the overall pattern of responses is likely to vary with each type of stress. Thus, determining the

103   conformational changes that a protein experiences under different stress conditions is important

104   for identifying common routes towards stabilization across all stress conditions via either

105   mutagenesis or formulation.

106   Molecular dynamics (MD) simulations have been extensively used to study protein stability

107   [16–21]. MD simulations offer atomic resolution insights into the early conformational events that

108   can take place under different conditions. To date, not many all-atom MD studies on antibody

109   fragments have been reported. MD simulations were used previously to study the aggregation

110   potential of an antibody Fab fragment, from a human IgG1k antibody, via multiple elevated

111   temperature MD simulations at 300 K, 450 K and 500 K [22]. This revealed that domain interfaces

112   deformed prior to the unfolding of individual domains, and that two V_H domain sites were

113   potentially labile to aggregation. Their structural deformation increased the solvent-accessible

114   surface area of the APRs in those regions. The unfolding process of an antibody Fab fragment

115   was also studied using an elastic network model, to reveal that the constant regions were more

116   flexible, and unfolded earlier, than the variable regions [23]. MD simulations at 450 K and 500 K

117   have also revealed the stability-limiting regions of an antibody single-chain variable fragment

118   (scFv) [24]. Disruption of the V_L-V_H interface was found to precede the unfolding of the domain

119   structures. In contrast to the study on the Fab above, the V_H domain of the scFv was found to be

120   more thermally resistant than the V_L domain.

121   Each Fab is composed of one light and one heavy chain (Fig 1 and Fig S1), each

122   comprising a variable (V_L or V_H) and a constant (C_L or C_H1) domain. Each domain forms an

123   immunoglobulin fold, having two layers of β-sheets, an inner β-sheet and an outer β-sheet.

124   Constant domains are formed of seven β-strands in a 4+3 arrangement, while variable domains

125   have two additional β-strands in a 5+4 arrangement. The variable domains contain the antigen-

126   binding site at their complementary determining regions (CDRs), formed by three loops in V_L and

127   three loops in C_L. There are five disulfide bonds in Fab, four of them intra-domain and the last one

128   between the light and heavy chains at the hinge region. Individual domains interact to form the

129   variable region interface (V_L-V_H), and the constant region interface (C_L-C_H1). Interface contacts

130   are shown in Fig 1 and the residues involved in the contacts are listed in Table S1. The variable

131   region interface is mainly formed by aromatic side chains that are tightly packed and located at

132   the center of the interface (six Tyr, two Trp, and two Phe), forming hydrophobic interactions.

133   However, fewer aromatic side-chains are involved in the constant region domain interface (four

134   Phe). Furthermore, no contacts at <3.5 Å were found between part of one of the β-strands (at

135   residues 177-180) in the C_L domain, and the C_H domain in our Fab A33 homology model (Fig 1).

136

137   **Fig 1. Fab A33 structure with interface contacts highlighted.** Fab is composed of light

138   (magenta) and heavy (yellow) chains. Each chain contains variable (V_L and V_H) and constant (C_L

139   and C_H1) domains. The antigen-binding region at the complementary determining regions (CDRs;

140   blue), are located in the variable domains. There are five disulfide bonds (gray highlights).

141   Contacts between heavy and light chains within 3.5 Å are indicated with green dashed arrows. β

142   -strand 177-180 in C_L domain does not have contacts with C_H domain, zoom in right-inset.

143

144   Here, we compare the early unfolding events of Fab A33 at both high temperature and

145   low pH, using all-atom MD simulations. A common feature to both stress conditions was that

146   unfolding was initiated by the loss of interfacial contacts between neighboring domains, and that

147   domain unfolding occurred later. However, our results revealed different unfolding pathways for

6

the two stress conditions, leading to partial unfolding of only the C_L domain at low pH, compared to destabilization of both C_L and V_H domains in the high temperature condition. These conformational changes exposed different predicted aggregation-prone regions (APR), which would additionally support divergent aggregation mechanisms. Salt-bridge analysis provided insights into the location of those that were broken most rapidly due to protonation in the low pH simulation, and also showed that high temperature led to an increased fluctuation of salt bridge formation and breaking, more generally throughout the structure. An *in-silico* mutational analysis by both FoldX and Rosetta, predicted that the constant domain interface had the greatest potential for further stabilization, a finding that was also supported by lower packing-density calculations. Taken together, our results determined the stability-limiting regions at low pH and high temperature for Fab A33, and also identified those with the greatest potential for mutations that simultaneously improve stability under both low pH and high temperature conditions.

Results

Interface contacts, RMSD of individual domains and structural alignments revealed different unfolding pathways at low pH and high temperature

To determine which domains of Fab A33 are more susceptible to unfolding under low pH and high temperature, we first followed the RMSD of each individual domain (V_L, V_H, C_L and C_H1) along the simulations, as changes in RMSD are indicative of a conformational change. Simulations in the unfolding trajectories (pH 3.5 and pH 4.5 at 300 K, for low pH; pH 7.0 at 340 K and 380 K, for high temperature) were compared to the simulations in the native trajectory (pH 7.0 at 300 K). For every condition of pH and temperature, three independent simulations were performed, and their average RMSD are shown in Figures 2 and 3. Additionally, structures from the unfolding trajectories (pH 3.5, for low pH; 380 K, for high temperature) were aligned to structures from the native trajectory (pH 7.0 at 300 K), to visualize the structural changes that individual domains experienced. For each domain alignment, ten structures were taken every 3 ns

174 from each simulation repeat, from the 20-50 ns range at which the RMSD had stabilized. Thus,

175 a total of thirty structures from each stress condition were compared to thirty from the native

176 trajectory. We also monitored the number of interface contacts between domains (V_L-V_H and C_L-

177 C_H1) during the simulations using a cutoff of 4 Å, to understand the temporal relationship between

178 breakage of contacts in each interface, and the unfolding of each domain. The RMSD and radius

