Civil and Environmental Engineering

## ACKNOWLEDGMENTS

First, I would like to thank my committee members, Dr. Simos Gerasimidis and Dr. Scott Civjan, for their advice, guidance, and support throughout this project. I am very grateful to have such excellent mentors, and I certainly could not have accomplished this without their help. I would also like to thank Mr. Mark Gauthier, who went above and beyond to ensure the success of the experimental portion of this project. I would also like to thank John Czach and Joe Rigney, whose input truly helped guide this project in the right direction.

Lastly, I would like to thank my loving parents for all of their support throughout my six years at UMass. I would not have finished if it weren't for them.

## **ABSTRACT**

### **POST-FIRE ASSESSMENT OF CONCRETE TUNNEL STRUCTURES**

MAY 2021

NICHOLAS C. MENZ, B.S., UNIVERSITY OF MASSACHUSETTS AMHERST

M.S.C.E., UNIVERSITY OF MASSACHUSETTS AMHERST

Directed by: Dr. Simos Gerasimidis

Although concrete tunnel structures can lose strength and long-term durability due to fire, the literature on the remaining capacity of structures after fire events is very scattered, and no published post-fire inspection protocols specifically for concrete tunnel structures are available. This work aims to summarize and synthesize the current state of knowledge of the deleterious effects of fire on the residual condition of concrete tunnel structures and how the extent and degree of fire damage can be assessed. The scope of this work includes an extensive literature review, heat testing of some common tunnel elements, and residual strength testing of a tunnel wall panel. The literature review includes a review of published standards, technical reports, academic papers, and a survey of post-fire inspection practices at other state DOTs and transit organizations. Topics covered in the review include the residual mechanical properties of concrete, steel, and the concrete/steel bond after fire, the residual strength and stiffness of structural members after fire, existing inspection tools and methods for assessing concrete structures after fire, and repair methods for fire-damaged concrete structures. The outcomes of the heat testing are presented, including the setup of a radiant heating system (which does not use a flame), procurement of sample specimens for testing, thermal and

physical testing of specimens, and evaluation of results. Lastly, based on the literature review and experimental testing, recommendations for future work are presented.

## CHAPTER 1

### INTRODUCTION TO FIRE AND CONCRETE STRUCTURES

#### 1.1. Overview and Motivation for Study

Tunnels are a vital part of the United States' transportation infrastructure. According to data from the 2019 FHWA National Tunnel Inventory, there are 522 tunnels being operated within the US [1]. Several recent tunnel fire events at transit organizations across the country have revealed the need for guides and resources which describe the potential effects of fire on concrete tunnel structures and describe methods which can be used to assess these structures after fire events. Though it is well known that fire can negatively affect concrete structures in a variety of ways, such as loss in strength and stiffness of structural members, excessive deflections/distortions, and reductions in the long-term durability of the structure, few comprehensive documents on the subject are available.

At present, there are two overarching topics in the field of research on fire and structures:

- the residual condition of structures after fire
- fire resistance design

The residual condition of structures after fire is mainly concerned with the strength and serviceability loss of a structure after a fire event, as well as the long-term health of the structure. On the other hand, fire resistance can broadly be defined as the “ability of an element (not a material) of building construction to fulfill its designed function for period of time in the event of a fire,” which pertains more to the design and retrofit of concrete tunnel structures [2]. This work focuses on the topic of the residual

condition of structures after fire, as this is more pertinent for a post-fire evaluation. At present, the research literature between the two topics is very unbalanced. Most of the research efforts have focused on fire resistance design, as it is important to design tunnel structures against a fire event, to prevent tragedies such as the 1996 Channel Tunnel fire or the 1999 Mont Blanc Tunnel fire, which both resulted in significant loss of life.

Published work on the residual conditions of structures after a fire is a much less explored field and this work aims at summarizing the current state of knowledge to help inform future research efforts.

## **1.2. Introduction to the Residual Condition of Structures after Fire**

The residual condition of concrete structures after fire is the focus of this work, as it has been extensively demonstrated that fire can harm the residual strength, residual serviceability, and long-term durability of concrete structures. The level of damage sustained by a structure is largely dependent on the decay in mechanical properties of concrete and steel, as their post-fire mechanical properties dictate the residual behavior of the structural members and the structure as a whole after fire. Both concrete and steel may suffer a permanent loss in strength and stiffness after a fire event, and as a result numerous studies have been conducted on the post-fire properties of these materials. Heat exposure can also result in thermal spalling of concrete, which can reduce the effective cross-section of structural members and expose reinforcing steel. Several studies have also been conducted on the residual strength and stiffness of structural members or subassemblies which have been exposed to fire. Since in most cases full-scale load tests of damaged structures or structural members are impractical, however, most post-fire

inspection techniques are aimed at characterizing the residual mechanical properties of concrete and steel material after fire.

Several factors govern the level of damage that a structure sustains after a fire event. The air temperature during the fire has a significant effect, as the decay in the mechanical properties of concrete and steel are heavily dependent on the maximum temperature experienced during the fire. In addition, the duration of the fire is also important, as longer fires generally result in heat penetrating deeper into the concrete, not only damaging a greater volume of concrete, but also potentially causing steel reinforcement to experience higher temperatures. Another important factor is the location of the fire during the fire event. Since concrete structures have excellent thermal insulation on account of the excellent thermal insulation properties of concrete, typically only regions of the structure near the fire location will sustain damage.

To develop a post-fire inspection protocol, all the possible detrimental effects of fire exposure on the residual condition of a structure and its structural elements must be considered. The purpose of this work is to elucidate these effects and present inspection methods which can identify the types of damage that are likely to occur due to fire.

### **1.3. Introduction to Fire Resistance Design**

Though the focus of this work is on the residual condition of structures after fire, the topic of fire resistance design is briefly summarized in this section, as some concepts overlap between the two fields of study. Fire resistance can broadly be defined as the “ability of an element (not a material) of building construction to fulfill its designed function for period of time in the event of a fire” [2]. In other words, fire resistance design is focused on the immediate safety of occupants during a fire by ensuring that a

structure can withstand fires of a certain duration. The majority of research on structures and fire has focused on fire resistance design, and several codes and standards are available to assist designers in creating fire-resistant structures. Fire resistance design can be categorized by three approaches: fire testing, prescriptive methods, and performance-based methods.

Fire testing usually involves exposing a structural element or sub-assembly of a structure to high temperatures in a testing furnace while the element is subjected to a service load with its expected support conditions. The air temperature in the furnace over the course of the test is usually stipulated by design fire curves. Several design fire curves exist, such those shown in Figure 1.1.

**Figure 1.1 Comparison of common fire design curves (curves which dictate the air temperature of the furnace over time) (used with permission from Taylor & Francis) [3]**

The ISO 834 and ASTM E119 fire curves are very similar and are intended for the design of typical buildings. The hydrocarbon (HC) and hydrocarbon modified (HCM)

curves are intended to represent the combustion of hazardous materials such as chemicals and fuels. Lastly, the Rijkswaterstaat (RWS) and RABT/ZTV fire curves were developed specifically for the design of tunnels, as experiences with several tunnel fires showed other fire curves may not be severe enough to represent tunnel fires [3].

Prescriptive methods for fire design are much simpler and are the most widely implemented of the three methods. Examples of prescriptive methods include requirements of minimum cover to reinforcement for certain design fires, and requirements of maximum temperatures within certain elements for a design fire.

Performance-based methods have gained traction in the last few decades, and some countries have implemented these methods in their codes. These methods involve the use of engineering calculations and/or finite element analysis to prove that structures can meet fire design criteria specified at the beginning of the design process, such as withstanding expected fire loads without collapse [2] [4].

#### **1.4. Additional Documents on the Residual Condition of Structures After Fire, and Fire Resistance Design**

For reference, a non-exhaustive list of standards, codes, and technical reports on the subjects of the residual condition of structures after fire and fire resistance design are shown in Table 1.1. Furthermore, a journal paper written by the author of this work and others also discusses the post-fire inspection of concrete tunnel structures [5].

## **CHAPTER 2**

### **EXISTING STUDIES ON THE EFFECT OF FIRE ON STRUCTURAL MATERIALS**

#### **2.1. Introduction**

It is well known that both concrete and steel experience decay in their mechanical properties at elevated temperatures and after cooling down from elevated temperatures, with the most significant effect being the potential reduction in strength [6], [7].

Understanding the behavior of these materials is critical for the assessment of concrete tunnels after fire. Since it is impractical to perform full-scale load tests on a tunnel exposed to fire to determine its residual strength, most inspection methods are aimed at relating the properties of the structural materials to the residual strength of structural members and of the entire structure. As a result, many studies have been conducted on the properties of concrete and steel with respect to fire. The vast majority of these studies have been conducted on individual concrete and steel specimens, such as concrete cylinders and steel coupons, allowing researchers to isolate the most important factors dictating the response of these materials to thermal exposure.

The difference between “at elevated temperature” and “residual” should be distinguished here. “At elevated temperature” refers to the properties of a material when it is in the “hot” state. This is most relevant to the behavior of materials during a fire scenario. “Residual” refers to the properties of a material after it has been heated and cooled. This is most relevant to the post-fire scenario. However, the properties of materials both at elevated temperatures and after cooling will be discussed herein, as it is

important to understand the differences between these two conditions for assessing a structure after fire.

To understand the results of these experimental studies, it is important to understand the main test methods which have been employed for analyzing the mechanical properties of concrete and steel at elevated temperature and after cooling down. Concrete and steel are the focus of this work as they are the most commonly used materials in a tunnel construction. The methods are summarized as follows:

- **Unstressed test:** Specimens are heated to a certain temperature (without the application of any load) until steady-state conditions (uniform temperature) are achieved in the specimen. The specimen is then loaded until failure while hot, typically with compression tests for concrete and tensile tests for steel. The results of these tests are most applicable for estimating the performance of structural materials which are under very low stress during a fire.
- **Stressed test:** Specimens are loaded to service level stress, and then heated to a certain temperature until steady state conditions (uniform temperature) are achieved. While it is still hot, the load on the specimen is then increased until failure occurs. The results of these tests are most applicable for estimating the performance of structural materials which are under service level stress during a fire.
- **Unstressed residual test:** Specimens are heated to a certain temperature (without the application of any load) until steady-state conditions (uniform temperature) are achieved in the specimen. The specimen is then cooled to ambient temperature, usually by air but sometimes by water, and then loaded until failure,

typically with compression tests for concrete and tensile tests for steel. These tests are applicable for estimating the performance of structural materials after a fire event.

- **Stressed residual test:** These types of tests are far rarer than the previous three. Specimens are loaded to service level stress, and then heated to a certain temperature until steady state conditions (uniform temperature) are achieved. The specimen is then cooled to ambient temperature, usually by air but sometimes by water, and then loaded until failure, typically with compression tests for concrete and tensile tests for steel. These tests are most applicable for estimating the performance of structural materials after a fire event.

Although the unstressed residual test and the stressed residual test are most applicable for post-fire assessment situations, results from elevated temperature testing (stressed and unstressed) are included in this work as well, since some design codes present equations both at elevated temperatures and after cooling (residual).

## 2.2. Concrete

Concrete is the most commonly used material in modern tunnel engineering and structural engineering in general. Its performance at elevated temperatures and after cooling has been researched extensively over the last 50-60 years, particularly due to its use in nuclear power plants. In terms of its performance with respect to fire, concrete has two advantages: it is incombustible, and it has good thermal insulating properties on account of its low thermal diffusivity, allowing it to shield parts of the structure from fire [3]. On the other hand, concrete can experience loss of strength, loss of stiffness, and

spalling due to heat exposure, reducing the residual strength and durability of a structure [2].

This section describes the physical and chemical processes and the loss of strength and stiffness that occur due to heat exposure in concrete, thermal spalling of concrete, and some studies on the temperature distribution in concrete due to fire.

### **2.2.1. Physical and Chemical Changes During Heating and Cooling of Concrete**

When heated, concrete undergoes several largely irreversible physical and chemical processes that can damage the concrete and lead to decay of its mechanical properties [2], [8]. Three main factors contribute to the decay of mechanical properties:

- physical and chemical changes in the cement paste,
- physical and chemical changes in the aggregate,
- differential thermal strains between the aggregate and the cement paste.

The critical physical and chemical changes in the aggregate and cement paste are summarized in Table 2.1. The dehydration of the cement matrix and aggregate is of particular importance, as some studies have directly linked dehydration to strength loss [9], [10].

Differential thermal strain between the aggregate and the cement paste occurs because cement paste physically expands until reaching it reaches temperatures up to 150–200°C, then begins to contract at temperatures above this range, while the aggregates will continuously expand with increasing temperature. It has been noted, however, that the effects of these differential thermal strains are reduced during heating when the concrete under load due to a phenomenon called load-induced thermal strain ('transient creep'), which causes the relaxation and redistribution of thermal stresses in

the concrete [2]. As concrete cools down after heating, the beneficial effect of load-induced thermal strain is no longer active, and the differential thermal strains of the cement paste and aggregate can create further damage in the concrete. This explains why the strength of concrete after cooling from a certain maximum temperature is generally lower than the strength of the concrete when it is at that maximum temperature [8].

**Table 2.1: Summary of mineralogical changes in concrete due to heating (used with permission from the Institute of Civil Engineers [11])**

Heating temperature: °C	Changes caused by heating	
	Mineralogical changes	Strength changes
70–80	Dissociation of ettringite	Minor loss of strength possible (<10%)
105	Loss of physically bound water in aggregate and cement matrix commences, increasing capillary porosity	
120–163	Decomposition of gypsum	
250–350	Oxidation of iron compounds causing pink/red discolouration of aggregate. Loss of bound water in cement matrix and associated degradation becomes more prominent	Significant loss of strength commences at 300°C
450–500	Dehydroxylation of portlandite. Aggregate calcines and will eventually change colour to white/grey	
573	5% increase in volume of quartz (-to-quartz transition) causing radial cracking around the quartz grains in the aggregate	Concrete not structurally useful after heating in temperatures in excess of 500–600°C
600–800	Release of carbon dioxide from carbonates may cause a considerable contraction of the concrete (with severe micro-cracking of the cement matrix)	
800–1200	Dissociation and extreme thermal stress cause complete disintegration of calcareous constituents, resulting in whitish-grey concrete colour and severe micro-cracking	
1200	Concrete starts to melt	
1300–1400	Concrete melted	

### 2.2.2. Strength of Concrete at Elevated Temperatures and After Cooling Down

Though concrete is incombustible and possesses excellent thermal insulating properties, it can experience a decay in its strength at elevated temperatures and after cooling down due to largely irreversible physical and chemical changes. In terms of the post-fire assessment of a structure, the loss in strength of the concrete is of particular concern [12]. Though the focus of this work is on the post-fire condition of structures, both the properties at elevated temperature and after cooling down are described, as it is important to understand the differences between these two conditions for assessing a

structure after fire. Although a great amount of research has been conducted on both the strength of concrete at elevated temperatures [13], [14] and the residual strength of concrete after cooling [6], [15] [16] [17] [18] [19], the heterogenous nature of concrete makes theoretical predictions of mechanical properties in these scenarios difficult. Therefore, the majority of existing models for estimating the strength of concrete at elevated temperatures or after cooling down are based on the results of experimental studies [6], [13], [19].

