Abstract

SUMO is an essential post-translational protein modification regulated in part by the activity of a family of SUMO-specific proteases known as SENPs. Mammalian cells express six different SENPs with essential and non-redundant functions. The molecular mechanisms that determine the substrate specificities of individual SENPs and their unique functions, however, remain unknown. Thymine-DNA glycosylase (TDG) is an important enzyme that recognizes and repairs G/U and G/T mismatches in the genome during the initial stages of base excision repair (BER), and this role is critical in genome integrity and also DNA demethylation. TDG is sumoylated *in vivo* and we are interested in exploring the functional importance and regulation of its modification. We previously found that SENP1 preferentially deconjugates sumoylated TDG *in vivo*, compared with SENP2, and that specificity is determined by the SENP1 catalytic domain (cSENP1). Here, we have used *in vitro* studies to further explore this specificity by comparing the activities of the SENP1 and SENP2 catalytic domains using multiple substrates, including AMC, RanGAP1 and TDG. Because TDG contains a SUMO interaction motif (SIM) that affects its modification *in vivo*, we hypothesized that non-covalent, intramolecular SUMO-SIM interactions impede TDG deconjugation. We also hypothesized that the cSENP1 is more efficient at disrupting the TDG SIM-SUMO interaction, thus explaining specificity. To test these hypotheses, we measured deconjugation rates of cSENP1 and cSENP2 over time for SUMO-modified RanGAP1, wild type and SIM mutant TDG. Our result supported a role for SIM binding in impeding

deconjugation, and also revealed interesting and unique substrate specificities for both cSENP1 and cSENP2.

Introduction

Covalent modifications of proteins allow fast and energetically inexpensive alterations in protein functions and these modifications, including phosphorylation, acetylation, ubiquitylation, and sumoylation, regulate most cellular processes (Johnson, 2004; Flotho & Melchoir, 2013). Sumoylation, one of the recently discovered post-translational modifications, involves the covalent attachment of a 15 kDa small ubiquitin-related modifier, or SUMO, to a target substrate (Boggio et al., 2004). Through this process, sumoylation regulates a diversity of essential cellular processes, such as nuclear-cytosolic transport, transcription regulation, cell cycle progression, as well as protein stability (Hay, 2005). The covalent linkage occurs between the lysine residue of a target substrate and the C-terminal glycine of the SUMO protein, and it is mediated by an enzymatic cascade of activating enzyme E1 (SAE1/UBA2), conjugating enzyme E2 (Ubc9), and E3 ligase (Bernier-villamor et al., 2002; Reverter & Lima, 2005; Melchoir et al., 2003). There are different SUMO paralogs, including SUMO1, SUMO2, and SUMO3. SUMO2 and SUMO3 have ~96% identity and are collectively termed SUMO2/3, while SUMO1 is ~45% identical to SUMO2/3 (Saitoh & Hinchey, 2000). SUMO modification influences a target protein not only through covalent modification but also through non-covalent interactions with SUMO-interacting motif (SIM) contained on a target or another protein, mediating protein-protein interactions (Geiss-friedlander & Melcoir, 2007). SUMO modification is reversed by Sentrin Isopeptidases, also known as SENPs, and this regulation produces a dynamic cycling between conjugation and deconjugation of the substrates (Mukhopadhyay & Dasso, 2007; Nayak & Muller, 2014).

There are six mammalian SENP paralogs, including SENP1, SENP2, SENP3, SENP5, SENP6, and SENP7, and they have diversified N-termini while sharing highly conserved catalytic domains.

Because sumoylation impacts proteins in ways ranging from changes in localization, altered activity and often stability of the sumoylated protein (Geissfriedlander & Melcoir, 2007; Cubenas-Potts et al., 2013), the dynamic cycle of conjugation and deconjugation must be precisely regulated. Therefore investigating the unique SENP specificities for sumoylated substrates is a critical step in further understanding the nature of sumoylation and its influences. This is particularly important because an imbalance in the SUMO system contributes to initiation and progression of cancer and tumorigenesis (Bawa-khalfe & Yeh, 2010; Ei & Vertegaal, 2015).