179 of gyration (R_g) of the whole protein are also shown at every condition in Fig S2; where increased

180 RMSD and R_g were observed at the conditions of low pH (3.5) and high temperature (380 K).

181   At low pH, almost no change was observed in the number of interfacial contacts within the

182 variable region (V_L-V_H) of Fab A33, when compared to at pH 7.0. For pH 7.0, 333 ± 24 contacts

183 were maintained (discarding the first frame), and 309 ± 24 contacts were maintained at pH 3.5

184 (Fig 2A). By contrast, a loss of interfacial contacts in the constant region (C_L-C_H1) was observed

185 between pH 7.0 with 335 ± 17 contacts, and pH 3.5 with 265 ± 12 contacts (Fig 2B). Interestingly,

186 this loss of constant region interfacial contacts at low pH took place very quickly, with pH 7.0

187 retaining 384 ± 14 contacts after 5 ns of the simulation, while simulations at pH 3.5 retained only

188 270 ± 11 contacts. This could be attributed to the lack of a well-defined hydrophobic core in the

189 C_L-C_H1 interface, resulting in numerous early-disrupted contacts. Notably, C_L was the only domain

190 to show a noticeable conformational change at low pH, revealed as an increase in RMSD from

191 1.8 ± 0.1 Å at pH 7.0 (calculated between 20-50 ns of the simulation), to 2.2 ± 0.1 Å at pH 3.5

192 (Fig 2E). This domain displacement occurred in the first 20 ns, after many interface contacts had

193 already been lost with respect to pH 7.0, which suggests that destabilization of the C_L-C_H1

194 interface preceded and potentially accelerated the unfolding of the C_L domain. The other domains

195 (V_L, V_H and C_H1) did not unfold significantly during the low pH simulations (Fig 2C, 2G and 2I).

196 Structural alignments confirmed this result, showing remarkably good alignment between the pH

197 7.0 and pH 3.5 structures in each case for V_L, V_H and C_H1 (Fig 2D, 2H and 2J). Alignments of the

198 C_L domain at pH 7.0 and pH 3.5 revealed a slight displacement at low pH, especially visible in the

199 loop regions (Fig 2F). These findings agreed with previous experimental work, which combined

8

200   SAXS, atomistic modelling and smFRET to reveal the displacement of the C_L domain in Fab A33

201   at low pH [14].

203   **Fig 2. Interface contacts, RMSD of individual domains and structural alignments for**

204   **simulations at pH 7.0, 4.5 and 3.5 (all 300 K).** A, B) Contacts between light and heavy chains

205   within 4.0 Å with simulation time, for variable (V_L-V_H) and constant (C_L-C_H) regions, respectively,

206   pH values as labelled. C, E, G, I) RMSD of individual domains with simulation time for V_L, V_H, C_L

207   and C_H1, respectively, pH values as labelled. In all cases, the average of three independent

208   simulations is shown with the SEM as error. D, F, H, J) Alignments of structures from simulations

209   at pH 7.0 and 3.5 for V_L, V_H, C_L and C_H1, respectively. Ten structures from the last 30 ns of each

210   simulation were used, totaling thirty structures from pH 7.0 and thirty from pH 3.5.

212   For thermal denaturation, MD simulations are commonly run at temperatures as high as

213   500 K to attempt to fully denature the protein. Here, we aimed to capture the early thermal

214   unfolding events of Fab A33, which involve only partial unfolding of the protein. For this reason,

215   and to reflect experimental conditions more closely, lower temperatures of 340 K and 380 K were

216   used in our simulations. Interfacial contacts were found to break across both the variable and the

217   constant regions (Fig 3A and 3B). At 380 K, there was an average of only 220 ± 24 contacts in

218   the variable interface and 204 ± 13 contacts in the constant interface. Those between the constant

219   domains broke earlier than those of the variable domains, with only 218 ± 14 present after just 5

220   ns of the simulations at 380 K. This is consistent with previous reports, which also found that the

221   constant region interface lost a larger fraction of its total interface contacts consistently faster than

222   the variable region interface at high temperature, and also that domain unfolding occurred later

223   than the loss of interfacial contacts [22]. Overall, more contacts were lost at both interfaces with

224   high temperature than at low pH.

225   While V_L and C_H1 experienced only small domain displacements (Fig 3C and 3I), clear

226   domain unfolding was observed for both C_L and V_H (Fig 3E and 3G). At 380 K from 20 ns to 50 ns,

227   the V_H domain displayed an increase in RMSD from 2.4 Å at pH 7.0, to 3.2 Å at pH 3.5. That for

228   the C_L domain increased from 1.8 Å at pH 7.0 to 2.4 Å at pH 3.5 (all averages were ± 0.1 Å). In

229   these cases, many interface contacts were also lost with respect to pH 7.0 and 300 K, before the

230   unfolding of individual structural domains, again consistent with destabilization of the interface

231   contributing to the loss of stability for the individual domains. For both V_L and C_H1, structures from

232   the simulations at 300 K and 380 K aligned well (Fig 3D and 3J), whereas for V_H and C_L (Fig 3H

233   and 3F) the domains were structurally perturbed at the higher temperature. The V_H domain

234   experienced a displacement of the loops on the N-terminal region, including the three CDR loops

235   (Fig 3H). Differences in the C_L domain at high temperature were found in the loops and within an

236   internal β-strand (Fig 3F). This was consistent with previous work which identified instability and

237   structural changes in the V_H domain of another Fab at high temperature [22]. Taken together,

238   these findings suggest a different unfolding pathway for Fab A33 at low pH and at high

239   temperature.