Due to the wide variety of concrete strengths, types, and mixtures available, identifying the main factors which affect the strength of concrete during and after thermal exposure has been a focus of several studies. A couple of factors have emerged as the most significant [6], [13]:

- Original concrete compressive strength
- Type of aggregate (siliceous, calcareous, etc.)

Although other factors, such as maximum aggregate size or water/cement ratio can significantly affect the strength of concrete during and after thermal exposure, it has been shown that their effects can be seen through more general predictors such as compressive strength and are therefore generally not explicitly considered [6]. As far as the conditions to which the concrete is exposed, maximum temperature of the concrete material and loading conditions have also been shown to significantly affect the strength of concrete during and after thermal exposure. Furthermore, there are notable differences between the strength of concrete at elevated temperature and the residual strength of concrete after cooling.

### 2.2.2.1. Codes and Standards

Design codes and standards produced by several organizations, including CEN (Eurocode) and American Concrete Institute (ACI), feature equations and curves which describe the strength and stiffness of concrete both at elevated temperatures (in the “hot state”), and after cooling from elevated temperatures (residual).

For instance, *EN 1992 1-2* provides a set reduction factors which can be applied to the original compressive strength and elastic modulus of concrete to estimate the compressive strength and elastic modulus of concrete at elevated temperatures (in the “hot state”) [20]. The reduction factors for compressive strength are plotted in Figure 2.1. *EN 1992 1-2* distinguishes between concrete made with siliceous aggregates and that made with calcareous aggregates. The factors shown in Figure 2.1 are only intended for normal strength concrete up to strength class C50/60 (concrete with a minimum 28-day cylinder compressive strength of 50 MPa). Additional strength reduction factors based on a more limited data are provided in *EN 1992 1-2* for high-strength concrete (concrete up to C90/105).

The reduction factors in Figure 2.1 show that concrete begins losing compressive strength at elevated temperatures in the range of 200-300°C, and that concrete at temperatures of 600-700°C will have about 50% of its original strength. Equations are also provided in *EN 1992 1-2* to transform the strength reduction factors for concrete at elevated temperatures into stress-strain curves for concrete at elevated temperatures, as shown graphically in Figure 2.2 for siliceous aggregate concrete.

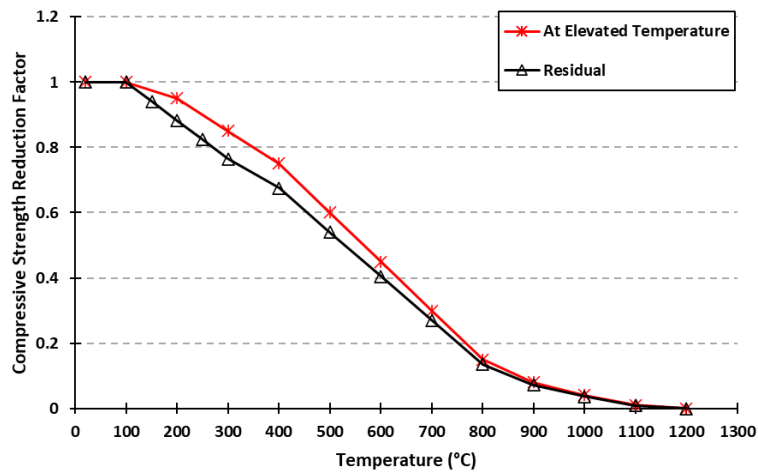

**Figure 2.1: Compressive strength reduction factors for concrete at elevated temperatures per EN 1992 1-2**

**Figure 2.2: Stress-strain curves for concrete made with siliceous aggregates at elevated temperature per EN 1992 1-2**

Though EN 1992 1-2 does not provide any guidance or equations on assessing residual strength of concrete or concrete members, EN 1994 1-2 does provide equations

for the residual strength of concrete [21]. The difference between *EN 1992 1-2* and *EN 1994 1-2* is that the former is a code for design of concrete structures, whereas the latter is a code for design of composite steel and concrete structures. Three equations are provided in *EN 1994 1-2* which modify the reduced strength factors for concrete at elevated temperatures to give the residual strength of concrete based on the maximum temperature of exposure. The comparison of the strength curve for the residual concrete strength and concrete strength at elevated temperature is shown in Figure 2.3.

**Figure 2.3: Comparison of reduction factors for compressive strength of concrete at elevated temperature and after cooling (residual) per *EN 1994 1-2***

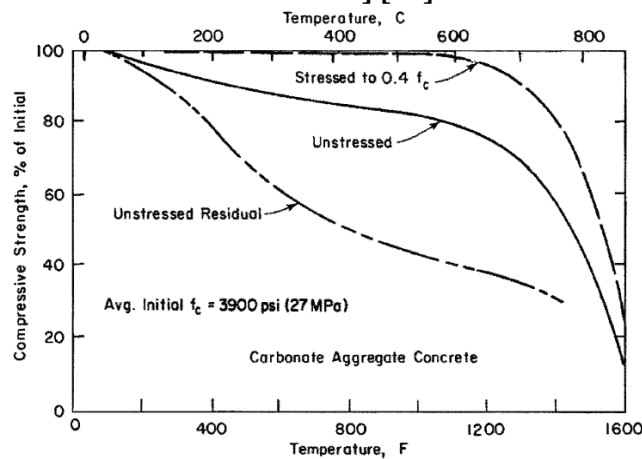

According to *EN 1994 1-2*, the residual strength of concrete is slightly lower than that of concrete at elevated temperatures, meaning that the concrete loses additional strength as it cools down. The additional loss of strength during cooling has been attributed in part to the differential thermal strains between the aggregate and the cement paste [8].

Though Eurocode provides a wealth of information on the design of structures for fire, it is worth pointing out that the codes are based on the common materials and construction practices in Europe, which may differ significantly from those in the United States. *ACI 216.1-14* is one of the US codes for fire design of concrete structures, which

also contains strength reduction curves to predict the residual strength and the strength at elevated temperature of concrete. As with Eurocode, *ACI 216.1-14* also distinguishes between concrete with siliceous aggregates and concrete made with carbonate/calcareous aggregates. The strength reduction curves are shown in Figure 2.4 (siliceous aggregate) and Figure 2.5 (carbonate/calcareous aggregate). According to [6], these curves were developed based on a single study which mostly used specimens with an initial compressive strength less than 6 ksi.

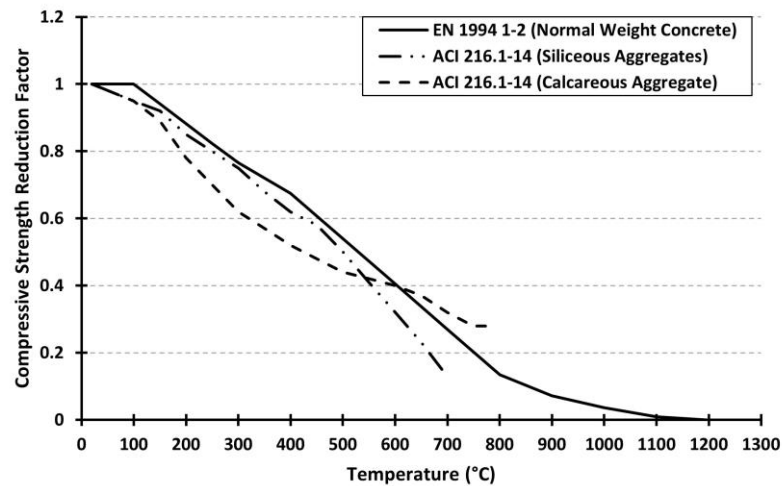

**Figure 2.4: Strength reduction curves for the compressive strength of concrete made with siliceous aggregates per *ACI 216.1-14* [Authorized Reprint from *ACI 216.1-14*, Nov. 2014] [22]**

**Figure 2.5: Strength reduction curves for the compressive strength of concrete made with calcareous/carbonate aggregates per *ACI 216.1-14* [Authorized Reprint from *ACI 216.1-14*, Nov. 2014] [22]**

In terms of the behavior of concrete at elevated temperatures, one notable difference between the documents is the addition of the curve to predict the properties of concrete at elevated temperatures with applied compressive stress in *ACI 216.1-14* (“stressed to  $0.4f_c$ ”). The *ACI 216.1-14* curves show that the presence of compressive strength has a significant benefit for the strength of the concrete when at elevated temperatures. Eurocode does not treat stressed and unstressed concrete differently in regard to temperature.

**Figure 2.6: Comparison of reduction factors for residual compressive strength of concrete per EN 1994 1-2 and ACI 216.1-14**

Figure 2.6 shows a comparison of reduction factors for the residual strength of concrete. The unstressed residual strength curves from *ACI 216.1-14* show reasonable agreement with the residual strength curves from *EN 1994 1-2*, though the *EN 1994 1-2* curve aligns more closely to the siliceous aggregate curve from *ACI 216.1-14*. The *ACI 216.1-14* curves predict that calcareous/carbonate aggregate concretes generally have a slightly lower relative residual compressive strength than siliceous aggregate concretes up until approximately  $500^{\circ}\text{C}$ , after which siliceous aggregates have a lower compressive strength.

### 2.2.2.2. Experimental Studies

Though both the ACI and Eurocode design documents provide valuable information regarding the compressive strength of concrete after fire, each has a notable shortcoming: the curves in *ACI 216.1-14* were developed from the data set of a single study and the Eurocode curves/equations are based on studies of concrete made using materials not native to North America. In an effort to study the data from a larger pool of studies which performed tests on concrete made with materials native to North America, [6] compiled nine studies and performed a meta-analysis of their data. The data points included in the study cover a variety of concrete strengths (both normal-strength and high-strength, and aggregates: calcareous, siliceous, and lightweight). In the study, concrete with a strength above 6 ksi (41.4 MPa) was considered to be high-strength. At the time this document was written, an excel sheet database containing data points from 14 studies compiled by the authors of [6] can be found at the University of Notre Dame's Fire Research Group webpage (<https://www3.nd.edu/~concrete/concrete-fire-database/>).

A regression analysis was performed to develop best fit lines for the compiled data. Several figures from the study are shown in Figure 2.7 and Figure 2.8 which present the data in a variety of ways, such as by splitting up by test type, or by comparing to curves from *ACI 216.1-14*.

**Figure 2.7: Compressive strength loss of normal-strength concrete (NSC), separated by type of aggregate: siliceous (left), calcareous/carbonate (center), lightweight (right) [authorized reprint from ACI Materials Journal, Vol. 107 No. 2] [6]**

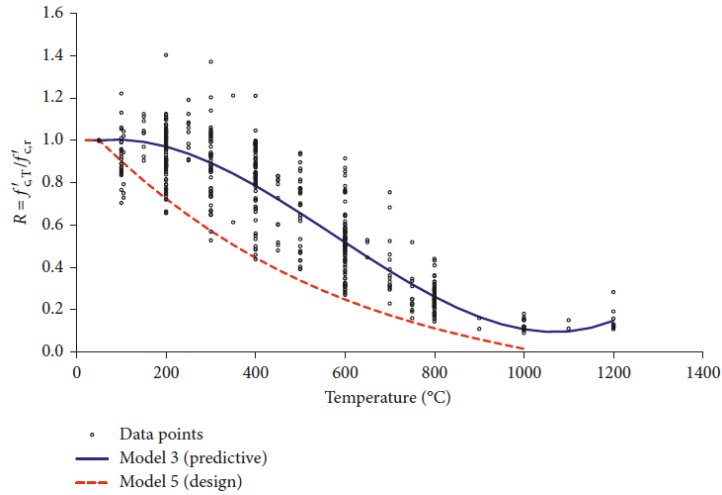

**Figure 2.8: Best fit lines (proposed models) for residual compressive strength loss of normal-strength (NSC) and high-strength concrete (HSC), compared to ACI 216.1-14 curves, separated by aggregate type: siliceous (left), calcareous (center), light-weight (right) [authorized reprint from ACI Materials Journal, Vol. 107 No. 2] [6]**

Several important conclusions can be drawn from the study's data:

- The strength loss for the stressed test type was generally lowest, whereas the strength loss for the residual test type was generally greatest. The presence of compressive stress at elevated temperature generally has a beneficial effect on the strength compared to when the concrete is unstressed.
- Siliceous aggregate concretes exhibit greater strength losses for all three test types above 446°C than calcareous or lightweight aggregate concretes.
- The strength loss of high-strength concrete is almost universally greater than that of normal-strength for a given temperature.

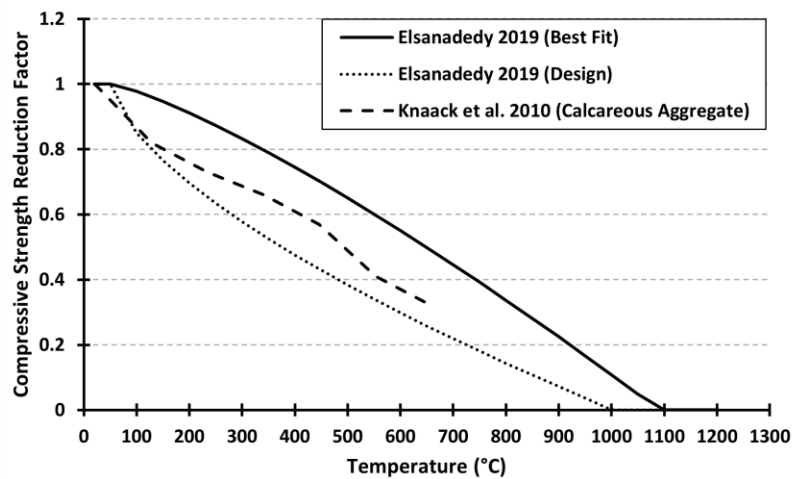

Given that high-strength concrete has been shown to behave differently than normal-strength concrete with heat exposure, some studies have focused specifically on the mechanical properties of high-strength concrete due to heat exposure. This is especially pertinent for tunnels, since high-strength concrete is frequently used for these structures. One recent study [19] conducted a meta-analysis of data from 54 studies to characterize the residual compressive strength of high-strength concrete (greater than 6 ksi was considered to be high-strength for this study). A regression analysis was performed to find a best fit curve for the data, and conservative design curve was

proposed which was more conservative than 90% of the data points. These curves are shown in Figure 2.9, where the black dots are individual data points, the solid line is the best-fit curve, and the dashed line is the proposed conservative design equation.