Human thymine-DNA glycosylase (TDG) is an important enzyme in DNA repair, DNA demethylation, and transcription activation (Bellacosa & Drohat, 2015; Kohli & Zhang, 2013; Sjolund et al., 2013), and it is sumoylated. TDG is best known for its role in initial stages of base excision repair (BER) where it specifically recognizes G/U and G/T mismatches in the genome, generated from spontaneous deamination of cytosine or 5-methylcytosine, respectively. TDG proceeds to hydrolyze the N-glycosidic bond between the sugar phosphate backbone of DNA and the mispaired base, thus creating an abasic (AP) site (Barret et al., 1998; Lari et al., 2002). Interestingly, product inhibition at AP sites by TDG is observed, resulting in prevention of apurinic/aprimidinic endonuclease 1 (APE1) from creating a single strand break and therefore unable to move on to the next steps of BER. Based on crystallography studies, sumoylation has

been proposed to induce a conformational change in TDG that alleviates product inhibition (Hardeland et al., 2002, Ulrich, 2003) (Figure 1).

TDG contains a SUMO-conjugation site at amino acid residue K330, and SIMs at residues 133-137 and 308-311. Once TDG is sumoylated at K330, by either SUMO1 or SUMO2/3, the attached SUMO interacts non-covalently with the SIM of TDG at E310 (Baba et al., 2005 & 2006; Smet-Nocca et al., 2011, Figure 1B). This intramolecular interaction leads to a conformational change in the N-terminus of TDG that results in the protrusion of the alpha-helix, and this is proposed to disrupt TDG binding to the AP site by decreasing DNA-binding affinity (Smet-nocca et al., 2011). However, the role of TDG sumoylation in alleviating product inhibition in BER was studied *in vitro* recently, revealing that sumoylation may not be sufficient (Coey et al., 2014). This study also revealed that the presence of APE1 may be sufficient to alleviate product inhibition. In addition, previous studies from the Matunis lab investigated the effects of sumoylation and SIM-SUMO interactions on TDG activity *in vivo*, and found that TDG base excision repair activity did not require sumoylation (McLaughlin et al., 2016). Interestingly during this study, a unique specificity of SENP1 for sumoylated TDG was observed compared with cSENP2. It was observed that over-expression of SENP1 completely deconjugated sumoylated TDG, however SENP2 could only deconjugate at lower efficiency. Chimeric SENP1 and SENP2 enzymes with swapped catalytic domains, confirmed that this specificity lies within the catalytic domain of SENP1 (cSENP1). The over-expression of a SENP2 chimera with the SENP1 catalytic domain completely deconjugated sumoylated TDG whereas a cSENP1 chimera could not.

In this study, we investigated the substrate specificities of cSEN1 and cSEN2 for TDG *in vitro* in intention to explain the phenomenon observed in our previous *in vivo* experiments. We hypothesized that non-covalent, intermolecular SIM-SUMO interactions impede deconjugation of TDG. We also hypothesized that the cSEN1 is more efficient at disrupting the TDG SIM-SUMO interaction, thus explaining the unique specificity of cSEN1 (Figure 2). We first confirmed our cSEN1 and cSEN2 proteins as properly functioning isopeptidases by conducting deconjugation assays with sumoylated AMC (7-Amino-4-methylcoumarin) molecule and compared results with previously published data (Kolli et al., 2011). Then the substrate, SUMO1-RanGAP1 419 (Ran GTPase-activating protein 1), was utilized in deconjugation assays. Due to its lack of a SIM, we could measure baseline or control deconjugation rates to compare with sumoylated TDG. Finally, deconjugation rates were measured using wild-type TDG (TDGWT) and also a TDG SIM-mutant variant (E310Q) to observe the impeding effect of SIM-SUMO1 interactions on deconjugation by cSENPs. We observed more efficient deconjugation rates in assays with the TDG SIM-mutant, confirming the impeding role of SIM-SUMO1 interactions on deconjugation. However, both cSENPs were influenced by SIM-SUMO1 interactions equally, indicating no specificity in disruption of the interactions by one enzyme over another. Additionally, we found unique preferences of cSEN1 for the TDG SIM-mutant and RanGAP1 over TDGWT and cSEN2 for RanGAP1 over TDG substrates, and we propose unique substrate specificities being determined by combined SUMO1 and substrate binding to cSENPs.