240

10

Loss in β-strand secondary structure confirms regions of unfolding

The unfolding of individual domains was additionally followed by their loss in secondary structure (SS); specifically, we monitored the change in β-strand structure. Constant domains are composed of seven β-strands named A to G, while variable domains contain two more strands, a total of nine, with the two additional strands termed C' and C" (Fig 4A and 4B). To calculate the loss in β-strand structure for each of the strands, we first tracked the secondary structure designation for each residue in Fab A33 throughout the simulations (Fig S3). The percentage of time occupied within β-strand was calculated for each residue, and then summed for each of the 32 β-strands in Fab A33. This value was averaged for each of the three repeats at each condition. The percentage change in β-strand occupancy was then calculated, to determine the loss relative to the reference simulations at pH 7, 300 K (Fig 4 and Fig S4).

Fig 4. Loss of secondary structure for each of the 32 β-strands of Fab A33. A, B) Strand order shown by lettering (A-G) for variable and constant domains, respectively. C, D) Percentage increase/decrease in β-strand secondary structure for each strand in Fab during the simulations, respect to pH 7.0 and 300 K, for: C) pH 3.5 and 300 K, D) pH 7.0 and 380 K. Error bars are the same and equal for positive and negative values.

At pH 3.5, the C_L domain had an overall loss in secondary structure content, confirming the results found in the previous section (Fig 4C). Strands F (-13 ± 3 %) and G (-12 ± 7 %) of the C_L domain showed the highest β-sheet structure loss, both located in the outer β-sheet. Strands B (-8 ± 6 %), C (-6 ± 4 %) and E (-8 ± 6 %) also experienced significant losses. Additionally, the β-strand C" of the V_L domain also showed a large variability between repeat trajectories. C" is the shortest strand, and is located at the extreme of the outer β-sheet connecting the CDR-2 loop, and so the large variability suggests that this is a flexible region prone to the loss of secondary structure in some but not all simulations.

11

277   At 380 K, the losses in β-strand content were located in both the C_L and V_H domains,

278   consistent with the unfolding described in the previous section (Fig 4D). Many strands in the C_L

279   domain showed significant losses, A (-7 ± 2 %), C (-8 ± 3 %), D (-16 ± 12 %) and G (-5 ± 1 %),

280   located at the extremes of the inner and outer β-sheets. The V_H domain also showed high losses

281   of β-strand. However, of these strands A (-18 ± 17 %) and G (-8 ± 9 %) also showed high variability

282   between repeats. Interestingly, these same two strands in V_H were previously found to deform at

283   high temperature in a different Fab [22]. Strand C" (-13 ± 4 %) of the V_H domain also showed a

284   significant loss of β-strand content.

285

286   **Salt bridge analysis identifies key stabilizing salt bridges**

287   To identify the ionizable residues that potentially drive the conformational changes at low

288   pH, a salt bridge analysis was performed. Salt bridges were identified over the simulation time for

289   all the MD simulations carried out, using an O-N bond distance cutoff of 3.2 Å. From these, the

290   occurrence (%) of each salt bridge during the simulation was calculated, and averaged for the

291   three independent repeats at each condition. Lastly, the most persistent salt bridges at each

292   condition were highlighted in the Fab A33 structure (Fig 5 and Fig S5).

293

294   **Fig 5. Salt bridge analysis.** A, B, C) Salt bridges formed during the simulation time for

295   representative MD simulations at A) pH 7.0 and 300 K, B) pH 3.5 and 300 K and C) pH 7.0 and

296   380 K. Presence of a salt bridge is indicated in white and absence in black. D, E, F) List of salt

297   bridges and its occurrence for simulations at D) pH 7.0 and 300 K, E) pH 3.5 and 300 K and F)

298   pH 7.0 and 380 K. Values shown are the average of three independent simulations with their SEM

299   as error. The more persistent salt bridges are highlighted for pH 7.0 (green), pH 3.5 (red) and pH

300   7.0 and 380 K (blue). G, H, I) The more persistent salt bridges are mapped into the Fab A33

301   structure. Two key stabilising salt bridges (Glu165-Lys103 and Glu195-Lys149) are highlighted in

302   a dashed circle.

12

303

304   At pH 7.0 and 300 K, a total of 36 salt bridges were present. Interestingly, many of these

305   salt bridges were flexible and able to form with different partners during a single trajectory, such

306   as Asp122 which partnered with both Lys126 and Lys436, or Asp304 which paired with both

307   Arg252 and Arg281. This is consistent with previous work, which found that salt bridges break

308   and reform, and not always with the same partner [25]. The most persistent (as % of time present)

309   salt bridges at pH 7.0 were Glu165-Lys103 (67 ± 4 %), Glu195-Lys149 (65 ± 4 %), Asp82-Arg61

310   (61 ± 14 %), Asp151-His189 (58 ± 24 %), and Asp304-Arg252 (55 ± 27 %), as shown in Fig 5A,

311   5D and 5G.

312   At low pH, pH 3.5, 300 K, a total of 27 salt bridges were observed, but most of them were

313   very short lived. The more persistent salt bridges at pH 3.5 were Asp151-His189 (86 ± 6 %),

314   Asp82-Arg61 (78 ± 11 %), Asp122-Lys126 (73 ± 1 %), Asp362-Lys335 (56 ± 6 %) (Fig 5B, 5E

315   and 5H). The protonation state at the end of the pH 3.5 simulations was calculated again using

316   these Fab conformations, which revealed these salt bridges to be still present due to predicted

317   pK_a values of below 3.5 for these aspartates. Comparison of the salt bridges at pH 7.0 and 3.5,

318   indicated the presence of two salt bridges that potentially trigger the conformational change

319   observed at low pH, and thus the loss of Fab A33 stability. Glu165-Lys103 and Glu195-Lys149,

320   were the most persistent contacts at pH 7.0, but were not present at pH 3.5. Glu165-Lys103

321   bridges the C_L domain to the V_L domain, and Glu195-Lys149 bridges the outer β-strands C and

322   F of the C_L domain. Loss of these salt bridges at low pH, would therefore destabilize the C_L

323   domain, and promote the observed C_L domain displacement.