**Figure 2.9: Relative residual compressive strength of high-strength concrete (black dots are individual data points of each specimen, the solid line is a best fit line, and the dashed line is a proposed conservative design curve) (reprinted from [19])**

This meta-analysis did not distinguish between type of aggregate or concrete mixture additives. In general, comparison of Figure 2.9 with the *ACI 216.1-14* curves in Figure 2.4 and Figure 2.5 show that the high-strength concrete may have a higher residual strength for given temperatures compared to normal-strength concrete.

**Figure 2.10: Comparison of residual compressive strength reduction factors for high strength concrete from experimental studies**

The findings of this study contrasted with that of [6], which stated that high-strength concrete experiences greater strength losses than normal-strength concrete, as shown in Figure 2.10. It is worth noting that [6] had more limited test data on high-strength concrete.

### 2.2.3. Stiffness of Concrete at Elevated Temperatures and After Cooling Down

Some studies have focused on the stiffness loss in concrete which can occur at elevated temperatures and after cooling down. One well-known study compiled the results of several studies, showing the relationship between modulus of elasticity and maximum temperature for various types of concrete [15]. The study only included figures for the unstressed (Figure 2.11) and unstressed residual (Figure 2.12) test types, as not enough data was available for the stressed test type.

**Figure 2.11: Relative modulus of elasticity of concrete from unstressed tests (each line shows data from a different study) (reprinted from [15])**

**Figure 2.12: Relative modulus of elasticity of concrete from unstressed residual tests (each line shows data from a different study) (reprinted from [15])**

Overall, the relative modulus of elasticity seems to diminish at a similar or even greater rate than the relative strength as temperature increases, which is expected given the close relationship between strength and modulus of elasticity in concrete [23].

In reviewing the literature, a couple of gaps in knowledge remain. For one, although it has been shown that the presence of compressive stress has a beneficial effect on the mechanical properties of concrete at elevated temperatures, none of the studies conducted residual strength tests on specimens which were subjected to any sort of stress during the heating and cooling phase. If this beneficial effect also occurs after concrete has cooled from elevated temperatures (residual), the curves which have been proposed for the residual strength of concrete may be overly conservative. Second, it is unclear if sustained heating at a particular steady-state temperature further damages the concrete in a significant manner. With that said, the latter point may be less important since sustained heating at a given temperature is unlikely to occur in an actual fire event.

#### **2.2.4. Thermal Spalling of Concrete**

In addition to strength and stiffness losses, another possible deleterious effect of thermal exposure on concrete is thermal spalling, a subject which has been extensively researched [24] [25] [26] [27] [28] [29] [30] [31] [32]. Though the potential mechanisms were not understood until more recently, spalling of concrete in structures during fire events has been observed since the early 1900s [28]. The potential for fire spalling raises considerable structural concerns; however, these concerns differ slightly depending on whether a scenario during a fire or a post-fire scenario is being considered. During a fire, spalling can reduce the strength of concrete members by reducing the effective cross-section of members, or by exposing reinforcing steel. The former can reduce load-bearing capacity of concrete in compression, whereas the latter can expose the reinforcing steel to very high temperatures and cause loss of bond, which is particularly concerning for flexural members [32]. Existing structural codes largely focus on the structural concerns of fire spalling during fire events, such that elements/structures can be designed to achieve the desired fire resistance rating. For instance, *EN 1992 1-2* provides recommendations to reduce the incidence of explosive spalling, such as recommendations for spalling-resistant mix designs and additives to reduce spalling [20]. In the post-fire scenario, spalling is still a major concern. If the spalling occurs during heating, reinforcing steel and deeper regions of the concrete may reach higher temperatures due to loss of the outer layers of concrete. Furthermore, spalling which occurs at any point in the process (during heating, cooling, or after cooling) can reduce the effective cross-section of structural members, potentially reducing their residual strength capacity. The occurrence of spalling also means that repairs will often be required to return the structure to its previous condition [12].

Four general types of fire spalling have been identified, each differing in nature and severity: explosive spalling, surface spalling, aggregate spalling, and corner spalling/sloughing-off. The characteristics of these types of spalling are summarized in Table 2.2, though it should be noted that these are typical characteristics, and deviations from these typical characteristics have been noted. Furthermore, other types of spalling, such as spalling which occurs in the days/weeks after a fire event, have also been observed [31].

Explosive spalling is recognized as the most severe type of fire spalling, and much of the existing research on thermal spalling has focused on explosive spalling [2]. Explosive spalling is often described as a violent form of spalling which is often accompanied by a loud explosive noise or “bang.” It can occur as a single explosion or a series of explosions which each remove a layer of concrete with dimensions generally ranging from 100-300 mm in length/width, and 15-20 mm in depth. It typically occurs in the first 7-30 minutes of a fire, when the concrete is in the range of 150-450°C [31], [32]. Explosive spalling has been observed in several well-known tunnel fires, such as the 1996 Channel Tunnel fire, the Mont Blanc Tunnel fire, and the Tauern Tunnel fire, often causing extensive damage to the concrete tunnel lining [32]. Currently, there is no consensus in the research community as to the mechanisms that drive explosive spalling. A detailed discussion of these theories is beyond the scope of this work, but the three most popular theories are described: the pore pressure theory, the thermal stress theory, and the combined pore pressure and thermal stress theory.

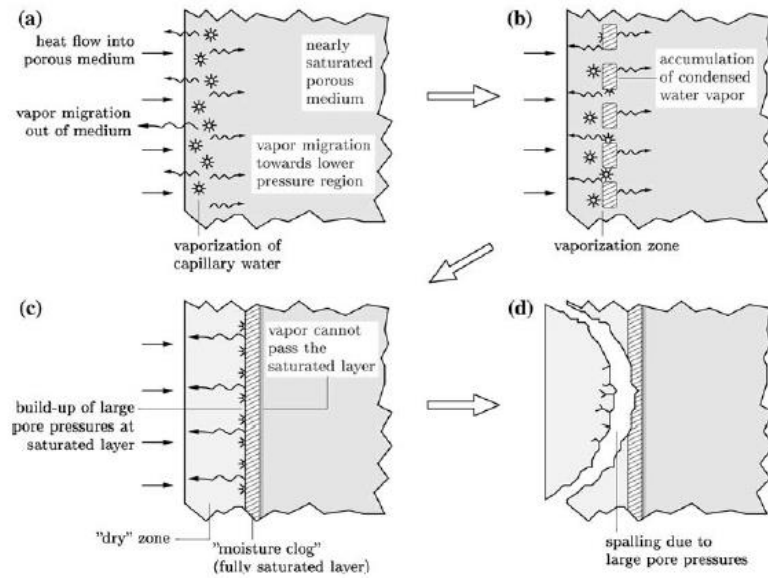

**Table 2.2: Summary of types of fire spalling (used with Permission from Wiley, reprinted from [2])**

<b>Table 1 Characteristics of the different forms of spalling</b>					
<b>Spalling</b>	<b>Time of occurrence (min)</b>	<b>Nature</b>	<b>Sound</b>	<b>Influence</b>	<b>Main influences</b>
Aggregate	7–30	Splitting	Popping	Superficial	H, A, S, D, W
Corner	30–90	Non-violent	None	Can be serious	T, A, F <sub>c</sub> , R
Surface	7–30	Violent	Cracking	Can be serious	H, W, P, F <sub>c</sub>
Explosive	7–30	Violent	Loud bang	Serious	H, A, S, F <sub>s</sub> , G, L, O, P, Q, R, S, W, Z

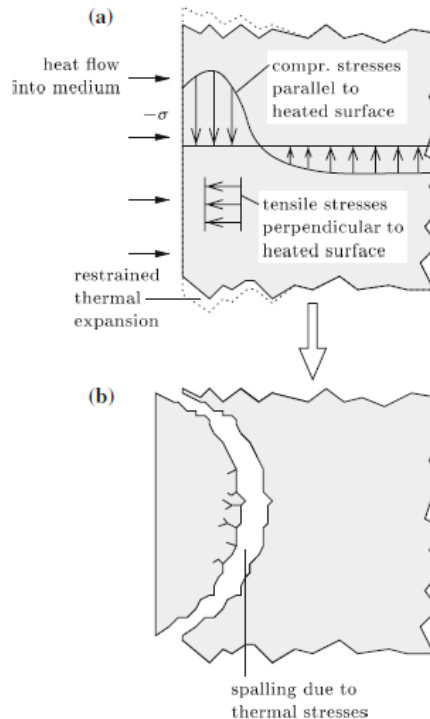

A = aggregate thermal expansion, D = aggregate thermal diffusivity, F<sub>s</sub> = shear strength of concrete, F<sub>t</sub> = tensile strength of concrete, G = age of concrete, H = heating rate, L = loading/restraint, O = heating profile, P = permeability, Q = section shape, R = reinforcement, S = aggregate size, T = maximum temperature, W = moisture content, Z = section size

The pore pressure theory, or moisture clog theory, attributes explosive spalling to the presence of moisture in the concrete. According to the pore pressure theory, as concrete is heated the temperature gradient in the concrete drives moisture from the surface of the concrete deeper into the concrete, creating three moisture zones: a dry zone at the surface, an intermediate zone with vaporized water, and moisture saturated zone (the “moisture clog”) (Figure 2.13). As moisture from the intermediate zone attempts to travel deeper into the concrete it will encounter the moisture clog, creating a zone of high pore pressure between the intermediate vapor zone and the moisture saturated zone, which can cause high tensile stresses at this interface and contribute to spalling [31], [32].

The thermal stress theory states that the temperature gradients which develop in heated concrete will induce compressive stresses near the surface of the concrete due to the restrained thermal expansion (assuming the member is axially restrained), as well as tensile stresses deeper in the concrete in the direction normal to the face of the member. This results in a triaxial stress in the concrete near the surface, as shown in Figure 2.14, which can rupture the concrete along this boundary [31], [32].

**Figure 2.13: The process of thermal spalling according to the pore pressure theory (Reprinted by permission from Springer Nature: Acta Geotechnica (Experimental insight into spalling behavior of concrete tunnel linings under fire loading, M. Zeiml, R. Lackner, H.A. Mang), [COPYRIGHT 2008] [27])**

**Figure 2.14: Illustration of combined thermal and applied stress on an axial member (Reprinted by permission from Springer Nature: Acta Geotechnica (Experimental insight into spalling behavior of concrete tunnel linings under fire loading, M. Zeiml, R. Lackner, H.A. Mang), [COPYRIGHT 2008] [27])**

Lastly, the combined pore pressure and thermal stress theory simply states that the stress increases due to pore pressure and thermal stress both contribute to spalling. This theory is supported by the fact that both moisture content and applied stress have been shown to have a significant effect on the likelihood of explosive spalling [32].

The incidence of explosive spalling has been described as stochastic and is still very difficult to predict using computer models [2]. Fortunately, a wealth of experimental data has revealed the main factors which increase the likelihood of explosive spalling. High-strength concrete has a much higher likelihood for explosive spalling compared to normal-strength concrete. It is thought that the higher incidence of explosive spalling in high-strength concrete can be attributed to densifying agents such as silica fume which are often used in high-strength concrete [32]. Similarly, higher concrete density has also been linked to explosive spalling, which has been attributed to the lower permeability of these concretes which may prevent moisture from escaping as easily. Higher moisture content in concrete has also been shown to increase explosive spalling, which supports the pore pressure theory of explosive spalling. Higher heating rates have long been linked to increased chance of explosive spalling, though explosive spalling can still occur at low heating rates. Greater applied stress has also been shown to increase the chance of explosive spalling. Other factors, such as amount and pattern of reinforcing steel, and the shape of the member, can also affect the chance of explosive spalling, though the exact nature of these relationships is still not entirely known [24].

Surface spalling is considered to be a subset of explosive spalling, differentiated by its lesser severity than explosive spalling [32].

Corner spalling/sloughing-off is associated with the chemical processes that occur in heated concrete such the reduced bond between aggregate and cement, which gradually remove layers of the concrete mainly at the edges of beams and columns [12], [31]. Though not a violent form of spalling, it can still have implications for the residual load-bearing capacity of structural members.

Aggregate spalling is not considered to have a major effect on the structural capacity of members. Its occurrence has been attributed to the water retained by aggregates such as flint or sandstone, which can create high vapor pressures which cause the aggregate to “burst” out of the concrete and leave a pitted surface [24], [31].

Recently, post-cooling fire spalling has also been observed in concrete. Post-cooling spalling occurs in a similar manner to sloughing-off, and is related to the rehydration of calcium oxide, which can cause a 44% increase in volume of the oxide. Post-cooling spalling can occur progressively over a couple of weeks after a fire, causing further damage to the structure [31]. An example of post-cooling spalling in a concrete cylinder is shown in Figure 2.15. Few studies are available regarding post-cooling spalling, and its incidence of occurrence is still unknown.