Materials & Methods

1. Preparation of SENP Catalytic Domains

DE3 Rosetta competent cells were transformed with plasmids pET28a-SENP1 (catalytic domain 419-644) and pET28a-SENP2 (catalytic domain 365-590). Both plasmids included 6 Histidine tags and kanamycin resistance gene. First, 1 ul of the plasmid (70 ng/ul) was added to 50 ul of DE3 cells and left on ice for 10 minutes. The cells were then heat-shocked at 42 °C in water bath then left on ice for 2 minutes. 450 ul of Super Optimal Broth (SOB) medium was added to the cells then the cells were incubated at 37 °C for 20 minutes for recovery. The whole 500 ul of the recovered cells were spread on chloramphenicol (34 ug/mL) & kanamycin plate for overnight incubation at 37 °C. One or two colonies were used to make starter culture then 1.5 L culture was incubated at 37 °C until optical density of 0.8 (600 nm GeneQuant 100, GE). The cells were induced with 0.5 mM IPTG for 4 hours at 30 °C then centrifuged at 4000 g-force for 20 minutes to pellets and flash-frozen. The frozen pellets were resuspended in Lysis Buffer A (20% sucrose, 20 mM Tris-HCl pH 8, 1 mM DTT, 350 mM NaCl, 20 mM Imidazole, 20 ug/mL lysozyme, 1:100000 Benzonase, 1 mM PMSF, and 0.1% NP-40) and left on ice for 30 minutes. The cells were lysed with French Press Machine twice between 10,000 and 15,000 psi, then centrifuged for 30 minutes at 60,000 g-force at 4 °C. The supernatant was collected to be incubated with 500 ul Ni-NTA Agarose, equilibrated with Wash Buffer A (20 mM Tris-HCl pH 8, 350 mM NaCl, 1 mM DTT, and 20 mM Imidazole), for 1 hour at 4 °C. The mixture was poured into the column then washed with 10 bed volumes of Wash Buffer A. To elute SENP catalytic domains, 20 mL of Elution Buffer A

(Wash Buffer A with 250 mM Imidazole) was used to collect in 4 fractions. Each fraction was diluted with 5 mL of Dialysis Buffer (Wash Buffer A with 0 mM Imidazole) to prevent precipitation. After checking protein concentration, the first fraction was dialyzed at 4 °C, consecutively three times, in Dialysis Buffer at 1:3000. For further purification, the proteins were purified via Gel Filtration Column (Superdex-200) with Size Exclusion Buffer A (20 mM Tris-HCL pH 8, 350 mM NaCl, and 1 mM DTT).

2. Preparation of SUMO1-RanGAP1 419

Co-transformation method is used to SUMOylate the substrates RanGAP1 419 and TDG *in vivo*. Approximately 350 ng of each of two plasmids, E1/E2/SUMO1 (includes chloramphenicol resistance gene) and pGEX6P1 GST-RanGAP1 419 (includes carbenicillin resistance gene), were added to BL21 competent cells and the previous transformation method was followed. The 500 ul of the recovered cells were spread on chloramphenicol (34 ug/mL) & carbenicillin (50 ug/mL) plate. About 20 colonies were used to inoculate starter LB culture of 100 mL then 4 L culture is incubated at 37 °C until optimal density of 0.8. The cells were then induced with 0.25 mM IPTG for 17 hours at 22 °C and were later centrifuged as previously described and flash-frozen. The pellets were resuspended in Lysis Buffer B (50 mM Tris-HCl pH 8, 150 mM NaCl, 0.5% Triton X, 1 mM DTT, protease inhibitor, lysozyme and benzonase) and set on ice for 30 minutes. The mixture was lysed and centrifuged as previously described, and the supernatant was collected to incubate with 500 ul of Glutathione beads, equilibrated with Lysis Buffer B without Triton-X and protease inhibitor, for one hour at 4 °C. The

complex was washed with Lysis Buffer B then with Cleavage Buffer (50 mM Tris-HCl pH 8, 150 mM NaCl, 1 mM EDTA, and 1 mM DTT). The mixture was poured into the column and was washed with 10 bed volume of Wash Buffer B (50 mM Tris-HCl pH 8, 150 mM NaCl, 1 mM DTT). The 500 ul bead-protein complex was incubated with 200 units of PreScission Protease overnight at 4 °C and SUMO1-RanGAP1 without GST-tag was eluted in supernatant via centrifugation. For further purification, the protein was dialyzed in Dialysis Buffer B (Buffer B with 0 M NaCl) then was purified by anion exchange HPLC using Mono Q Column (GE) with IE-A Buffer (20 mM Tris-HCl pH 8, 0 M NaCl and 1 mM DTT) at flow rate of 1 mL/min with a gradient of 0-50% IE-B Buffer (IE-A Buffer with 1 M NaCl) over 2 hours.