324   At high temperature, pH 7.0 and 380 K, a total of 45 salt bridges were observed. The

325   greater number than at 300 K, reflects an increased conformational flexibility of many salt bridges

326   at the higher temperature, in which they often broke, but then reformed with a different partner.

327   Indeed, at the high temperature, salt bridges broke and reformed much faster (Fig 5C). At 380 K,

328   the total time present for the most persistent salt bridges observed at 300 K, had decreased to 47

13

329   ± 9 % for Glu165–Lys103, 58 ± 3 % for Glu195-Lys149, 21 ± 7 % for Asp151-His189, and 43 ±

330   22 % for Asp304-Arg252. However, Asp82-Arg61 increased in occurrence to 70 ± 3 % (Fig 5C,

331   5F and 5I). These findings indicate that the increased dynamics at high temperature, results in

332   constant rupture and formation of salt bridges, and this transient disruption leaves Fab A33 more

333   susceptible to unfolding.

334

335   **FoldX, Rosetta and packing density calculations predict sub-optimal stability of C_L and the**

336   **C_L-C_H1 interface**

337   Computational tools such as FoldX and Rosetta-ddG [26,27] predict the relative changes

338   in folding free energy ($\Delta\Delta G$) between the Gibbs free energies (ΔG) of the protein carrying a

339   simulated point mutation and the wild-type protein, to find those mutations that will most

340   significantly reduce the free energy of the protein. These approaches are often also combined to

341   find consensus predictions [28,29]. To predict stabilizing mutations in Fab A33, we calculated the

342    $\Delta\Delta G$ with both FoldX and Rosetta-ddG, of all possible single-mutant variants when accessing all

343   19 other substitutions across the 442 residue positions in Fab A33, totaling 8398 mutations. FoldX

344   identified 1879 of these mutations as stabilizing (22.4 %), while Rosetta-ddG identified 2386 (28.4

345   %). Of these, 956 (11.4 %) were predicted by both algorithms. Fig S6 shows the correlation

346   between the mutations predicted by FoldX and Rosetta, and Table S2 lists the 25 most stabilizing

347   mutations predicted by both algorithms, with their respective $\Delta\Delta G$ values.

348   Fig 6A compares the greatest stabilization predicted by FoldX and Rosetta, at each of the

349   442 residues in Fab A33, regardless of the specific mutation selected by each algorithm. Six

350   residues were highlighted in magenta in Fig 6A and 6B, as those predicted by both algorithms to

351   have the greatest potential for stabilization. These residues corresponded to S176, N137, S397,

352   S159, S12 and T180, and all of their mutations predicted to be most stabilizing, were to more

353   hydrophobic amino acids, such as Trp, Leu, Ile, Phe and Tyr (Fig S6 and Table S2). Four of the

354   six residues (S176, N137, S397 and T180), are located in the constant domain interface, between

14

355   C_L and C_H1 domains (Fig 6B), suggesting significant potential for further stabilization within the

356   C_L-C_H1 interface. Furthermore, S159 is in the C_L domain, but interacts with an outer β-strands of

357   C_L, and S12 is in the V_L domain, but interacts with the C_L domain (Fig 6B). Thus overall, the C_L

358   domain has a relatively high potential for stabilization, through repacking of the C_L-C_H1 interface,

359   within the C_L domain itself, and also through improved interaction between C_L and V_L. This is

360   consistent with the MD simulations which found the displacement of C_L away from the interface

361   with C_H, and subsequent unfolding of the C_L domain, to be critical steps in early or partial

362   unfolding.

363   Further highly stabilizing mutations at residues S395 and S267, as predicted only by

364   FoldX, are highlighted in green in Fig 6. S395 is also located in the C_L-C_H1 interface. However,

365   S267 is in CDR2 of the V_H domain, and so not a good candidate for general framework

366   stabilization due to its role in antigen binding. Highly stabilizing mutations at residues K103 and

367   T72, as predicted only by Rosetta-ddG are highlighted in yellow. These were both located in the

368   V_L domain, but K103 also interacts with the C_L domain, further suggesting that the interactions

369   within and around the C_L domain are the least optimized for stability.

370

371   **Fig 6. Predicted residues that can be stabilized further by FoldX and Rosetta-ddG.** A)

372   Correlation between FoldX and Rosetta predictions. Residues predicted by both software to be

373   most stabilizing are shown in magenta on the bottom left. Residues predicted only by FoldX to be

374   stabilizing are shown in green and mutations predicted only by Rosetta in yellow. B) Residues

375   predicted to be stabilized further the most are mapped in Fab A33 structure, following the same

376   colour scheme as in A).

377

378   The packing density of each Fab A33 residue was calculated using the package occluded

379   surface (OS) software, which calculates occluded surface and atomic packing [30,31]. The

380   occluded surface packing (OSP) value of each atom is calculated from normal vectors that extend

15

381   outward from the atom surface until they intersect a neighboring van der Waals surface (Fig S7).

382   This value is 0.0 for completely exposed residues and 1.0 where 100% of molecular surface is in

383   contact with other van der Waals surface. The average OSP for all 28 β-strand residues within

384   domain interfaces (V_L-V_H and C_L-C_H1) was 0.49 ± 0.01 (OSP values shown in Table S3). By

385   contrast, the average OSP of the five constant-domain interface residues (S176, N137, S397,

386   T180, and S395), identified by FoldX and Rosetta as having high stabilization potential, was 0.41

387   ± 0.05 (OSP values shown in Table S3). This can be visualized in Fig 7, where OSP values were

388   mapped in the structure of Fab A33, with red to indicate high packing density, and blue to indicate

389   low packing density. β-strand residues within domain interfaces were highlighted as sticks (Fig

390   7A). Residues in the constant interface (C_L-C_H1) were lighter colored than residues in the variable

391   interface (V_L-V_H), indicating less tight packing of the constant interface. An insight of the residues

392   identified by FoldX and Rosetta is provided in Fig 7B, where a lighter color than the residues in

393   the variable interface was also observed. This result shows that the predicted residues are under-

394   packed, and therefore have the potential to be mutated to pack the C_L-C_H1 interface more tightly.