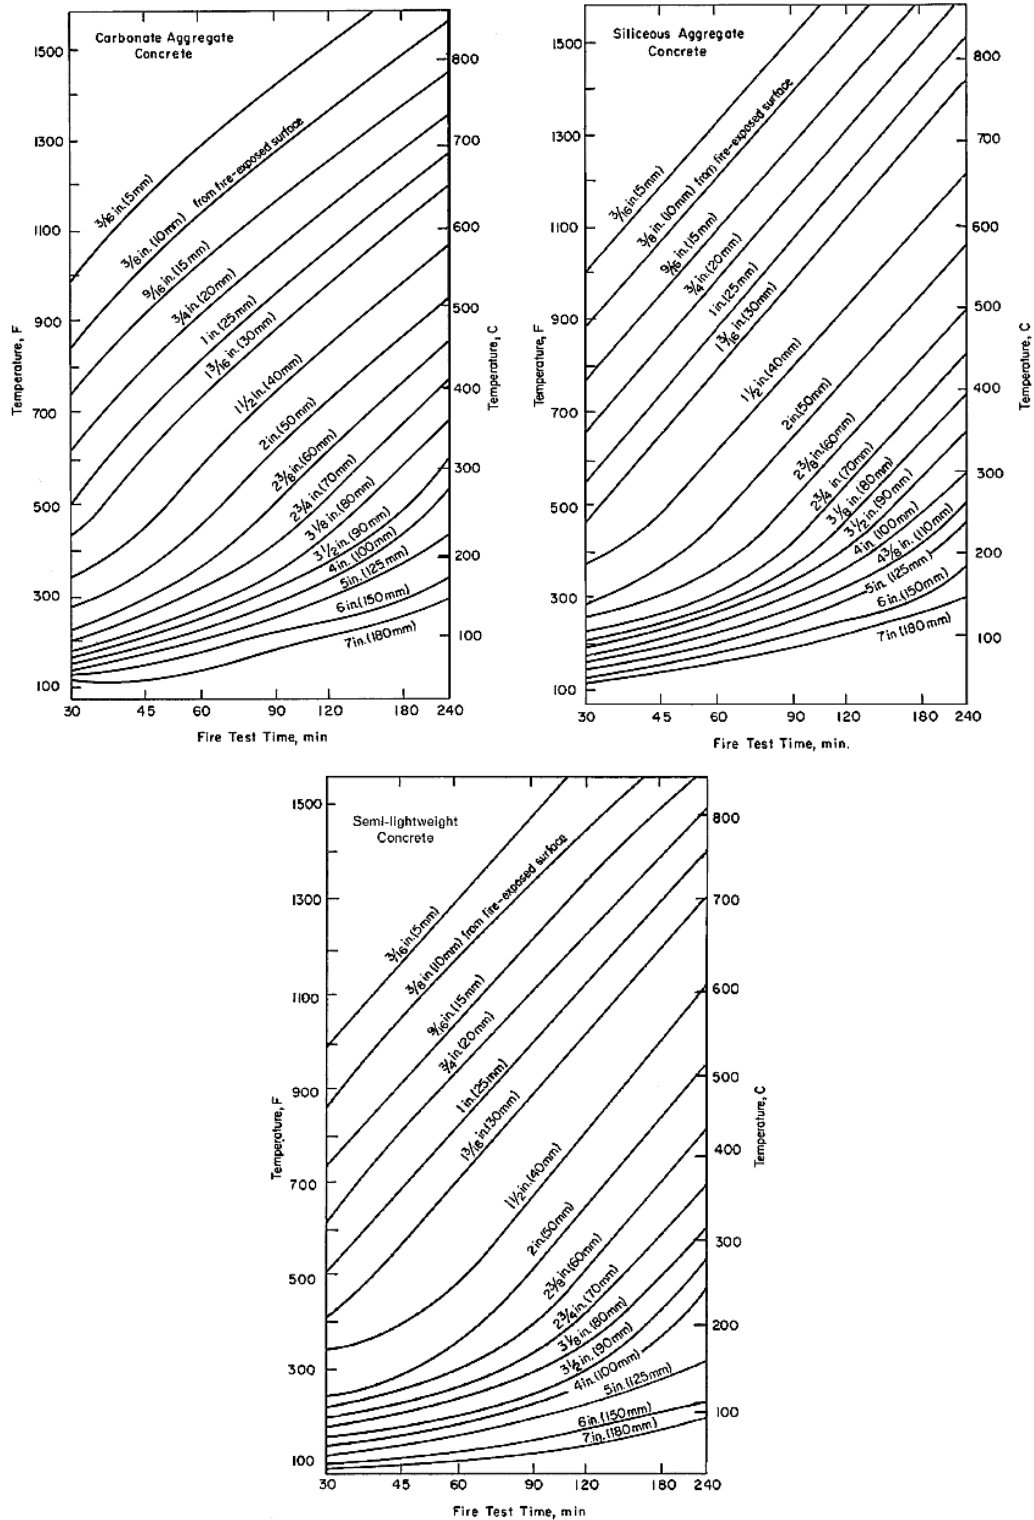

**Figure 2.15: Progression of post cooling spalling in a cylinder: before heat exposure (left), after 120 min in ISO fire (center), a week after heat exposure (right) (reprinted from [29])**

### **2.2.5. Internal Temperature Distribution of Concrete Exposed to Fire**

To fully understand how the loss in strength and stiffness of concrete due to fire will affect a structure, it is important to recognize the insulating properties of concrete. Though the air temperatures in a fire can exceed 1000°C, the insulating properties of concrete will result in a large temperature gradient in the material, in which the outer layers have a high temperature while the inner layers remain relatively cool. Estimating the maximum temperature reached at different depths within the concrete can help estimate the extent of the damage, since relationships between maximum temperature and residual strength loss are known.

For example, *ACI 216.1-14* provides charts for estimating the temperatures within concrete slabs subjected to the ASTM E119 heating curve, as shown in Figure 2.16. Each line shows the temperature at given depth into the concrete versus the heating time under the ASTM E119 heating regime. As another example, Figure 2.17 shows the temperature of the concrete along the depth of slabs and 380 mm square columns exposed to an unspecified design fire. Each line shows the temperature at certain depths in the members after certain durations of exposure to the design fire. To help visualize the depth of damage in concrete exposed to fire, another study superimposed the damage level of concrete with the temperature distribution from exposure to the ISO 834 fire, as shown in Figure 2.18. The dehydration of calcium hydroxide ( $\text{Ca(OH)}_2$ ) and calcium silicate hydrate (C-S-H) have both been directly linked to the strength loss which occurs in concrete during and after thermal exposure.

Given the importance of estimating the distribution of maximum temperatures within the concrete during the fire, some of the inspection techniques described in Chapter 4 are aimed at this purpose.

**Figure 2.16: Temperature distributions within slabs during ASTM E119 fires tests: carbonate aggregate concrete (top left), siliceous aggregate concrete (top right), and semi-lightweight aggregate concrete (bottom) [Authorized Reprint from ACI 216.1-14, Nov. 2014] [22]**

### 2.2.6. Summary of the Effects of Heat on Concrete

Concrete can experience significant loss in strength and stiffness after heating and cooling to room temperature, and these effects can pose serious safety issues in a tunnel after a fire event. Several physical and chemical transformations occur in concrete during both heating and cooling, which can contribute to spalling and the decay in mechanical properties of concrete at elevated temperatures and after cooling down.

Experimental studies on the residual compressive strength of concrete have identified maximum temperature reached as the main factor in the residual strength and stiffness of concrete. The residual strength of concrete is generally lower than the residual strength of concrete at elevated temperatures, due to damaging processes that occur during cooling. Aggregate type also has a significant impact on the residual strength and stiffness of concrete, with siliceous aggregate concrete being particularly affected by thermal exposure. From observing the residual compressive strength models from the codes, standards, and experimental studies presented in this section, the following benchmarks can be observed (strength of concrete after cooling, according to maximum temperature reached):

- 200-300°C → The residual strength of concrete begins to decrease.
- 500°C → the residual strength is 40-60% of its original value.
- 800°C → the residual strength is 10-20% of its original value.

In addition to loss in strength and stiffness, thermal spalling can affect the residual strength of members by reducing cross-sectional area and exposing rebar, which can subsequently reach much higher temperatures than if the cover had remained intact. Of the four main types of spalling which are generally recognized in the research sphere, explosive spalling is most severe. Though the exact causes of explosive spalling are still

heavily debated, the leading theories postulate that pore pressure buildup during heating, restrained thermal dilation, or a combination of both, cause explosive spalling.

Lastly, due to its thermal insulating properties, concrete exposed to fire will generally only reach temperatures that affect strength and stiffness on its surface layers, while the interior layers will remain relatively unaffected, meaning that structural components, especially those with thick cross-sections, such as tunnel linings, could likely be repaired by replacing the damaged surface layers of concrete after a fire event.

### **2.3. Steel**

Steel is another ubiquitous tunnel construction material that can be affected by heat exposure. Numerous studies have analyzed the mechanical properties of steel both at elevated temperatures and after exposure to elevated temperatures, and many structural codes provide equations to describe the strength and stiffness of steel in these scenarios. Though steel is often referred to as a monolithic entity, in fact many different types of steel are used for structural purposes, each with unique mechanical properties. When discussing the effect of thermal exposure on the mechanical properties of steel, four main categories of steel are usually distinguished: hot rolled structural steel (W-shapes, angles, etc.), reinforcing steel, heat treated/cold worked or work hardened steel, and prestressing steel.

Though a detailed review of metallurgical concepts is beyond the scope of this work, the changes in the mechanical properties of steel exposed to heat can generally be attributed to changes in microstructure and/or the chemical composition in the steel [7], [33]. Furthermore, the manufacturing method for different types of steel can have a

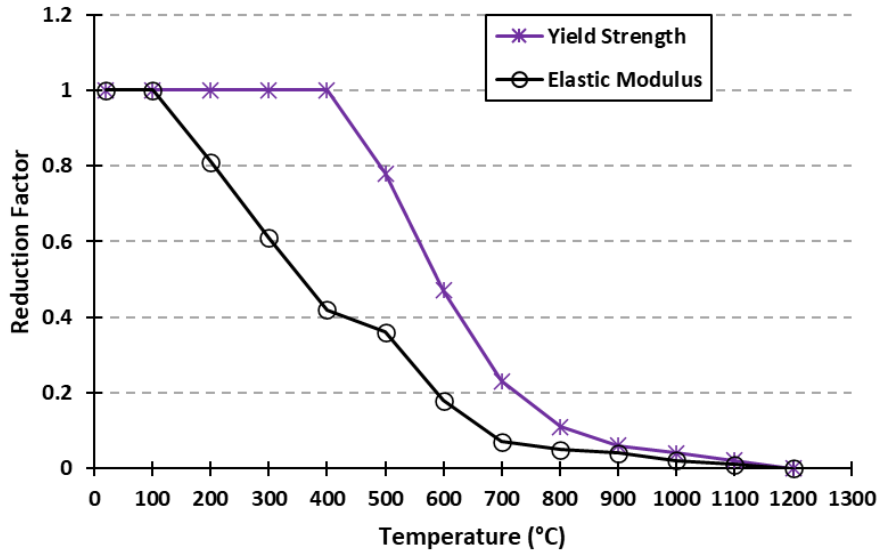

pronounced effect on both the behavior at elevated temperatures and the residual behavior. For example, reinforcing steel typically undergoes a greater degree of deformation than structural steel during the hot rolling process. As a result, the effect of heat on the stress-strain curves for each type is different [7]. Moreover, heat treated/cold worked steels and prestressing steels generally lose strength faster with temperature than structural or reinforcing steels as high temperatures can damage the microstructural arrangements that the heat treating and cold working processes create.

This section focuses on the residual mechanical properties of these four types of steels, but the mechanical properties at elevated temperatures are also discussed for comparison. The specific mechanical properties discussed are yield strength, ultimate strength, and stiffness.

### **2.3.1. Structural Steel**

As mentioned previously, of the four main types of steel used in structures, hot rolled structural steel is generally least susceptible to the effects of thermal exposure, both at elevated temperatures and after cooling. First, the properties of hot rolled structural steel at elevated temperatures are discussed.

*EN 1993 1-2* provides equations and curves describing the stress-strain behavior of several European grade hot rolled structural steels at elevated temperatures. *EN 1993 1-2* gives reduction factors to be applied to the yield stress and elastic modulus of hot rolled structural steel at room temperature, which give the yield stress and elastic modulus of structural carbon steel at elevated temperatures up to 1200°C. The reduction factors are shown in plotted form in Figure 2.19.

**Figure 2.19: Reduction factors for the yield stress and elastic modulus of hot rolled structural steel at elevated temperatures**

A 2004 study performed stressed tests, in which the specimen was subjected to loading during heating, on a European structural steel (S350GD + Z) [34]. The reduction factors for yield strength determined from these tests, along with those from *EN 1993 1-2*, are shown in Figure 2.20.

**Figure 2.20: Reduction factors for yield strength of S350 GD + Z steel based on the experimental results (lines with dots), and reduction factors for yield strength of hot rolled structural steel from *EN 1993 1-2* (solid line) [used with permission from Wiley, reprinted from [34]]**

The experimental results suggest the reduction factors for *EN 1993 1-2* are unconservative for all temperatures up to 800°C. Further studies with other types of steel

would be helpful to clarify the reliability of the models for structural steel at elevated temperatures in *EN 1993 1-2*.

The residual properties of hot rolled structural steel are discussed below. A 2013 study [7] performed a meta-analysis of the test results across eight studies on the residual properties of structural steel (stress-strain curves, yield strength, ultimate strength, and modulus of elasticity), though it should be noted that only one of these studies used ASTM steels, which are standard in the United States. Furthermore, the majority of the tests were unstressed residual tests, though the researcher noted that the difference between results from stressed residual tests and unstressed residual tests was minor. The yield strength of steels in the eight studies ranged from 231-789 MPa, and most of the test specimens were coupons which were heated and then cooled by air. Figure 2.21 shows the relative residual yield strength and the relative residual ultimate strength as a function of maximum temperature from the results of the studies, with the individual data points plotted as circles and with best-fit curves (Eq. (3) and Eq. (4)) for each plot.

**Figure 2.21: Relative residual yield strength of hot rolled structural steel (left), relative residual ultimate strength of hot rolled structural steel (right) [used with permission from ASCE, this material may be downloaded for personal use only.**

**Any other uses requires prior permission of the American Society of Civil Engineers] [7]**

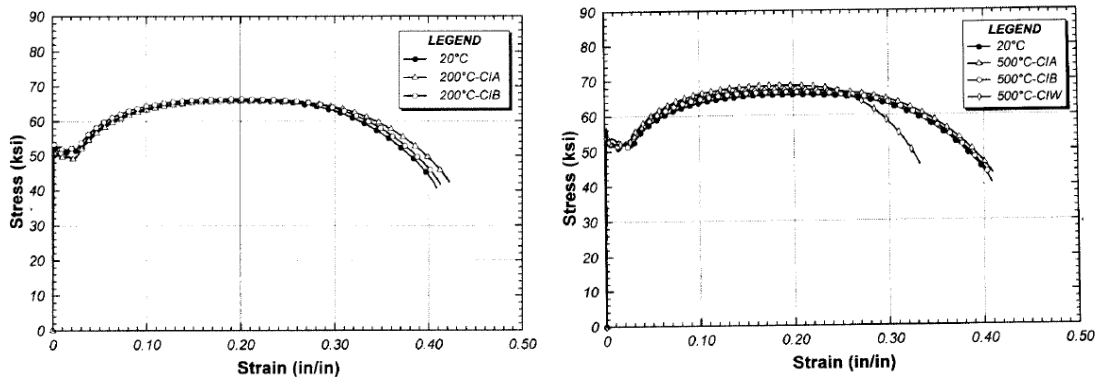

The residual ultimate strength of hot rolled structural steel is less affected by heat than the yield strength, with only about a 10% reduction after exposure to 1000°C, in comparison to about a 25% reduction in yield strength after exposure to 1000°C. Comparing the residual yield strength to the yield strength at elevated temperature stipulated by *EN 1993 1-2* (Figure 2.19), it can be seen that hot rolled structural steel regains much of the strength loss that occurs at elevated temperatures after it has cooled. For instance, *EN 1993 1-2* states a 95% reduction in the yield strength of hot rolled structural steel at 1000°C, whereas the data from the studies in [7] shows only a 25% reduction in yield strength after the steel has cooled from 1000°C.