3. Preparation of SUMO1-TDGWT and SUMO1- SIM-Mutant (E310Q) TDG

Co-transformation method described above was also used for *in vivo* SUMOylation of both TDGWT and SIM Mutant TDG. Site-directed mutagenesis was performed to generate E310Q construct (includes Histidine 6 tag and kanamycin resistant gene) from pET28-hTDG construct. Co-transformation protocol was identical as that of RanGAP1 and used E1/E2/SUMO1 plasmid with either of the WT and SIM-Mutant constructs. After incubation with Ni-NTA agarose beads, the agarose-protein mixture was poured over the column to be washed with Wash Buffer C (50mM Tris-HCl pH 8, 300mM NaCl, 20mM Imidazole and 10mM DTT). The proteins were then eluted with Elution Buffer B (Wash Buffer C with 150mM Imidazole) in 10mLs and the first two fractions are dialyzed

in IE-A Buffer. For further purification, the proteins were purified using the same anion exchange HPLC method as RanGAP1.

4. In Vitro Analysis of Isopeptidase Activity for SUMO1-AMC

100 ul of assay mixture with Assay Buffer I (25mM Tris-HCl pH8, 150mM NaCl, 2mM DTT and 0.1% Tween 20) containing 1.6 uM of SUMO1-AMC (Boston Biochem UL-758) and purified cSENPs (0.1 nM for cSEN1P1 & 1 nM for cSEN2P2) were added to the wells on 96-well-microplate (Greiner Bio-One 655207). The microplate was inserted into spectrofluorometer and the emission fluorescence at 460 nm is recorded (excitatory wavelength of 360 nm) every 20 seconds with a range of 50 at 37 °C. A standard curve was generated with fluorescence recordings from the wells containing only the AMC molecules at concentrations of 0 uM, 0.05 uM, 0.1 uM, 0.2 uM, and 0.5 uM, to convert fluorescence into molar concentrations for quantification purposes. The converted data was plotted into a graph that represents deconjugation rates of the substrate using Prism 6 software. The data was obtained in triplicate.

5. In Vitro Analysis of Isopeptidase Activity for Sumoylated RanGAP1, TDGWT, and SIM Mutant TDG

In 1.5 mL tubes (Denville), master mixes of 100 uls consisting Assay Buffer I, 1 uM of the substrate, and cSENPs (1 nM for cSEN1P1 & 20 nM for cSEN2P2) were incubated in 30C water bath. At different time points (0, 30, 60, 90, 120, 300, 600, and or 900 seconds), 10 uls of the mix was drawn and was added into new tubes containing 1X

Sample Buffer to quench the reaction. The tubes containing 13 μ l of quenched reactions were then boiled on heat block (VWR) at above 100 °C for 10 minutes, then were left on ice for 3 minutes and quickly centrifuged. The reactions were loaded into 12.5% SDS-gels for electrophoresis then stained with Bio-Safe Coomassie G-250 Stain (161-0786) for 1 hour. The gels were destained with MilliQ water overnight at room temperature, then scanned with Odyssey Imaging Systems (LI-COR Biosciences) for analysis and quantification using Image Studio. The quantified data was plotted into graphs, using Prism 6 software, showing deconjugation rates. The data was obtained in triplicate.

Results

1. cSENP1 deconjugates SUMO1-AMC more efficiently than cSENP2

SUMO1-AMC, or sumoylated 7-Amino-4-methylcoumarin, is a commercial sumoylated substrate for SENPs and AMC's characteristic as a fluorophore (excitation and emission at 360 nm and 460 nm, respectively) allows measurement of isopeptidase activity (Fig. 3A). Previous studies showed a kinetics data comparing isopeptidase activities of cSENP1 and cSENP2 for SUMO1-AMC, and demonstrated that cSENP1 is a far more efficient isopeptidase than cSENP2 in SUMO1-AMC deconjugation (Kolli et al., 2010). We utilized this finding to test our purified cSENPs as functional isopeptidases, by looking at relative activities of cSENP1 and cSENP2 in deconjugation of SUMO1-AMC.