395

396   **Fig 7. Packing density of every residue in Fab A33, computed using Occluded Surface.** A)

397   The occluded surface packing (OSP) values were added as B-factors to the PDB file for the Fab

398   A33 homology model. High packing values are shown in red and low values in blue. Residues in

399   β-strands within domain interfaces (V_L-V_H and C_L-C_H1) are highlighted in sticks and ball

400   representation. B) Residues identified by FoldX and Rosetta that could be stabilised further (S176,

401   N137, S397, T180, and S395) are highlighted in sticks and ball, and sphere representation.

402

403   **Comparison to natural sequence variations in Fabs**

404   The natural variability of Fab sequences was identified from within one hundred light

405   chains and one hundred heavy chains curated from those available in the Protein Data Bank [32].

406   Sequence alignment and sequence entropy calculations for each residue were obtained using

16

407   Bioedit [33]. An entropy of zero indicates a fully conserved residue, whereas 3.04 is the maximum

408   entropy, originating from 21 possibilities (all amino acids plus the stop codon). There is significant

409   positional bias in the sequence variability of Fabs due to the hypervariability of the CDRs [34], the

410   presence of kappa (κ) and lambda (λ) light chain isotypes, allotypic diversity across individuals,

411   and idiotypic variability within the variable domains of individuals. The sequence entropy analysis

412   (Fig S8) clearly shows this, with the highest sequence entropy (>2), for the six CDRs, and a

413   slightly lower variability on average within the C_H domain. Similarly, the higher sequence entropy

414   on average for the C_L domain, compared to the C_H domain results from the grouping of kappa (κ)

415   and lambda (λ) light chain isotypes.

416   Even though residues in the constant regions have more restricted variability, many

417   natural variations are still observed that may affect stability. Except for the fully conserved S176,

418   the sites predicted as having the most potential for stabilizing mutations by both FoldX and

419   Rosetta, had natural variations, with sequence entropy values of N137: 0.74, S397: 0.15, S159:

420   0.96, S12: 0.96, T180: 0.43. This was also true for mutations identified only by FoldX (S267: 1.69

421   and S395: 0.69), and only by Rosetta-ddG (K103: 0.16, T72: 0.91). Comparisons between the

422   existing mutations and the stabilizing mutations suggested by FoldX and Rosetta are shown in

423   Table 1. In general, the mutations found in existing Fabs were conservative changes to residues

424   with properties similar to the original residue. For instance, S397 and S395 are only naturally

425   mutated to Thr, whereas T180 can also be Ser, and K103 can be Arg. By contrast, FoldX and

426   Rosetta predictions were typically from polar to more hydrophobic residues, typically to Ile, Leu,

427   Trp, Val, and Tyr. A few suggested mutations were also found naturally, such as N137I, S12Y,

428   and S267P. S159 also shows the potential to be mutated to more hydrophobic residues, Val and

429   Met. Overall, this analysis shows that despite their low natural variability, many residues in the

430   constant domains had significant scope for stabilization through non-natural mutations.

431

432 **Table 1. Comparison between the mutations in existing human and mouse Fabs and the**

433 **stabilizing mutations suggested by FoldX and Rosetta.**

| Original Residue | Light chain | | | | Heavy Chain | | Suggested mutation by FoldX and Rosetta |
| | Kappa (κ) | | Lambda (λ) | | Human | Mouse | |
	Human	Mouse	Human	Mouse			
S176	-	-	-	-	N.A.	N.A.	W, M, R, L Y

434 N.A. (Not Applicable), mutation does not apply to the chain (light or heavy); -, no existing

435 mutations were found on that chain.

436

437 **Solvent exposure of different aggregation-prone regions promotes different aggregation**

438 **pathways for low pH and high temperature**

439 　　The aggregation pathways of Fab A33 at low pH and high temperature at pH 7.0, are

440 already known to result in different aggregate morphologies [12]. Here we explored whether the

18

441 two conditions also exposed different aggregation-prone regions (APRs). APRs can be predicted

442 from sequence information, and either assume a fully unfolded protein, or otherwise refine the

443 prediction by factoring solvent exposure of the APR based on structure and dynamics information.

444 The sequence-based predictions are based on either the intrinsic properties of amino acids, or

445 their compatibility with protein structural features in known amyloid fibril structures. Examples of

446 sequence-based predictors include PASTA 2.0 [35], TANGO [36], AGGRESCAN [37], MetAmyl

447 [38], FoldAmyloid [39] and Waltz [40]. As the ability of APRs to trigger aggregation depends upon

448 their solvent accessibility, more recent structure-based predictors consider the three-dimensional

449 structure of the protein and in some cases also their potential modes of partial unfolding.

450 Examples include AGGRESCAN 3D [41], AggScore [42], SAP [43] and Solubis [44]. Here, we

451 want to compare the solvent accessibility of APRs in Fab A33, between our MD simulations at

452 the unfolding conditions and at the reference trajectory. Thus, we used sequence-based APR

453 predictors to determine the APRs in Fab A33, and then determined their solvent accessible

454 surface area (SASA) from the MD simulations, for relative comparisons.

455   We used four sequence-based predictors to determine the APRs in Fab A33, PASTA 2.0,

456 TANGO, AGGRESCAN and MetAmyl. APRs were selected when three out of the four predictors

457 identified an aggregation-prone sequence (Fig S9A). Seven APRs were found, namely residues

458 31-36, 47-51, 114-118 and 129-139 in the light chain and residues 261-165, 325-329 and 387-

459 402 in the heavy chain. The presence of these APRs was confirmed using Amylpred2 [45], a

460 consensus tool of eleven existing algorithms (Fig S9A). The location of the seven APRs revealed

461 that they are all located in the interior of Fab A33, and thus protected from the solvent (Fig S9B).