The meta-analysis included very limited data on the residual modulus of elasticity of hot rolled structural steel, but the available data showed a maximum reduction of 10% for hot rolled structural steel for temperatures up to 1000°C.

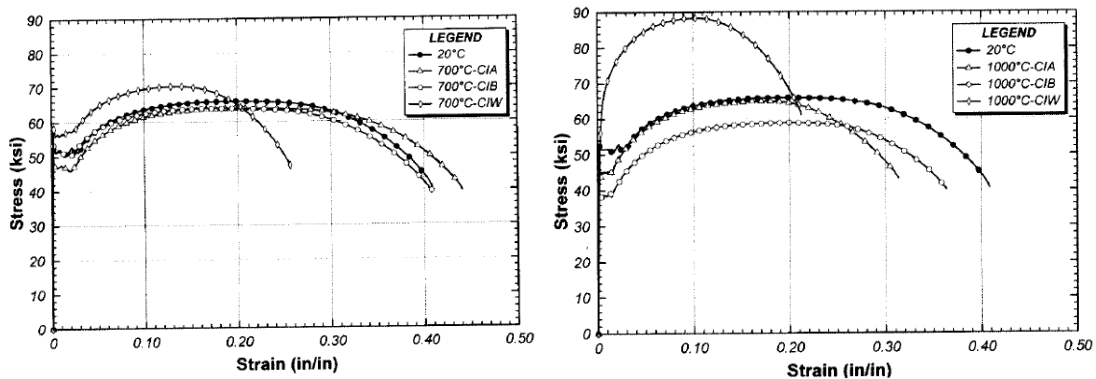

Since the 2013 meta-analysis mostly included studies of steels less common in the US, it is worth taking a closer look at the study which performed tests on ASTM A992 steel, the most commonly used steel grade for wide flanged w-shapes in the United States [35]. The study evaluated the effect of different cooling methods on the residual stress-strain properties of the coupons. After heating coupons in a furnace, three different cooling methods were employed: cooled in blanket (CIB), cooled in air (CIA), and cooled in water (CIW).

The residual stress-strain curves for the specimens heated to 200°C, 500°C, 700°C and 1000°C and cooled by the three different methods are shown in Figure 2.22 and Figure 2.23. Overall, the cooled in blanket and cooled in air specimens exhibited similar stress-strain behavior and strength reductions, with permanent residual yield and ultimate

strength losses beginning at temperatures of 700°C. For both of these cooling methods, temperature had a greater effect on the yield strength than the ultimate strength. The cooled in water method, on the other hand, gave noticeably different results at higher temperatures. In addition to the different stress-strain behavior, which can be most clearly seen in Figure 2.24, increasing temperature generally increased the strength of the steel, rather than decreasing it as was observed for the other two cooling methods. The difference in behavior has been attributed increased hardness due to the formation of bainite and martensite, which can occur at very high cooling rates such as the cooled in water method [7].

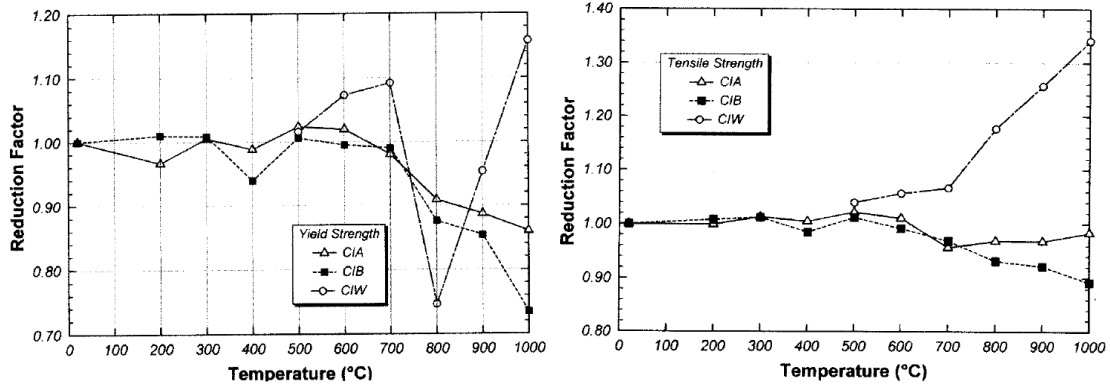

**Figure 2.22: Residual stress-strain curves for A992 steel after heating to: 200°C (left), 500°C (right) and cooling by each method (reprinted from [35])**

**Figure 2.23: Residual stress-strain curves for A992 steel after heating to: 700°C (left), 1000°C (right) and cooling by each method (reprinted from [35])**

For comparing the changes in yield strength and ultimate strength for the different maximum temperatures and cooling method, Figure 2.24 shows the yield strength reduction factor and the ultimate strength reduction for the three cooling methods.

**Figure 2.24: Reduction factors for yield strength of A992 steel based on maximum temperature (left), reduction factors for ultimate strength of A992 steel based on maximum temperature (right) (reprinted from [35])**

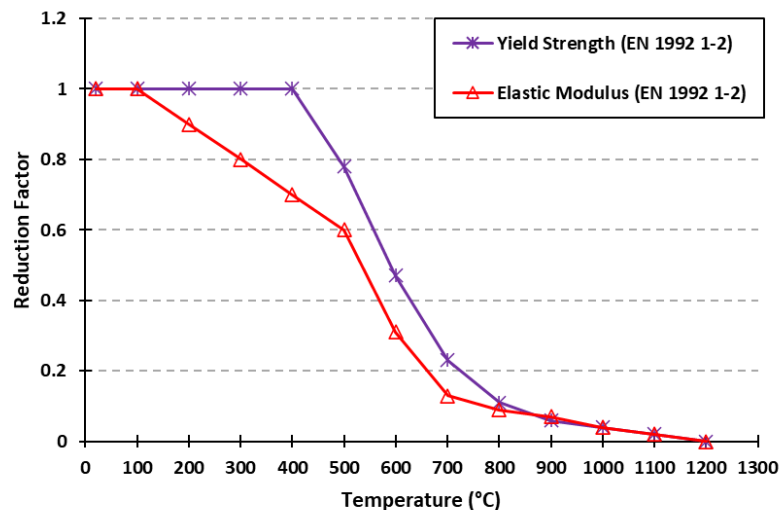

Lastly, the study also included data on the residual elastic modulus for each cooling method. The reduction factors for the elastic modulus for each cooling method are shown in Figure 2.25. In general, temperature exposure up to 1000°C has only a very minor effect (about +/- 7%) on the elastic modulus of A992 steel.

**Figure 2.25: Reduction factor for elastic modulus of A992 steel for each cooling method (reprinted from [35])**

### 2.3.2. Reinforcing Steel

Given its widespread use in concrete structures, numerous studies have been conducted on the mechanical properties of reinforcing steel at elevated temperatures and after cooling down. First, the properties of reinforcing steel at elevated temperatures are discussed. Equations/curves for reinforcing steel at elevated temperatures can be found in *EN 1992 1-2* and *ACI 216.1-14*. For example, similar to the provisions for hot rolled structural steel, *EN 1992 1-2* provides reduction factors to be applied to the yield stress and modulus of elasticity of reinforcing steel at ambient temperatures, which give the yield stress and modulus of elasticity of reinforcing steel at elevated temperatures up to 1200°C. The reduction factors given for “Class N” hot rolled reinforcing steel are shown in Figure 2.26, and the code also provides equations for cold worked reinforcing steels. *ACI 216.1-14* also contains provisions for the strength of reinforcing steel at elevated temperatures, shown in Figure 2.27. This graph also includes data for prestressing steel, which is discussed in Section 2.3.4.

**Figure 2.26: Reduction factors for the yield stress and elastic modulus of Class N hot rolled reinforcing steel at elevated temperatures per *EN 1992 1-2***

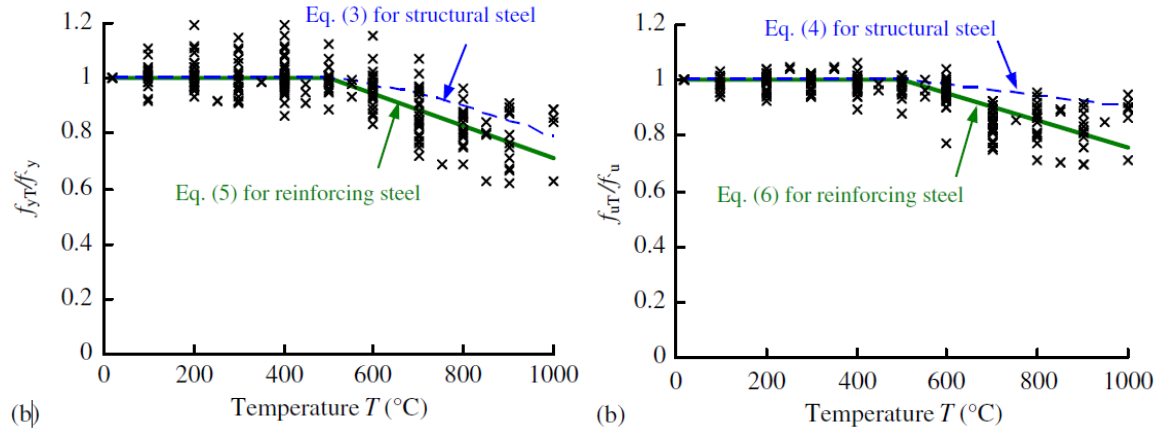

**Figure 2.27: Strengths of different types of reinforcing steel at elevated temperatures per ACI 216.1-14 [Authorized Reprint from ACI 216.1-14, Nov. 2014] [22]**

The *EN 1992 1-2* and *ACI 216.1-14* provisions for yield strength of hot-rolled reinforcing steel vary quite significantly in the range of 20–400°C, as *EN 1992 1-2* does not show any loss of strength whereas *ACI 216.1-14* shows a strength reduction of 14%. Beyond 400°C, the *EN 1992 1-* provisions are generally more conservative than the ACI provisions. *ACI 216.1-14* also provides a strength curve for high strength alloy steel bars.

In addition to the studies on the properties of reinforcing steel at elevated temperatures, several studies on the residual properties of reinforcing steel have been conducted [36] [37] [38]. The 2013 study presented in the previous section [7] also conducted a meta-analysis of studies on the residual mechanical properties of reinforcing steel, comprised of test results from 18 studies. These tests were typically conducted on reinforcing bar specimens which were heated, cooled, and tested to failure. Only data for hot rolled reinforcing steel was included for this part of the analysis. Figure 2.28 shows the relative residual yield strength and the relative residual ultimate strength as a function of maximum temperature from the results of the studies, with the individual data points plotted as circles and with best-fit curves (Eq. (5) and Eq. (6)) for each plot. The data for

structural steel, which are also shown in Figure 2.21, are shown alongside the data for reinforcing steel for comparison.

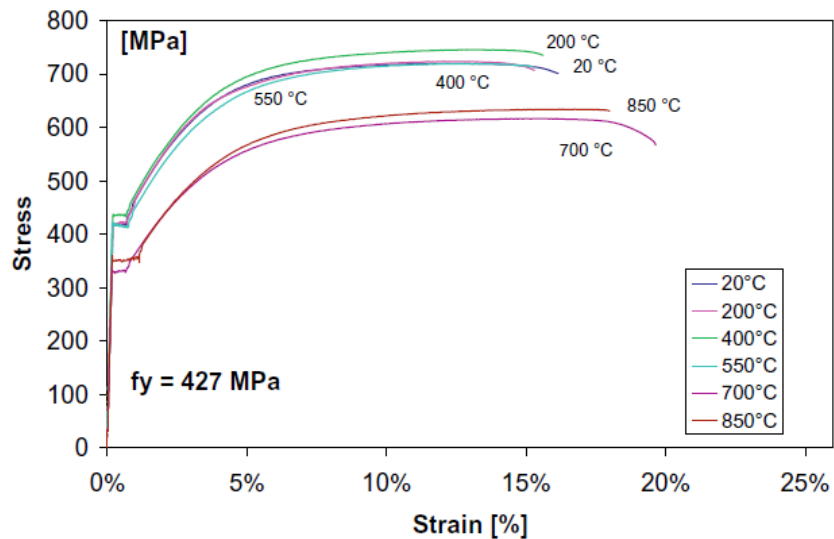

**Figure 2.28: Relative residual yield strength of hot rolled reinforcing steel (left), relative residual ultimate strength of hot rolled reinforcing steel (right) [used with permission from ASCE, this material may be downloaded for personal use only. Any other uses requires prior permission of the American Society of Civil Engineers] [7]**

Overall, the residual capacity of reinforcing steel is more affected by thermal exposure than hot rolled structural steel, which is due to the higher degree of deformation experienced by reinforcing steel than structural steel during the hot-rolling process [7]. Furthermore, as with structural steel, reinforcing steel appears to gain back much the strength loss that occurs at elevated temperatures after it is cooled. For example, at 700°C (before cooling), the Eurocode provisions predict the steel would have 23% of its original yield strength, and *ACI 216.1-14* predicts the steel would have 34% of its original yield strength. The data from the meta-analysis indicates that the residual yield strength after cooling from 700°C would be about 90% of its original yield strength, meaning that steel regains nearly all of its strength after cooling.

Noting that the data from the meta-analysis contained data of steels from wide variety of countries, one study focused more specially on the differences in residual

properties of reinforcing bars more common in the United States (carbon steel bars) and reinforcing bars more common in Europe (quenched and self-tempered steel bars (QST)) [39]. Quenched and tempered steel is a type of heat treated steel, and therefore will be discussed in the next section rather than here. Figure 2.29 and Figure 2.30 shows stress-strain curves from the study for deformed carbon steel bars and smooth carbon steel bars, respectively, after heating and cooling. Both types of bars experienced little change in the residual yield and ultimate strength after cooling from 550°C, which agrees with the data from the 2013 meta-analysis of reinforcing steels. After cooling from 850°C, the deformed and smooth bars experience a 20-25% loss in residual yield strength, and a 15% loss in ultimate strength.

**Figure 2.29: Stress-strain curves for  $\phi 29$  mm deformed carbon steel reinforcing bars after heating and cooling (Reprinted from *Construction and Building Materials*, Vol. 23, No. 12, Residual behavior of steel rebars and R/C sections after a fire, 2009, with permission from Elsevier [39])**

**Figure 2.30: Stress-strain curves for  $\phi 24$  mm smooth carbon steel reinforcing bars after heating and cooling (Reprinted from *Construction and Building Materials*, Vol. 23, No. 12, Residual behavior of steel rebars and R/C sections after a fire, 2009, with permission from Elsevier [39])**

### 2.3.3. Cold Worked and Heat Treated Steel

It has been noted that cold working and heat treating processes can result in significantly different behavior at elevated temperatures and after cooling down compared to hot rolled steels [7].