We observed a consistent decrease in the percentage of SUMO1-AMC over time in both assays with cSENP1 and cSENP2 (Fig. 3B). The figure shows the the initial rates of deconjugation of substrates within the initial 15 percent of product formation, and the slopes are -0.0587 and -0.1281 for cSENP1 and cSENP2, respectively. Notably a 10 times higher concentration of cSENP2 was needed in the assays to allow for accurate activity comparisons. The normalized slope values, where the slope of cSENP2 is divided by 10, are -0.05857 and -0.01281, respectively. The normalized rate ratio of cSENP1 to cSENP2 was 4.57. Therefore, consistent with the previous study (Kolli et al., 2010), cSENP1 showed more efficient deconjugation of SUMO1-AMC than cSENP2.

2. cSEN1 deconjugates SUMO1-RanGAP1 more efficiently than cSEN2

From the SUMO1-AMC assays, we found that our cSENPs were properly active as isopeptidases, and used sumoylated RanGAP1 419 as the next substrate of study. Because RanGAP1 419 does not contain a SIM, and SUMO1 is expected to be freely accessible for isopeptidase recognition. Activity assays with RanGAP1 and SENPs therefore provided an adequate control model for comparison with TDG, which has SIM. SENP1 in general shows better isopeptidase activity for SUMO1-proteins than SENP2, therefore the assays with RanGAP 419 provide baseline of relative activity for our cSENPs (Mikolajczyk et al., 2007; Reverter & Lima, 2009; Kolli et al., 2010). We sought to record the deconjugation rates of cSENPs for SUMO1-RanGAP 419 for this purpose.

Previous *in vitro* studies showed that the amount of cSEN1 and cSEN2 required to deconjugate 50% of sumoylated RanGAP1 N (amino acids 418-588) in an hour was 3.4 nM and 10.8 nM, respectively (Reverter and Lima, 2009). Consistent with the previous study, our results showed faster deconjugation of SUMO1-RanGAP 419 by cSEN1 compared with cSEN2 (Fig. 4A & 4B). On lane 7 of Figure 4A (at 300 seconds), cSEN1 activity assays showed a complete deconjugation of the SUMO1-RanGAP 419 (30 kDa). However, cSEN2 activity assays revealed only partial deconjugation of SUMO1-RanGAP 419 at 300 seconds and also later time points (Fig. 4B). The intensities of the protein bands on coomassie gels were used to quantify the results, as shown on the lane 2 of Figure 4A, and the quantification was plotted into a

graph that shows the change in percentage of SUMO1-RanGAP 419 over time. The quantification utilized the following equation: $\{(Modified)/(Modified + Unmodified)\} \times 100$.

Figure 4C from our findings showed that cSENP1 is far more efficient than cSENP2 in deconjugating SUMO1-RanGAP 419, requiring 91.75 seconds and 137.9 seconds, respectively, for 50% deconjugation. The regression equations were generated with the data from the first 30 seconds of the incubation where 10-15% of products were formed. The slopes representing deconjugation rates are -0.5449 and -0.3624 for cSENP1 and cSENP2, respectively. Notably, 1 nM of cSENP1 and 20 nM cSENP2 were used in the assays. These concentrations of the enzymes were based on titrations that resulted in similar and comparable deconjugation of the substrate. In addition, this ratio provided an optimal intensity of protein bands on coomassie gels for quantification purposes. The normalized slopes are -0.5449 and -0.01812 for cSENP1 and cSENP2, respectively, and the ratio of the normalized slopes revealed a 30 fold difference in activity.

3. SIM-SUMO1 interactions in TDG Impede deconjugation

We previously found that SENP1, but not SENP2, deconjugates sumoylated TDG *in vivo* and that specificity is determined by the SENP1 catalytic domain (Mclaughlin et al., 2016). From here, we hypothesized that this unique specificity is due to non-covalent interactions between SUMO1 and the SIM of TDG that impedes SENP2 recognition and deconjugation. We further hypothesized that the catalytic domain of

SEN1 is more efficient at disrupting the TDG SIM-SUMO interaction, thus explaining the specificity.