462 Exposure of one of these APRs as a result of a conformational change by an environmental

463 stress, has the potential to trigger aggregation. Thus, the SASA of each APR during the

464 simulations was calculated, as well as the difference in solvent accessibility, ΔSASA, between

465 unfolding conditions and the reference simulation (Table 2).

466   At low pH, only one APR (residues 387-402), was found to increase its solvent accessibility

19

467   significantly at pH 3.5, with an increase of 57 ± 25 Å^2 (10 % increase) (Table 2), consistent with

468   previous experimental findings [14]. This APR is located in the C_H1 domain and its exposure can

469   be explained by the C_L domain displacement observed at low pH (Fig 8A). At high temperature,

470   two APRs were found to increase their solvent accessibility, APR 261-265 located in V_H and APR

471   129-139 located in C_L (Fig 8B). APR 261-265 increased its SASA 15 ± 6 Å^2 (107 % increase) and

472   APR 129-139 increased its SASA 20 ± 16 Å^2 (13 % increase) (Table 2). The location of these

473   APRs agrees with the domains found to unfold previously at high temperature. Notably, the APRs

474   exposed at low pH and high temperature are different, suggesting the potential to follow different

475   aggregation mechanisms depending on the stress applied.

476

477   **Table 2. SASA of the APRs in Fab A33 during simulations and SASA differences between**

478   **unfolding simulations and the reference simulation.** Solvent accessible surface area of the

479   seven aggregation-prone regions in Fab A33 during all simulations, and relative differences

480   (ΔSASA) between the unfolding trajectories (pH 3.5 and 4.5 at 300 K, for low pH; pH 7.0 at 340

481   K and 380 K, for high temperature) and the reference trajectory (pH 7.0 and 300 K).

APR	Fab domain	SASA (Å^2) pH 7.0 300 K	SASA (Å^2) pH 4.5 300 K	ΔSASA (Å^2) pH(4.5-7.0)	SASA (Å^2) pH 3.5 300 K	ΔSASA (Å^2) pH(3.5-7.0)	SASA (Å^2) pH 7.0 340 K	ΔSASA (Å^2) T(340-300 K)	SASA (Å^2) pH 7.0 380 K	ΔSASA (Å^2) T(380-300 K)
31-36	V_L	118 ± 4	112 ± 5	-5 ± 7	115 ± 16	-3 ± 17	120 ± 8	3 ± 9	106 ± 4	-12 ± 6

Fig 8. Fab A33 predicted APRs that increase its solvent accessibility at low pH and high temperature. A) APR 387-402 increases its SASA at pH 3.5 and B) APR 261-265 and APR 129-139 increase its SASA at 380 K (Table 1). All mapped in red in Fab A33 homology structure.

Discussion

Antibody-based products are the main class of approved biopharmaceuticals, due to their high target specificity [1]. However, there are many barriers to their successful development into therapeutics, with protein aggregation being perhaps the most common and challenging to prevent [5]. There is a need to identify potential instabilities of therapeutic proteins during their early development, particularly against stresses that they will encounter during manufacture, storage and delivery. This would allow their early elimination from further development, or otherwise rational mutagenesis into more stable products. In this context, we have elucidated the first unfolding events that take place on a humanized Fab A33 using atomistic MD simulations, and compared these to predictions of potentially stabilising mutations using computational tools.

Our simulations showed that contacts at the interface between domains (V_L-V_H and C_L-C_H1) were lost before individual domains unfolded. Interfacial contacts in the constant domain were the least stable, and were lost very quickly during the simulations under both stresses of low pH and high temperature. In line with these results, FoldX and Rosetta agreed that the residues

21

503 that can be stabilized the most, are located in the constant domain interface. Further validation

504 was provided by packing density calculations, which revealed that the residues identified by the

505 stability predictors, were under packed relative to the other residues located in the interface

506 between domains. Based on these findings, we speculate that improvement of Fab A33 stability

507 should be targeted to the constant domain interface. Only one of the top mutations suggested by

508 FoldX and Rosetta, N137I was found to be present in our analysis of natural variation within

509 existing Fab sequences. However, there was significant scope for improvement through mutating

510 the interfacial residues S176, N137, S397, T180, and S395, to the suggested hydrophobic

511 residues.

512 The further goal could be to improve the stability of the individual domains. The C_L domain

513 was found to unfold at both, low pH and high temperature. Salt bridge analyses identified two key

514 salt bridges at the heart of this domain unfolding at low pH, Glu165-Lys103 and Glu195-Lys149.

515 Glu165-Lys103 bridges the C_L domain to the V_L domain, and Glu195-Lys149 is located in outer

516 β-strands of the C_L domain, bridging β-strands C and F. FoldX and Rosetta also identified

517 stabilizing mutations in the C_L domain. To stabilize the interaction between the C_L and V_L domain,

518 hydrophobic mutants of S12 and K103 were predicted. Interestingly, the mutation S12 to Tyr is

519 found naturally. In the C_L domain, S159 was identified, which interacts with an outer β-strand,

520 suggesting this interaction can also be improved. Lastly, the V_H domain was also found to unfold

521 at high temperature. The only mutation identified in this domain is S267, to a Pro, which notably

522 is found naturally. Overall, the results found with MD simulations and stabilizing software

523 predictors strongly agree in the domains of Fab A33 that can be stabilized further.

524 In order to gain insights into the mechanisms by which aggregation might occur, APRs in

525 Fab A33 were identified, and their solvent accessibilities were compared. All APRs in Fab A33

526 are located in the interior of the protein, however, at low pH and high temperature the SASA of

527 certain APRs increased. Notably, different APRs were exposed under both stresses, suggesting

528 that different aggregation mechanisms occur under each stress. This result stresses the

22

529   importance of identifying the stability of a protein under the different stresses it might encounter.