First, the properties at cold worked reinforcing steel at elevated temperatures are discussed. Equations/curves for cold worked reinforcing steel at elevated temperatures can be found in *EN 1992 1-2*. Figure 2.31 shows a comparison of the reduction factors for the yield strength and elastic modulus for both hot rolled and cold-worked reinforcing steel. Notably, the reduction factors for both yield strength and elastic modulus are lower for cold-worked steel than for hot rolled steel, suggesting that the former has worse mechanical properties during a fire.

**Figure 2.31: Comparison of yield strength and elastic modulus reduction factors for hot rolled and cold-worked reinforcing steel at elevated temperatures per EN 1992 1-2**

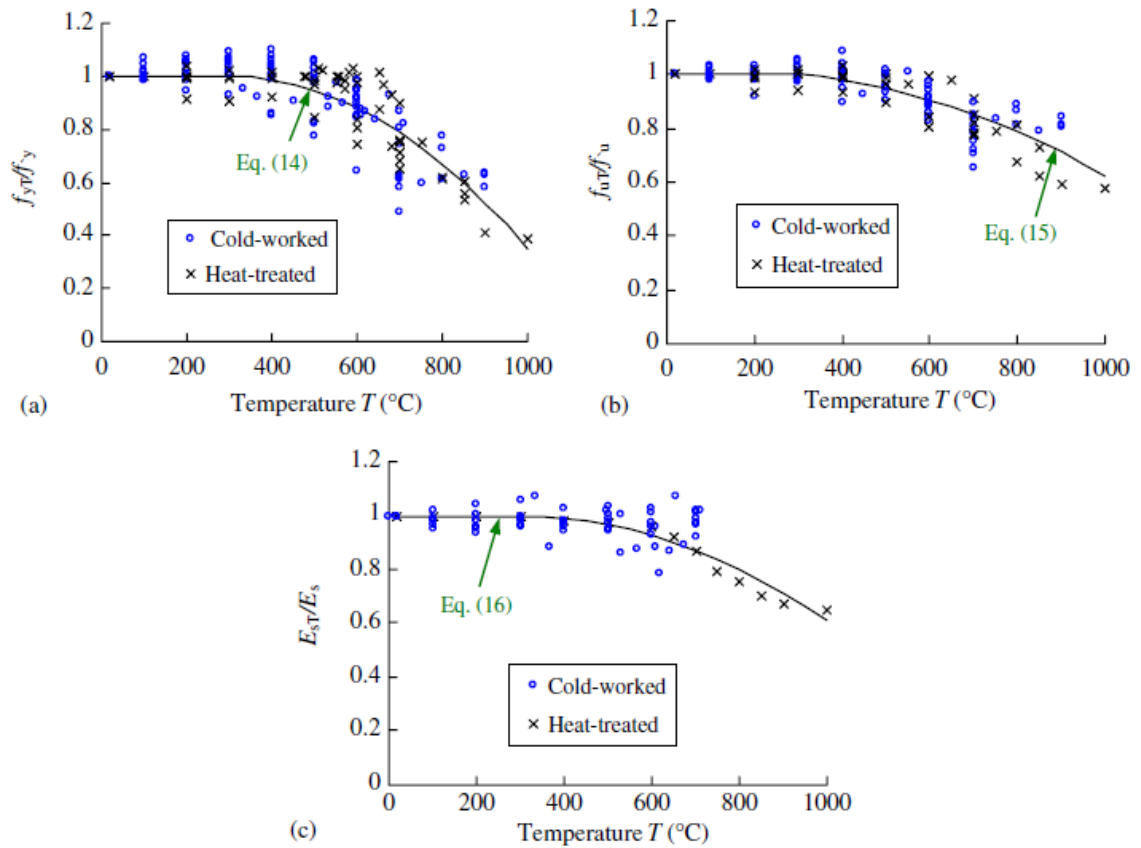

The residual properties of cold worked and heat treated steel are discussed below.

The 2013 study presented in the previous two sections also conducted a meta-analysis of studies on the residual mechanical properties of heat treated and cold worked steel [7].

The meta-analysis grouped these two types of steel together as they exhibited very similar residual behavior. Figure 2.32 shows the relative residual yield strength, the relative residual ultimate strength, and the relative residual elastic modulus of heat treated and cold worked steels from the collection of studies.

Compared to the data for hot rolled structural and reinforcing steel in Figure 2.28, heat treated/cold worked steel has markedly lower strength and ductility above 300-400°C, where the residual properties of heat-treated and cold-worked steel begin to degrade. For example, the residual yield strength after cooling from 800°C is about 30-35% for the heat treated/cold worked steels, as compared to 15-20% for the hot rolled structural and reinforcing steels after cooling from 800°C. Comparing with the Eurocode provisions shown in Figure 2.31, it appears that heat treated and cold worked steel does

regain some its strength capacity after cooling down, but to a lesser extent than hot rolled steel.

**Figure 2.32: Relative residual yield strength of heat treated/cold worked steel (top left), relative residual ultimate strength of heat treated/cold worked steel (top right), and relative residual elastic modulus of heat treated/cold worked steel (bottom) [used with permission from ASCE, this material may be downloaded for personal use only. Any other uses requires prior permission of the American Society of Civil Engineers] [7]**

### 2.3.4. Prestressing Steel

Similar to the other types of steel, numerous studies and code equations are available on the mechanical properties of prestressing steel at elevated temperatures [36], [37], [40]. The condition of prestressing steel during and after a fire is considered to more critical than that of other types of steel, as prestressing steel can experience significant

strength reductions even after exposure to temperatures in the range of 200-400°C [41]. Three main types of prestressing steel are used in concrete structures: cold-drawn wires, strands, and high-strength bars. Cold-drawn wires are created by drawing hot-rolled steel rods through dies while they are cold, a process which increases the strength of the steel. Many cold-drawn wires are also heat treated after the cold drawing process. “Stress-relieved” wires are heated for a short time, while “low-relaxation” wires are heated while being held in tension. Strands are produced by wrapping several individual cold-drawn wires around a central “core” wire, and the types of wires used for strands include “Stress-relieved” and “low-relaxation” wires. Lastly, high-strength bars are created by adding alloys to the steel and by subsequent cold working processes [33].

Equations/curves for prestressing steel at elevated temperatures can be found in *EN 1992 1-2* and *ACI 216.1-14*. *EN 1992 1-2* gives strength reduction factors for the yield strength and elastic modulus of prestressing steel at elevated temperatures, shown in Figure 2.33. *EN 1992 1-2* distinguishes between cold worked strands and quenched and tempered bars. Figure 2.27 shows the *ACI 216.1-14* curve for the yield strength of cold-drawn prestressing steel at elevated temperatures.

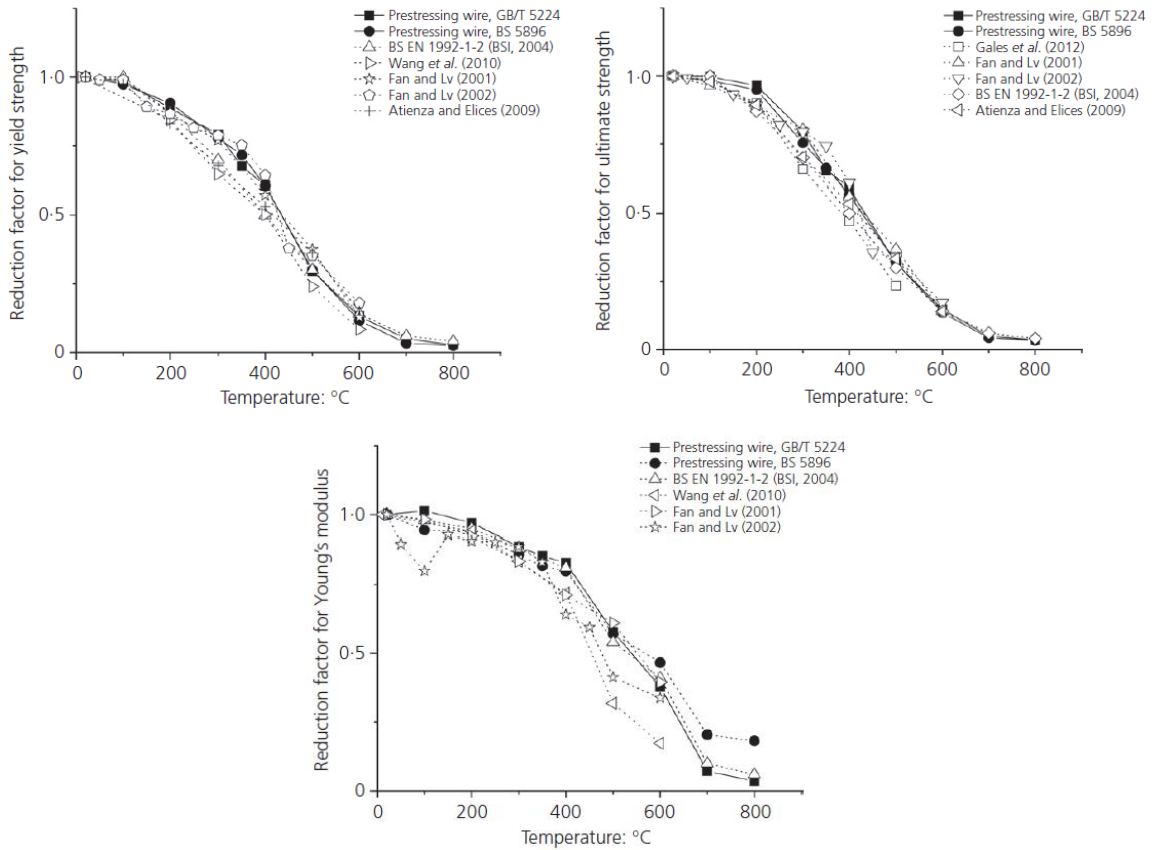

**Figure 2.33: Reduction factors for yield strength and elastic modulus of different types of prestressing steel per EN 1992 1-2**

The *EN 1992 1-2* yield strength reduction factors are generally slightly more conservative, though both sources have similar strength reduction values overall.

A 2017 study compared various models for the mechanical properties of prestressing wires at elevated temperatures, including models created based on their own data, models in Eurocode, and models proposed by other researchers [40]. Figure 2.34 shows the comparisons of various models for yield strength, ultimate strength, and elastic modulus, where the two lines in each plot labelled “prestressing wire, *x*” are the models proposed by the researchers. In general, there was excellent agreement among the models from the different studies and Eurocode.

**Figure 2.34: Comparison of reduction factors for yield strength of prestressing wires (top left), reduction factors for ultimate strength of prestressing wires (top right), and reduction factors for elastic modulus of prestressing wires (bottom) at elevated temperatures (Republished with permission of Institution of Civil Engineers, from Mechanical Properties of Prestressing Steel in and After Fire, L. Zhang, F.T.K. Au, Y. Wei, J. Li. Vol. 69, No. 8, 2017; permission conveyed through Copyright Clearance Center, Inc. [40])**

The properties of prestressing steel after cooling from elevated temperatures are discussed below. As noted previously, the post-fire condition of prestressing steel is of particular concern, as the residual strength losses for given temperatures are much greater than those for other types of steel. A 2014 study performed a meta-analysis on studies of the residual mechanical properties of prestressing steel after thermal exposure [33]. The types of steel used in the studies included a variety of as-drawn, stress-relieved, and low-relaxation strands and wires. Figure 2.35 shows the residual 0.1% proof stress of prestressing steel reported in the studies, along with the yield strengths of hot rolled

reinforcing steel and heat treated/cold worked reinforcing steel from the meta-analysis discussed in previous sections [7] for comparison. Proof stresses are often used as an arbitrary definition for the yield point of high-strength steel, and this particular study adopts a 0.1% proof stress definition as required by Australian Standard AS 3600.

**Figure 2.35: Residual 0.1% proof stress of prestressing steel and yield strengths of reinforcing and heat treated/cold worked steel (Reprinted by permission from Springer Nature: Materials and Structures (Mechanical properties of prestressing steel after fire exposure, Z. Tao), [COPYRIGHT 2015] [33])**

The residual yield strength (0.1% proof stress) is considerably lower for prestressing steel than hot rolled or heat treated/cold worked reinforcing steel at any temperature above 200°C. Figure 2.36 shows the residual ultimate strength of prestressing steel compared to the data for of hot-rolled reinforcing steel and heat treated/cold worked reinforcing steel from [7]. As with the residual yield strength, the relative residual ultimate strength of prestressing steel is far lower than that of hot rolled reinforcing steel and heat treated/cold worked reinforcing steel. Comparing with the models for prestressing steel at elevated temperatures in Figure 2.34, it can be seen the

prestressing steel also regains some of its strength upon cooling, as with the other types of steel, but to a lesser extent than the other types of steel.

**Figure 2.36: Residual ultimate strength of prestressing steel, reinforcing steel, and heat treated/cold worked reinforcing steel (Reprinted by permission from Springer Nature: Materials and Structures (Mechanical properties of prestressing steel after fire exposure, Z. Tao), [COPYRIGHT 2015] [33])**

In addition, while most of the studies included in the meta-analysis performed residual tests on specimens which were unstressed during heating, some studies did conduct residual tests in which the specimens had a working stress applied during heating, with the stress usually ranging from 40-70% of the ultimate strength of the steel. The effect of applying a working stress during heating was found to not have an effect on the residual strength, but several studies reported that rupture of the steel will occur above 300°C if the stress of the steel is held constant during the experiment. As a result, some researchers used strain relaxation tests in which the strain of the steel, rather than the stress, was held constant during the experiment, allowing them to perform stressed residual tests to temperatures greater than 300°C.

Another concern unique to prestressing steel is the possibility of loss of tension/prestressing force. Tension force/prestressing force in prestressing steel can be reduced by fire due to loss of elastic modulus in the concrete, relaxation due to creep, and unrecoverable extension of the steel. Not much data is available on this phenomenon, though some tests have been conducted to assess the relaxation of prestressing steel due to heat. Figure 2.37 shows the relaxation of prestressing steel over time at various temperatures up to 400°C. Increasing temperature increases the rate of relaxation, and for a given time duration will generally increase the amount of relative relaxation that occurs [12]. Each test is performed on the same type of wire, but the initial stress for each test is set to the proportional limit of the steel at that temperature.