To first test the impact of SIM-SUMO1 interactions on TDG deconjugation, we compared SUMO1-TDGWT to a SUMO1-SIM mutant variant of TDG by measuring deconjugation rates with our cSENPs. Our findings showed that both cSEN1 and cSEN2 prefer the SIM mutant variant of TDG over TDGWT (Figure 5E). The observed initial slopes of deconjugation by cSEN1 were -0.42 and -0.53 for TDGWT and SIM mutant, respectively. The slopes with cSEN2 were -0.049 and -0.062, and both cSENPs resulted in a higher rate of deconjugation for the SIM mutant. The Figures 5A ~ 5D show results from deconjugation assays and reveal protein bands for modified (80 kDa) and unmodified (65 kDa) versions of TDGWT and SIM mutant TDG, respectively, over time. From cSEN1 assays (Figures 5A & 5B), we observed faster rates of deconjugation in assays with the SIM mutant TDG, where almost all of the substrate was deconjugated after 600 seconds of incubation (last lanes of Figures 5A & 5B). In addition, cSEN2 assays (Fig. 5C & 5D) also showed a similar trend where SIM mutants were deconjugated faster than TDGWT. The last lanes of Figures 3 & 4 revealed that nearly 50% of the modified SIM mutant TDG was deconjugated whereas the TDGWT was significantly deconjugated less at the same time point. Overall, our results showed faster deconjugation of the SIM-mutant TDG over TDGWT with both cSENPs.

4. SIM-SUMO1 interactions in TDG equally affect cSEN1 and cSEN2

The assays with TDGWT and the SIM mutant TDG demonstrated the preferences of the cSENPs for SIM-mutant over TDGWT. However we originally hypothesized that this SIM-SUMO1 interaction would be disrupted better by cSEN1 than cSEN2.

To further test our hypothesis, we compared the initial deconjugation slopes of cSEN1 to cSEN2 for both substrates. The initial deconjugation slope for the TDG SIM mutant was divided by the initial deconjugation slope of TDGWT to generate the ratio. Notably, this SIM mutant-to-TDGWT ratio was 1.27 for both cSEN1 and cSEN2 (Figure 5E). Our findings therefore suggest that the SIM-SUMO1 interaction impedes deconjugation by both cSENPs with equal efficiency.

5. cSEN1, not cSEN2, deconjugates the TDG SIM-mutant similar to

***RanGAP1* 419**

The cSEN1 deconjugation assays for all three substrates (RanGAP1, TDGWT, and TDG SIM mutant) were combined to observe differences in deconjugation rates among the substrates. Our result in Figure 6A showed that the initial slopes of RanGAP1 and the TDG SIM mutant were -0.5449 and -0.5379, respectively. The ratio of the two slopes was 1.013, revealing that cSEN1 exhibits a very similar specificity for both substrates. On the other hand, a similar analysis of cSEN2 revealed that the initial slopes for RanGAP1 and the TDG SIM mutant were -0.3624 and -0.0645 (Figure

6B). The ratio of the two slopes for cSENP2 was 5.8, indicating much slower deconjugation of the TDG SIM mutant compared to RanGAP1.

Discussion

A proposed *in vitro* model generated from crystallography structures of sumoylated TDG suggested that sumoylation functioned to alleviate product inhibition following base excision (Hardeland and Steinacher, 2002, Figure 1). However, previous studies from the Matunis lab investigated the effects of sumoylation and SIM-SUMO interactions on TDG activity *in vivo*, and found that TDG base excision repair activity did not require sumoylation (McLaughlin et al., 2016). Interestingly, the unique specificity of cSEN1 for TDG, compared with cSEN2, was also observed in this study and we intended to define the variables dictating this phenomenon through the studies reported here.

In our experiments, we hypothesized that SIM-SUMO1 interactions in sumoylated TDG impedes deconjugation, and that cSEN1 more efficiently disrupts this interaction, explaining the *in vivo* phenomenon. Our *in vitro* experiments demonstrated that TDG SIM-SUMO1 interactions do impede deconjugation. Faster deconjugation rates were observed for SIM-mutant TDG compared to TDGWT with both cSEN1 and cSEN2, consistent with the first hypothesis.

However, the impact of SIM-SUMO1 interactions on TDG deconjugation rate was nearly identical for cSEN1 and cSEN2, therefore not supporting our second hypothesis that cSEN1 more efficiently disrupts the interaction compared to cSEN2. Since both cSENPs were affected equally, whether or not cSENPs play a catalytic role in disruption of the SIM-SUMO1 interaction remains to be further investigated in the future. There is a possibility that cSEN binding to TDG may induce a conformational

change leading to the disruption of the SIM-SUMO1 interaction and deconjugation. Therefore, crystallographic studies of enzyme-substrate structures will be helpful in elucidating the mechanism of TDG deconjugation.