530   Taken together, this work provides insights into the stability and robustness of the therapeutically

531   relevant Fab A33, and offers a path to the engineering and design of a more aggregation resistant

532   antibody fragment.

533

534

535   **Materials and Methods**

536

537   **Fab A33 homology model**

538   The homology model of wild-type Fab A33 was built from the crystal structure of human

539   germline antibody 5-51/O12 (PDB ID: 4KMT) and the amino-acid sequence of Fab A33 (Fig. S1)

540   [46,47]. The C226S heavy-chain variant was used to avoid the formation of linked Fab dimers.

541   We used the Rosetta method "minirosetta", as detailed in previous works [48].

542

543   **Molecular dynamics simulations**

544   Molecular dynamic (MD) simulations on the Fab A33 homology model were conducted in

545   Gromacs v5.0 [49]. MD simulations were carried out at neutral pH and room temperature (pH 7.0

546   and 300 K) and under two stresses, low pH (pH 3.5 and pH 4.5 at 300 K) and high temperature

547   (pH 7.0 at 340 K and 380 K). Many high temperature simulations are performed at relatively high

548   temperatures (e.g. 500 K), to achieve complete denaturation of the protein, however, in this case,

549   we aim to partially unfold Fab A33 and detect the regions prone to early unfolding. Simulations

550   were carried out using the OPLS-AA/L all-atom force field [50]. The Fab PDB file was first

551   converted to a topology file with its five (four intra-chain and one inter-chain) disulfide bonds

552   retained. The protonation state of each residue was entered manually, and these were determined

23

553   at each pH using the PDB2PQR server, which performed the pKa calculations by PropKa [51].

554   This gave the following total charges: +9 (pH 7.0), +18 (pH 4.5) and +35 (pH 3.5). The Fab A33

555   structure was centered in a cubic box with a layer of water up to at least 10.0 Å from the protein

556   surface. The box was solvated with SPC/E water molecules, Cl- added to neutralize the net

557   charges, and NaCl added to an ionic strength of 50 mM for all simulations. The system was energy

558   minimized using the steepest descent algorithm (2000 steps) followed by the conjugate gradient

559   method (5000 steps). The solvent and ions around the protein were equilibrated in position-

560   restricted simulations for 100 ps under NVT ensemble to stabilize at the specified temperature,

561   and then at 100 ps under NPT ensemble to stabilize at atmospheric pressure. Lastly, MD

562   simulations were carried out for 50 ns in triplicates under the five conditions (pH 7.0 and 300 K;

563   pH 4.5 and 300 K; pH 3.5 and 300 K; pH 7.0 and 340 K; pH 7.0 and 380 K). Jobs were submitted

564   to the UCL Legion High Performance Computing Facility. The time step of the simulations was

565   set to 2 fs and trajectories were saved every 10 ps.

566

567   **Analysis of MD trajectories**

568   MD trajectories were saved reduced, every 0.2 ns (total of 250 frames). Interface contacts

569   over simulation time were calculated using the native contacts extension of the visual molecular

570   dynamics (VMD) program [52]. A cutoff distance of 4 Å was used in the calculations. Variable

571   domain contacts (V_L-V_H) were calculated between residues 1-108 (V_L) and 215-334 (V_H). Constant

572   domain contacts (C_L-C_H1) were calculated between residues 109-214 (C_L) and 335-442 (C_H1).

573   RMSD of individual domains during the simulations were calculated using the RMSD trajectory

574   tool in VMD. All the structures of the trajectory were first aligned and the RMSD was calculated

575   (no hydrogens included). Domains were V_L (1-108), V_H (215-334), C_L (109 to 214) and C_H1 (335

576   to 429). Averages and SEM of three independent repeats are shown. Structural alignments of the

577   last 30 ns of the trajectories were also performed using VMD. Secondary structure (SS)

578   assignments of each residue along the trajectory were done using the DSSP module [53,54]. To

24

579   analyze the loss in β-strand structure, we monitored the percentage of β-sheet SS per residue.

580   These values were summed for each of the 32 β-strands in Fab A33 and differences were

581   calculated between the unfolding simulations and the reference simulations (pH 7 and 300 K).

582   Lastly, salt bridges were calculated along the trajectories using VMD and a cutoff distance

583   between O and N groups of 3.2 Å. From these, the occurrence (%) of each salt bridge during the

584   simulation was calculated, and averaged for the three independent repeats at each condition.

585

586   **Mutational study and ΔΔG calculations by FoldX and Rosetta**

587   The effect of mutations on the stability of Fab A33 was studied using FoldX (foldx.crg.es)

588   [26] and the Rosetta method "ddg_monomer" (www. rosettacommons.org) [27]. Both tools

589   predicted the difference in folding free energy, ΔΔG, between the protein carrying a point mutation

590   and the wildtype. Each of the 442 residues in the Fab A33 were mutated to the other 19

591   possibilities, totaling 8398 single mutants. FoldX was used as a plugin in the graphical interface

592   YASARA [55]. The "Repair" command was used first to energy minimize the homology model of

593   Fab A33, by rearranging the amino acid side chains. Next, the "BuildModel" command was used

594   to introduce the point mutations, optimize the structure of the new protein variant, and calculate

595   the stability change upon mutation. The Rosetta "ddg_monomer" method was used, where an

596   example of mutation and option files, listing the parameters of the executable, can be seen in

597   previous work [48]. Jobs were submitted to the UCL Legion High-Performance Computing Facility.

598

599   **Packing Density**

600   Occluded surface (OS) program was used to calculate the atomic packing of Fab A33

601   [30,31]. The occluded surface packing (OSP) values are useful for identifying regions of loose

602   packing in a protein. OSP value for each residue are calculated from the collection of extended

603   normals (ray-lengths) that extend outward from the molecular surface until they intersect

604   neighboring van der Waals surface. Analysis of these normals, their respective lengths and the

605   surface area involved in the interaction, defines the packing of each atom in the protein.