**Figure 2.37: Relaxation of untreated cold-drawn prestressing wire due to thermal exposure (Reprinted from Fire Safety Journal, Vol. 16, No. 4, Repairability of fire-damaged structures, 1990, with permission from Elsevier [12])**

### **2.3.5. Summary of Effects of Heat on Steel**

Exposure to heat can reduce the residual yield strength, residual ultimate strength, and residual stiffness of all types of steel. However, different types of steel are more affected by heat than others. In general, reinforcing steel and structural steel are least affected, heat treated and cold worked steels are more affected, and prestressing steels are most affected. The latter two suffer greater reductions in strength and stiffness in part due to damage to the microstructural arrangements created during the heat treating and cold working processes. For example, after heating to 600°C (an arbitrary value) and cooling, the residual yield strength of the 4 types of steels studied are roughly as follows:

- Hot rolled structural steel – 90-100% of original.
- Hot rolled reinforcing steel – 80-100% of original.
- Heat treated/cold worked steel – 70-100% of original.
- Prestressing steel – 40-60% of original.

The condition of prestressing steel after a fire is most concerning given that its reductions in yield and ultimate strength are greatest, and that there is some evidence that heat can result in loss of prestressing force, which could further reduce the capacity of a structural member. Additional studies should be conducted on the potential loss of prestressing force to help quantify the potential additional loss in strength due to this effect.

### **2.4. Residual Bond Between Concrete and Steel**

In addition to deteriorating steel and concrete material alone, heat can also deteriorate the residual bond between concrete and steel in reinforced concrete and composite members [2], [12]. Experimental studies have indicated that two types of bond

failure can occur. Pullout failure can occur when the concrete cover is thick or the rebar is under a high degree of confinement. In this failure mode, concrete between the ribs of deformed rebar will gradually crush, eventually leading to a pullout failure. Alternatively, if the cover is thinner, splitting failure can occur due to cracks which propagate radially from the rebar [42], [43]. The crushing and splitting of concrete due to interaction with rebar are depicted in Figure 2.38.

To study the change in bond strength after heating and cooling, researchers typically perform either the pullout test or the beam test. For the pullout test, reinforcing steel is cast in the center, edge, or corner of cylindrical or cube-shaped concrete specimens. Specimens are then heated to a certain temperature, allowed to cool in air or water, and subsequently the force required to pull the reinforcing steel out of the concrete specimens is measured. The average bond stress can be calculated by dividing the pullout force by the surface area of the embedded portion of the bar. The pullout test for assessing bond strength should not be confused with the pull-out test method for measuring the compressive strength of concrete which is presented in Section 4.2.2. The reason for varying the location of the rebar placement, such as the center versus the corner, is that reinforcing steel placed in the center of a sufficiently thick specimen will typically experience bond failure during a pullout test, whereas reinforcing steel placed near an edge or corner is more likely to fail due to concrete splitting. For the beam test, rebar is cast into bottom of a concrete beam specimen, and the specimen is heated to a certain temperature and allowed to cool in air or water, then the specimen is subjected to a three-point bending test. The bond strength can be determined by the relative slip between the rebar and the concrete.

**Figure 2.38: Schematic of the crushing and splitting of concrete with an embedded deformed rebar under tension (Reprinted from *Construction and Building Materials*, Vol. 198, Analytical model for the bond stress-slip relationship of deformed bars in normal strength concrete, 2019, with permission from Elsevier [44])**

One study analyzed the effect of embedment length on residual bond strength of normal strength concretes and deformed (ribbed) rebar using the pullout test [45].  $\phi 8$  mm bars were cast into the center of concrete cylinders 100 mm in diameter and 200 mm in height with embedment lengths of 6 cm, 10 cm, and 16 cm. Two different concrete strengths were used: C20 and C35 (minimum 28-day compressive strength of 20 MPa and 35 MPa, respectively). For reference, the required bond length for  $\phi 8$  mm bars in tension per ACI 318-19 is 37 cm for the C20 concrete, and 28 cm for the C35 concrete. The specimens were heated to various temperatures up to 700°C and held at the maximum temperature for 3 hours to ensure the specimens were uniformly heated. Afterwards, they were cooled either in air or in water before the pullout tests were performed. Figure 2.39 shows the bond strength (pullout force) for the rebar cast into C20 concrete, and Figure 2.40 shows the bond strength (pullout force) for the rebar cast into C35 concrete.

In general, shorter bond lengths result in greater relative losses of bond strength after heat exposure. For instance, after being exposed heated to 700°C, the bond strength

of rebar embedded 16 cm into the C35 concrete decreased by about 37% compared its original bond strength, while the rebar embedded only 6 cm into the C35 concrete decreased by about 70% compared its original bond strength. Another conclusion which can be drawn is that the bond strength increases as compressive strength of the concrete increases. The cooling method did not have a clearly discernible effect on the residual bond strengths.

**Figure 2.39: Residual bond strength of C20 (20 MPa) concrete (Reprinted from Fire Safety Journal, Vol. 44, No. 6, Residual bond strength between steel bars and concrete after elevated temperatures, 2009, with permission from Elsevier [45])**

**Figure 2.40: Residual bond strength of C35 (35 MPa) concrete (Reprinted from Fire Safety Journal, Vol. 44, No. 6, Residual bond strength between steel bars and concrete after elevated temperatures, 2009, with permission from Elsevier [45])**

Another study sought to analyze the effect that position of the rebar in the concrete (i.e., center, edge, or corner) has on the residual bond strength after heating and cooling [43].

Deformed rebar were cast into the center, edge, and corner of cube-shaped concrete specimens. The embedment length of each bar was the diameter of the bar multiplied by eight (128 mm). The specimens were heated to various temperatures up to 700°C and held at the maximum temperature for 3 hours to ensure the specimens were uniformly heated. Afterwards, the specimens were cooled to room temperature in air before the pullout tests were performed. The average bond stress (pullout force divided by surface area of portion of bar embedded in concrete) was used to evaluate the relative differences in bond strength.

Rebar placed at the edge and corner of the cubes had a lower average bond strength overall and had slightly greater relative strength losses compared to rebar placed at the center for a given temperature, but the relative strength decreases were not vastly different among the different placement locations. Still, the reduction in residual bond strength was apparent even at 300°C, the lowest temperature tested.

Noting that many existing studies only analyzed the residual bond strength of normal strength concrete, one study sought to analyze the residual bond behavior of high strength concrete (80 MPa, 11,600 psi) and deformed rebar [46]. In contrast to the two studies previously shown which used pullout tests to determine residual bond strength, in this study the beam test was employed. A schematic of the beam specimen is shown in Figure 2.41. The notch in the bottom center of the beam allows the slip of the rebar to be measured at both the center (S1+ and S2+) and the end of the beam (S1 and S2).

**Figure 2.41: Beam test specimen for assessing residual bond strength (Reprinted from Fire Safety Journal, Vol. 69, Beam test on bond behavior between high-grade rebar and high-strength concrete after elevated temperatures, 2014, with permission from Elsevier [46])**

Beam specimens were heated to various temperatures up to 600°C and allowed to cool to room temperature in air. Afterwards, they were subjected to a three-point beam test. Figure 2.42 shows the degradation of the bond strengths as measured by the beam test and the degradation of the concrete strength measured by compression tests on separate specimens made of the same concrete mixture as the beams. At and below 400°C, the compressive strength and bond strength degradation are nearly identical, but above 400°C, the bond strength decreases more than the concrete compressive strength. The results are also compared to bond strength obtained in a similar experiment previously performed by the researchers (labelled “Bond strength obtained by pull-out test [9]”) which used the pull-out test rather than the beam test.

**Figure 2.42: Degradation coefficients for bond strength measured by beam test, concrete compressive strength, and bond strength measured by a pullout test on similar concrete (Reprinted from Fire Safety Journal, Vol. 69, Beam test on bond behavior between high-grade rebar and high-strength concrete after elevated temperatures, 2014, with permission from Elsevier [46])**

#### **2.4.1. Summary of the Effects of Heat on the Residual Bond Strength between Concrete and Steel**

The residual strength of the concrete/steel bond after heating and cooling from certain temperatures decreases to a similar or greater degree compared to the decrease in residual concrete compressive strength. Embedment length and concrete cover to reinforcement both can have a significant effect on the residual bond strength. Greater embedment length generally results in smaller relative decreases in residual bond strength. Reinforcement with a thinner cover generally has a lower residual bond strength than concrete with a thicker cover due to transformation from a compression to a splitting failure mechanism.

However, it is not entirely clear what effect the loss of bond strength has on the potential loss of strength of an actual structural member. The studies presented in this section all used development lengths well shorter than those required by code, meaning

that the effects of bond strength loss may not be significant, given that code-prescribed bond lengths are intended to ensure yield failure of the steel well before bond failure would occur. Furthermore, it is difficult to isolate bond strength loss from loss of compressive strength of the concrete, since other factors such as friction and chemical adhesion also determine bond strength. Additional studies with development lengths required by code should be conducted to see if bond strength is a major concern for the post-fire condition of structural members, or if the yielding of steel is the controlling factor regardless.

In addition, many tunnel structures are constructed with epoxy-coated reinforcement. Additional studies should be conducted on the bond strength of epoxy-coated reinforcement to determine if it is more susceptible to residual bond strength loss than uncoated reinforcement. It was demonstrated in the experimental part of this work presented in Section 7.5 that heat exposure can cause melting of the epoxy used to coat reinforcing. Further efforts should also be directed at determining the likelihood of epoxy damage in members subjected to a variety of heat exposures (e.g. 400, 600, 800°C for 2 hours) with typical concrete cover.

## **CHAPTER 3**

### **EXISTING STUDIES ON THE EFFECT OF FIRE ON STRUCTURAL MEMBERS**

Although studies on the residual strength of concrete, steel, and the concrete/steel bond are valuable in understanding the residual behavior structural members, it is difficult to use these properties alone to fully predict the residual strength and stiffness of structural members. Therefore, many experimental studies on the residual strength and stiffness of structural members have been conducted [47] [48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63].

Experimental tests to determine the residual strength of structural members are typically performed by exposing the member to a design fire in a furnace, either while loaded or unloaded, allowing the member to cool to room temperature, and testing the member to failure. One of the key differences between residual strength tests for concrete and steel versus structural members is that a non-uniform temperature distribution in the specimen is desired in the latter case, as this is more representative of the exposure conditions that a structural member would experience in a fire.

The following section will summarize five experimental studies on the residual strength of concrete members. Particular focus will be given to the construction/dimensions of the members, heat exposure conditions/temperature distributions within the members, and the ultimate strength reductions (if any) in the members.

### **3.1 Existing Experimental Studies on the Residual Strength of Structural Members**

#### **3.1.1. El-Hawary et al. (1996) – Reinforced Concrete Beams in Flexure**

El-Hawary et al. in 1996 conducted experimental studies on the residual strength of reinforced concrete beams after heating and cooling [47]. Four beam specimens were prepared for the study, each 200 mm in depth, 120 mm in width, and 1800 mm in length, with a concrete compressive strength of 25 MPa. Each beam was reinforced with 2 –  $\phi$ 10 mm longitudinal bars with a minimum yield strength of 358.5 MPa, another 2 -  $\phi$ 10 mm longitudinal bars with a minimum yield strength of 255 MPa, and  $\phi$ 8 mm stirrups with a minimum yield strength of 255 MPa spaced at 8 cm.

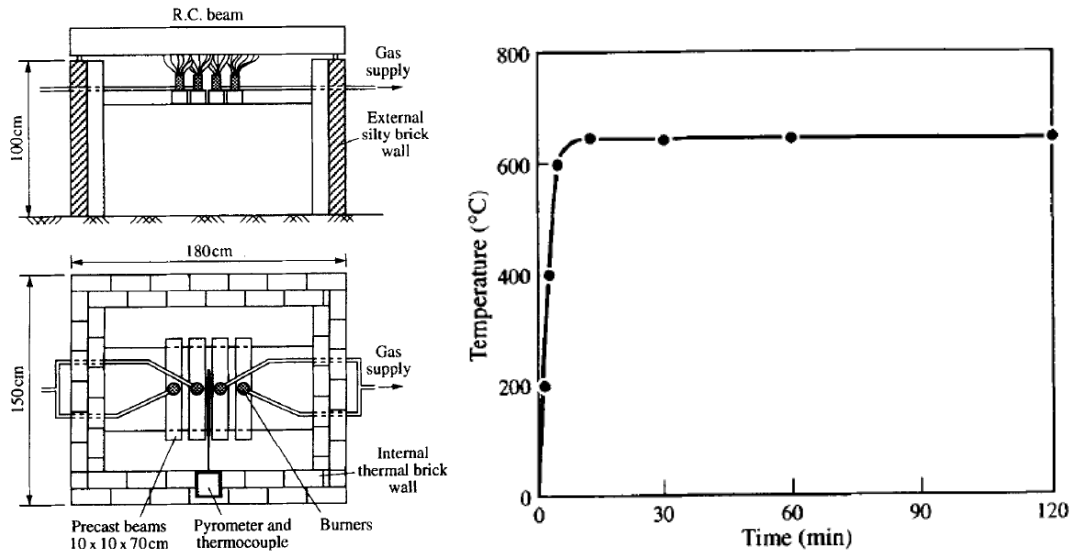

The four beams specimen were denoted B, B1, B2, and B3. B was not heated and was used as a control, while B1, B2, and B3 were exposed to 650°C heat for 30 minutes, 60 minutes, and 120 minutes, respectively, and were not subjected to any load during heating. The furnace used for heating and a curve showing the measured furnace air temperature over time are shown in Figure 3.1. After heating, the specimens were sprayed with water until cooled to room temperature and subjected to four-point bending tests.

The study did not report the visual condition of the beams, such as any potential spalling or exposed rebar, after heating; however, they did perform some non-destructive testing with a rebound hammer, a technique which is discussed in Section 4.2.1. Compared to the control beam, the beams exposed to heat experienced significant reductions in flexural strength and stiffness, and the magnitude of these reductions increased with increased exposure time. The ultimate strengths in flexure and the load-deflection plots for the beams are shown in Figure 3.2. Beams B1, B2, and B3 had

88.2%, 80.7%, and 61.3%, respectively, of the flexural strength of the control beam (B).

Furthermore, the stiffness steadily decreased with increased exposure time, with B3

having a 76.3% greater midspan deflection at failure compared to the control beam.