Previously, X-ray crystallography studies (Reverter and Lima, 2004) revealed that, in addition to an extensive interface between the protease and the globular SUMO domain, cSEN2 also contacts the substrate lysine and SUMO consensus conjugation site during deconjugation. Site-directed mutagenesis in cSEN2 residues that are found to establish hydrophobic interactions with RanGAP1 residues resulted in less efficient deconjugation, suggesting the role of enzyme-substrate interactions in the substrate recognition and binding. Our results showed that cSEN1 has similar preferences for RanGAP1 and the SIM-mutant TDG, as it was able to deconjugate the SIM-mutant TDG at a similar rate when compared to RanGAP1 419. It may suggest that cSEN1 recognizes only SUMO1 for its isopeptidase activity, at least for these two substrates (Figure 7A). On the other hand, cSEN2 showed a unique preference for RanGAP1 relative to both TDGWT & the SIM mutant TDG. cSEN2 deconjugation rates for SIM-mutant TDG was not similar to RanGAP1 but more similar to TDGWT, suggesting that cSEN2 recognizes the two substrates differently, compared with cSEN1. Our Figure 7B demonstrates a proposed model of cSEN2 recognizing not only SUMO1 but also part of the substrate, RanGAP1 419, for isopeptidase activity. The model, consistent with the previous study, suggests that the interaction of cSEN2 with the substrate, in addition to with SUMO1, may enhance substrate binding and deconjugation.

Conclusion

In conclusion, we observed an impeding effect of SIM-SUMO1 interactions in deconjugation of sumoylated TDG. However, both cSEN1 and cSEN2 activities toward sumoylated TDG were equally enhanced by mutating the SIM, indicating no specificity in disrupting SIM-SUMO1 interactions. How, and if, SIM-SUMO1 interactions are disrupted prior to deconjugation must be studied to better understand its impeding effect. Additionally, cSEN1 and cSEN2 showed unique substrate specificities beyond SUMO1 recognition *in vitro*. We observed that cSEN1 showed similar preferences for RanGAP1 and SIM-mutant TDG, whereas cSEN2 showed a unique preference for RanGAP1 relative to both TDGWT & SIM-mutant TDG. Finally, we propose models of substrate recognition for cSEN1 and cSEN2 that may explain the difference in substrate preference. Further structural studies that explore the substrate recognition of cSENs will help to further elucidate SUMO isopeptidase substrate specificities.

Figure Legends

Figure 1. Proposed model of TDG sumoylation alleviating product inhibition

During initial stages of BER, endogenous unmodified TDG (green) recognizes G/U or G/T mismatches (red) and hydrolyzes the mispaired base, producing an AP site. TDG remains tightly bound on the AP site, preventing the downstream enzyme APE1 (orange) to bind and proceed. This product inhibition is proposed to be alleviated by sumoylation (yellow) of TDG. TDG sumoylation induces conformational change that results in reduction of its DNA affinity and therefore dissociation from the AP site. The sumoylated TDG is deconjugated by SENPs and recycled. The image is adapted from Hardeland et al., 2002

Figure 2. Hypothesized model of cSEN1 interacting with sumoylated TDG

Figure in green represents sumoylated TDG with sumoylation site at K330 and SIM at E310. The attached SUMO1 (yellow) is non-covalently interacting with SIM of TDG. We hypothesize that SIM-SUMO1 interaction impedes deconjugation by cSENPs and that cSEN1 is more efficient at disrupting these interactions. Once SIM-SUMO1 interactions are disrupted, the SUMO1 protein is more accessible for deconjugation.

Figure 3. SUMO1-AMC deconjugation assays.

(A) SUMO1-AMC is a sumoylated commercial substrate which consists of isopeptide bond between SUMO1 and AMC. Once SUMO1 is deconjugated by cSENPs, the AMC molecule is capable of being excited at 360 nm wavelength and of emitting 460 nm wavelength, which can be detected by spectrofluorometer. This image is adapted from Kolli et al., 2010.

(B) Graph comparing the percentage of 1.6 μ M SUMO1-AMC over time after incubation with 0.1 nM cSEN1 (red) vs with 1 nM cSEN2 (blue). SUMO1-AMC substrate was incubated with either cSEN1 or cSEN2 in 96 well plate, and excitation and emission wavelengths at 360 nM and 460 nM, respectively, are applied to measure the rate of deconjugation, every 20 seconds. The measured fluorescence are converted to protein concentrations first with the standard curve (not shown here) then the percentage out of the initial SUMO1-AMC concentration is calculated and plotted into the graph. The box shows the initial velocities of deconjugation within the first 10~15% product formation period. The data was obtained in triplicate.