606

607   **Sequence Entropy of Fab sequences**

608   Fab sequences were retrieved from the Protein Data Bank (PDB) [32], totaling one

609   hundred light chains and one hundred heavy chains. For light chains, kappa (κ) and lambda (λ)

610   chains were included. For κ light chains, λ light chains and heavy chains, sequences from the

611   species human and mouse were used. Sequence alignment and calculation of the sequence

612   entropy for each residue were calculated using Bioedit [33]. The maximum entropy for 21 possible

613   amino acids (including stop codon) is 3.04 and zero represents a fully conserved residue.

614

615   **Aggregation-prone regions (APR) predictions**

616   Aggregation prone regions (APR) of Fab A33 were predicted using PASTA 2.0 [35],

617   TANGO [36], AGGRESCAN [37] and MetAmyl [38], using the protein sequence as input. The

618   regions in which three out of the four software identified an APR were selected, resulting in seven

619   APRs. Amylpred2 consensus tool was used to confirm the presence of these APRs [45]. To

620   calculate the solvent accessible surface area (SASA) of each APR during the trajectories, the

621   average area per residue over the trajectory was calculated first, using gromacs analysis tool

622   "sasa", then summed for each APR.

Fig S1. Fab A33 sequence. Fab A33 amino acid sequence separated by domains (V_L, C_L, V_H, C_H1 and hinge region). The six CDRs in the V_L and V_H domains are highlighted in red.

817

Table S1. Residues located in the interface between light and heavy chains in Fab A33.

819

Fig S2. All protein RMSD and radius of gyration (R_g) with simulation time. A, B) RMSD of the whole protein with simulation time for different A) pHs and B) temperatures, values as labelled. In all cases, the average of three independent simulations is shown with the SEM as error. C, D) Radius of gyration (R_g) of Fab A33 with simulation time for different A) pHs and B) temperatures, values as labelled. In all cases, the average of three independent simulations is shown with the SEM as error.

826

Fig S3. Secondary structure (SS) of each residue in Fab A33 with simulation time, calculated using DSSP. Representative SS evolution are shown for A) pH 7.0 and 300K, B) pH 3.5 and 300K and C) pH 7.0 and 380 K, secondary structure type as indicated in the legend.

830

Fig S4. Loss of secondary structure for each of the 32 β-strands of Fab A33. A, B) Strand order shown by lettering (A-G) for variable and constant domains, respectively. C, D) Percentage increase/decrease in β-strand secondary structure for each strand in Fab during the simulations, respect to pH 7.0 and 300 K, for: C) pH 4.5 and 300 K, D) pH 7.0 and 340 K. Error bars are the same and equal for positive and negative values.

836

34

837   **Fig S5. Salt Bridge analysis for simulations at pH 4.5 at 300 K, and pH 7.0 at 340 K.** A, B)

838   Salt bridges formed during the simulation time for representative MD simulations at A) pH 4.5 and

839   300 K, B) pH 7.0 and 340 K. Presence of a salt bridge is indicated in white and absence in black.

840   C, D) List of salt bridges and its occurrence for simulations at A) pH 4.5 and 300 K, B) pH 7.0 and

841   340 K. Values shown are the average of three independent simulations with their SEM as error.

842   The more persistent salt bridges are highlighted for pH 4.5 (red) and for high temperature 340 K

843   (blue). E, F) The more persistent salt bridges are mapped into the Fab A33 structure.

844

845   **Fig S6. Stabilizing mutations predicted by FoldX and Rosetta. Correlation between FoldX**

846   **and Rosetta predictions.** Mutations predicted by both software to be most stabilizing are shown

847   in magenta and highlighted in a gray square on the bottom left. Mutations predicted only by FoldX

848   to be stabilizing are shown in green and mutations predicted only by Rosetta in yellow.

849

850   **Table S2. List of the most stabilizing mutations identified by FoldX and Rosetta-ddG.**

851   Mutation and $\Delta\Delta G$ of the 25 most stabilizing mutations predicted by FoldX and Rosetta.

852

853   **Fig S7. Normals used to calculate the packing of each atom in Fab A33 using occluded**

854   **surface software.** To calculate the occluded surface packing (OSP) value for each residue,

855   normals that extend from the surface outward until they intersect a neighboring van der Waals

856   surface are used. The normals used to calculate the OSP value of the inter-domain residues

857   identified by FoldX and Rosetta (S176, N137, S397, T180, and S395), are shown.

858

859   **Table S3. Packing indicated by the occluded surface packing (OSP) value of the residues**

860   **located in β-strands within domain interfaces (V_L-V_H and C_L-C_H1) of Fab A33 homology**

861   **model**. OSP values were calculated using the occluded surface software.

862   *, residues identified by FoldX and Rosetta in the constant domain interface that can be stabilized

863   further.

864

865   **Fig S8. Sequence entropy of Fab sequences.** (A) Entropy (Hx) of one hundred Fab light chains,

866   including κ and λ light chains. (B) Entropy (Hx) of one hundred Fab heavy chains. Light and heavy

867   chains are from human and mouse species. Alignment and entropy calculation were done with

868   Bioedit. Variable domains are indicated with a (V) and constant domains with a (C), separated by

869   a vertical line. CDRs are indicated in red.

870

871   **Fig S9. Aggregation prone regions (APR) in Fab A33.** A) The normalised aggregation

872   propensity for each residue in Fab A33 was predicted using PASTA 2.0, TANGO, AGGRESCAN

873   and MetAmyl software, each being colour-coded as shown in the legend. Aggregation-prone

874   sequences where three of the four software agreed were selected, and highlighted with an

875   asterisk. Amylpred2 consensus tool was also used to confirm the identification of those APRs,

876   indicated in red on the top. B) Using the native Fab A33 homology model, regions with greater

877   aggregation propensities are shown in red and reduced propensities in blue.