Figure 4. SUMO1-RanGAP1 419 deconjugation assays.

(A) Coomassie gel scan of 1 μ M SUMO1-RanGAP 419 (~30 kDa) incubated with 1 nM cSEN1 at time points 0, 30, 60, 90, 120, 300, 600, and 900 seconds. Over time, more unmodified RanGAP 419 (~15 kDa) are observed. Red boxes in lane 1 shows the method of quantification $\{\text{unmodified}/(\text{unmodified}+\text{modified})\}$. This quantification is used to plot the data into graph shown in Figure 4C.

(B) Coomassie gel scan of 1 μ M SUMO1-RanGAP 419 (~30 kDa) incubated with 20 nM cSENP2 at identical time points as Figure 4A. The descriptions are identical as Figure 4A.

(C) Graph comparing the percentage of SUMO1-RanGAP 419 over time after incubation with 1 nM cSENP1 (red) vs with 20 nM cSENP2 (blue). The protein bands on gel scans are quantified as described in Figure 4A. The box shows the initial velocities of deconjugation within the first 10~15% product formation period. The data was obtained in triplicate.

Figure 5. SUMO1-TDGWT and SUMO1-SIM-mutant TDG deconjugation assays.

(A) Coomassie gel scan of 1 μ M SUMO1-TDGWT (~80 kDa) incubated with 1 nM cSENP1 at time points 0, 30, 60, 90, 120, 300, and 600 seconds. Over time, more unmodified TDGWT (~65 kDa) are observed as well as an increase in free SUMO1 (~15 kDa). The quantification method is identical as RanGAP assays.

(B) Coomassie gel scan of 1 μ M SUMO1-SIM-mutant TDG (~80 kDa) incubated with 1 nM cSENP1 at identical time points as Figure 5A. The descriptions are identical as Figure 5A.

(C) Coomassie gel scan of 1 μ M SUMO1-TDGWT incubated with 20 nM cSENP2 at identical time points as Figure 5A.

(D) Coomassie gel scan of 1 μ M SUMO1-SIM-mutant TDG incubated with 20 nM cSENP2 at identical time points as Figure 5A.

(E) Graph comparing the percentage of SUMO1-TDGWT vs SUMO1-SIM-mutant TDG over time after incubation with cSENPs. The box shows the initial velocities of deconjugation within the first 10~15% product formation period. Comparison of these initial velocities show that in cSEN1 assays, SIM-mutant TDG (magenta) is deconjugated more efficiently than TDGWT (red). Similarly, in cSEN2 assays, SIM-mutant TDG (cyan) is deconjugated more efficiently than TDGWT (blue) than cSEN2. Notice the ratio of these initial velocities, comparing SIM-mutant to TDGWT, is 1.27 for both cSEN1 and cSEN2 assays.

Figure 6. Comparison of TDG and RanGAP assays.

(A) Graph comparing the percentages of 1 uM SUMO1-TDGWT (red), 1 uM SUMO1-SIM-mutant TDG (magenta), and 1 uM SUMO1-RanGAP1 419 (black) over time after incubation with 1 nM cSEN1. The box shows the initial velocities of deconjugation within the first 10~15% product formation period, and shows very similar velocities between SIM-mutant and RanGAP1 419.

(B) Graph comparing the percentages of 1 uM SUMO1-TDGWT (blue), 1 uM SUMO1-SIM-mutant TDG (cyan), and 1 uM SUMO1-RanGAP 419 (black) over time after incubation with 20 nM cSEN2. The box shows the initial velocities of deconjugation within the first 10~15% product formation period, and shows more similar velocities between TDG substrates than with SUMO1-RanGAP 419.

Figure 7. Proposed models of substrate recognition by cSENPs

(A) Model 1 shows cSEN1 recognizing the substrates, SUMO1-RanGAP 419 and SUMO1-TDGWT without SIM-SUMO1 interactions, to cleave isopeptide bonds. The model proposes that cSEN1 recognizes only the attached SUMO1 for isopeptidase activity. RanGAP1 419 is modified at K524 and TDG is modified at K330. E310 on TDG indicates SIM residue.

(B) Model 2 shows cSEN2 recognizing the substrate, SUMO1-RanGAP 419 to cleave isopeptide bond. The model proposes that cSEN2 not only recognize the attached SUMO1 but also interacts with the substrate residues (red dotted lines) therefore enhancing its isopeptidase activity.