**Figure 3.1: Schematic of the furnace (left), and the time-temperature curve of the furnace (right) (Reprinted from Construction and Building Materials, Vol. 10, No. 2, Effect of fire on flexural behaviour of RC beams, 1996, with permission from Elsevier [47])**

**Figure 3.2: Ultimate load for each beam (left), load-deflection plots for each beam (right) (Reprinted from Construction and Building Materials, Vol. 10, No. 2, Effect of fire on flexural behaviour of RC beams, 1996, with permission from Elsevier [47])**

The results suggest that exposure time has a significant impact on the residual strength of reinforced concrete beams, as the three heated beams were exposed to the same temperature (650°C) but for varying amounts of time. Moreover, as evidenced by the 11.8% strength loss in the beam heated for 30 minutes, even short heating times can reduce the residual flexural capacity of reinforced concrete beams.

### **3.1.2. Kodur (2010) – High-Strength Reinforced Concrete Beams in Flexure**

Kodur et al. performed residual strength tests on reinforced concrete beams and compared the results of the tests with a simplified method for calculating the residual strength of reinforced concrete beams that the researchers developed [50]. The beams were each 406 mm deep, 254 mm wide, and 3960 mm long. One of the beams, denoted B1, was made with high-strength concrete (58.2 MPa), and the other two beams, denoted B2 and B3, were made with super-high-strength concrete (106 MPa). Each beam was reinforced with three  $\phi$ 19 mm longitudinal bottom bars, two  $\phi$ 13 mm longitudinal top bars, and  $\phi$ 6 mm shear stirrups spaced at 150 mm. The longitudinal bars had a yield strength of 420 MPa. Each beam was fitted with thermocouples at three cross-sections along the beam, as shown in Figure 3.3.

Two different time-temperature curves for the fire exposure were used: a short design fire (SF) and a long and severe design fire (LF), shown in Figure 3.4. B1 and B2 were subjected to the SF fire, while B3 was subjected to the LF fire. During the heat exposure, point loads were applied to each beam which loaded the beams to 55% of their flexural capacity according to standard flexural equations from ACI 318.

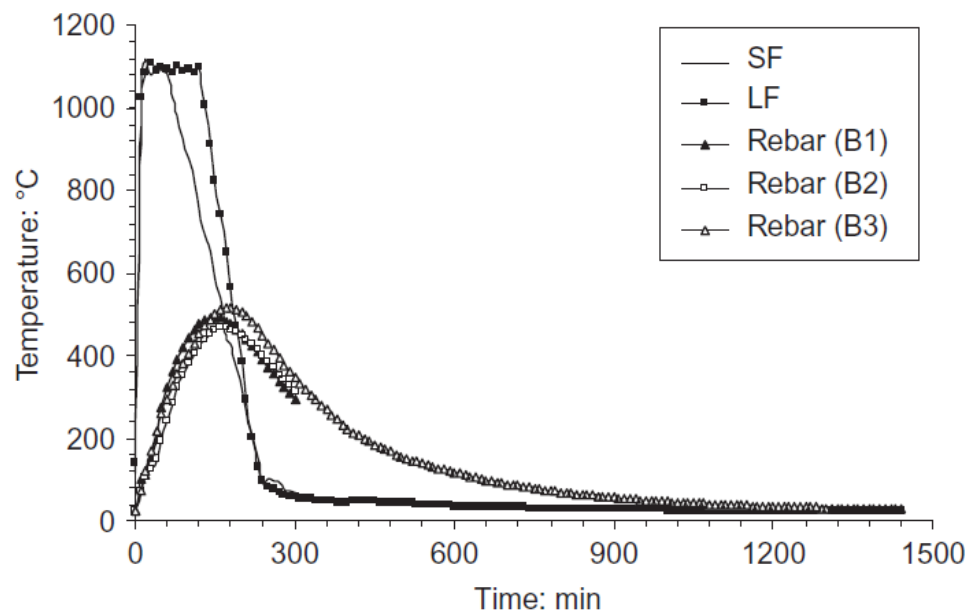

**Figure 3.3: Location of thermocouples (labelled "TC") in each beam (Republished with permission of Institution of Civil Engineers, from An approach for evaluating the residual strength of fire-exposed RC beams, V. Kodur, M.B. Dwaikat, R.S. Fike, Vol. 62, No. 7, 2010; permission conveyed through Copyright Clearance Center, Inc. [50])**

**Figure 3.4: The two design fires used in the experiment (Republished with permission of Institution of Civil Engineers, from An approach for evaluating the residual strength of fire-exposed RC beams, V. Kodur, M.B. Dwaikat, R.S. Fike, Vol. 62, No. 7, 2010; permission conveyed through Copyright Clearance Center, Inc. [50])**

The temperatures measured by the thermocouples during heating are shown in Figure 3.5, where SF is the average recorded furnace temperature during the SF fire, LF is the average recorded furnace temperature during the LF fire, and rebar B1, B2, B3 are the recorded temperature of the bottom rebar in each beam specimen. It was noted that the temperatures of the bottom rebar would likely have the greatest impact on the residual strength of the beams, since the beams were heated from the bottom.

**Figure 3.5 Bottom rebar temperatures during heating (Republished with permission of Institution of Civil Engineers, from An approach for evaluating the residual strength of fire-exposed RC beams, V. Kodur, M.B. Dwaikat, R.S. Fike, Vol. 62, No. 7, 2010; permission conveyed through Copyright Clearance Center, Inc. [50])**

After the beams had cooled, spalling was observed in B2 and B3, possibly due to the use of super-high-strength concrete for these specimens. After cooling, the beams were loaded to failure, and the results of the tests are shown in Table 3.1. For the two super-high-strength concrete specimens, the beam subjected to a longer duration fire had 77% of the residual strength of the beam subjected to the shorter duration fire. Furthermore, the residual flexural capacity of all of the beams were greater than the

capacity predicted by ACI 318 code equations (92.7 kN for B1, and 94.5 kN for B2 and B3).

**Table 3.1: Details about the beam specimens and the results of the load testing (Republished with permission of Institution of Civil Engineers, from An approach for evaluating the residual strength of fire-exposed RC beams, V. Kodur, M.B. Dwaikat, R.S. Fike, Vol. 62, No. 7, 2010; permission conveyed through Copyright Clearance Center, Inc. [50])**

Beam	Support condition*	Fire exposure	Concrete type	Maximum rebar temperature: °C	Initial deflection: mm	Measured residual load capacity: kN	Predicted residual load capacity: kN
B1	AR	SF	NSC	493	13.8	119.5	85.7
B2	SS	SF	HSC	466	28.0	129.7	87.4
B3	AR	LF	HSC	552	28.8	99.3	84.5

\*AR, axially restrained; SS, simply supported

Table 3.1 also includes predictions of residual strength using a simplified hand method developed by the researchers, which is intended to allow one to estimate the residual strength of a fire-damaged reinforced concrete beams without performing a finite element analysis.

The method consisted of four steps:

1. (Estimate the fire temperature and duration based on eyewitnesses or visual assessment of coloration in concrete.
2. Estimate the maximum temperature reached in the rebar based on a simplified empirical equation proposed by the researchers.
3. Estimate the residual strength of the rebar based on strength-temperature relationships for reinforcing steel.
4. Compute the residual capacity of the beam per ACI 318 equations for flexural strength at ambient temperatures, using the reduced strength of steel found in (3), and a reduction factor to account for the loss of concrete section.

The researchers proposed an equation for the temperature of the rebar:

$$T_{smax} = \lambda T_{fmax} \text{ where, } \lambda = 1.45(t_h + \frac{t_c}{w})^{0.2} \left(0.4 + 0.03 \frac{H}{B}\right) - 5a \text{ (Eq. 4.1)}$$

Where  $T_{smax}$  is the maximum rebar temperature,  $T_{fmax}$  is the maximum fire temperature, and  $\lambda$  is a modification factor for the cross-section dimensions and fire exposure,  $t_h$  is the duration of the heating phase (in hours),  $t_c$  is the duration of the cooling phase (in hours),  $H$  is the section depth (m),  $B$  is the section width (m) and  $a$  is the axis distance (m). This empirical equation was developed based on the results of hundreds of finite element heat transfer analyses with 17 different design fires performed by the researchers. After the temperature of the rebar is estimated, the residual strength of the rebar can be estimated based on a residual strength-temperature relationship.

The residual strength of the section can then be estimated using the equation:

$$M_n = A_s f_{yT} \left( d^* - \frac{A_s f_{yT}}{1.7 b^* f_c} \right) \text{ (Eq. 4.2)}$$

Where  $A_s$  is the area of tension steel,  $f_{yT}$  is the residual strength of reinforcing steel,  $d^*$  is the effective depth of the damaged concrete section,  $b^*$  is the width of the damaged concrete section,  $f_c$  is the initial compressive strength of the concrete.

Observing that the experimentally determined ultimate loads were 17-48% higher than the predicted ultimate loads using this method, the researchers noted that the method, as with the ACI 318 flexural strength equations for ambient temperatures, does not take strain hardening of steel into account.

Though this method presents an interesting addition to the arsenal of post-fire assessment tools, some the parameters required may be very difficult to determine, such as the heating and cooling lengths of the fire. Furthermore, this method is only applicable to standard reinforced concrete beams.

### 3.1.3. Federal Highway Administration (FHWA) (2007) – Prestressed Concrete Box Beams in Flexure

Unlike the other studies presented in this section, in which the specimens were heated in laboratories and testing facilities under controlled conditions, a 2007 study by the FHWA analyzed the residual flexural strength of concrete box beams from a bridge that had been exposed to a fire in service [48]. On July 12, 2005, a gasoline tanker truck on a bridge near Ridgefield, CT overturned and caught fire. Burning fuel covered portions of the deck and spilled into the Norwalk River beneath the bridge. Figure 3.6 shows the condition of the exterior of the bridge after the fire.

**Figure 3.6: Fascia of the bridge after the fire (reprinted from [48])**

After the fire, the Connecticut Department of Transportation (ConnDOT) elected to replace all the beams in the bridge, since it could not be determined if the fire had damaged the prestressing strands in the beams. It was then decided that four of the interior beams which were removed would be inspected and tested to see if they had actually lost significant flexural capacity.

The bridge, constructed in 1957, consisted of 15 adjacent prestressed box beams, which spanned 14.6 m. A cross section of a typical beam is shown in Figure 3.7. The reinforcement mostly consisted of 9.5 mm prestressing strands, though there were also 2-

#4 rebars at the top. The concrete cover for the prestressing strands varied from 33-46 mm.

**Figure 3.7: Cross-section of a typical prestressed box beam in the bridge (reprinted from [48])**

Before the load tests were performed, each beam was subjected to a visual inspection and petrographic analysis. The visual inspection revealed extensive concrete scaling on the bottom of the beams, shown in Figure 3.8. The average scaling depth was found to be 10 mm, but some areas had scaling up to 15 mm.

**Figure 3.8: Visual condition of the bottom of beam 4 (reprinted from [48])**

Furthermore, a petrographic analysis indicated that cracking in the concrete due to the fire extended approximately 25 mm from the exposed surface, for a total average damage depth in the concrete of 35 mm (scaling depth plus cracking depth).

After the visual inspection and petrographic examination, the beams were loaded to failure in a three-point bending test, and the ultimate loads and deflections were recorded. The experimental results were compared with the findings of a 1999 rating report of the bridge, which estimated the ultimate strength of a typical interior beam to be 1,407 kN-m. Table 3.2 provides a summary of the ultimate load and deflections determined experimentally for the four beams and a comparison of their ultimate strengths to the estimated strength of the interior beams per the 1999 rating report. The ultimate strengths include both the beam self-weight and the applied loading.

**Table 3.2: Strength results from the load testing of the beams**

<b>Beam #</b>	<b>Measured Ultimate Deflection (mm)</b>	<b>Measured Ultimate Flexural Strength (kN-m)</b>	<b>Ratio of Measured Strength to Analytically Determined Strength</b>
<b>Beam 3</b>	343	1,692	1.20
<b>Beam 4</b>	284	1,678	1.19
<b>Beam 7</b>	236	1,633	1.16
<b>Beam 14</b>	236	1,572	1.12

The measured ultimate flexural strength of each beam exceeded the flexural strength estimated in the 1999 rating report, suggesting that the beams had not lost significant strength due to the fire. Since all the beams from the bridge were damaged by the fire, it was not possible to have a control specimen for comparison. Although the flexural strength of the beams was not affected, it was noted that accelerated corrosion of the strands remained a long-term concern, as the depth of cracking due to the fire had extended to the bottom in the prestressing strands in some areas.

### 3.1.4. Agrawal & Kodur (2019) – Super-High-Strength Reinforced Concrete Beams in Flexure

Agrawal and Kodur investigated the residual strength of super high-strength concrete beams exposed to different fire scenarios [56]. Four beam specimens were prepared for the study, each with a depth of 406 mm, a width of 254 mm, and a length of 3960 mm, with 3- $\phi$ 19 mm bottom longitudinal bars, 2- $\phi$ 13 mm top longitudinal bars, and  $\phi$ 6 mm stirrups spaced at 150 mm, with the longitudinal bars having a yield strength of 420 MPa. The beams were denoted B1, B2, B3, and B4. B1 and B3 were tested 16 and 8 months after casting respectively, while B2 and B4 were tested 9 years after casting. The concrete of B1 and B3 had a compressive strength of 106 MPa, while the concrete in B2 and B4 had compressive strengths of 103 MPa and 106 MPa, respectively. To measure the temperature within the specimens during heating, each beam was fitted with several thermocouples. The cross-section of the beams and the locations of the thermocouples are shown in Figure 3.9.

**Figure 3.9: Beam cross-sections and locations of thermocouples (bottom left is cross-section A, bottom center is cross-section B, and bottom right is cross-section C) (used with permission from Wiley, reprinted from [56])**

Each of the beam specimens was subjected to a different heating regime in a furnace. The measured air temperatures for each heating regime are shown in Figure 3.10. Two of the heating regimes were called “short design fires” (SF), while the other two were called “long and severe” design fires (LF). One of the SF fires (SF2) and one of the LF fires (LF2) had very fast cooling rates, which was intended to simulate a scenario in which the fire was put out quickly.

During heating, B1, B2, and B3 were stressed to 53% of their flexural capacity per ACI 318, while B4 was stressed to 63% of its flexural capacity per ACI 318. B3 failed during heating due to excessive deflection, and therefore its residual strength capacity could not be tested. After heating, each beam was cooled in air to room temperature. For each residual strength test, the beam was loaded to failure in a four-point beam test. B1 was tested 24 hours after cooling, and B2 and B4 were tested a week after cooling. The results of the loading tests are shown in Table 3.3. Note that since no unheated control beam specimen was used, the original capacity of the beams before heating was determined using a finite element model. The original ultimate capacity of the beams was found to be 194 kN using the model. Furthermore, after heating, the researchers quantified the percentage of concrete lost due to spalling by comparing the final volume of the beam to the original volume of the beam.

**Table 3.3: Details about the beam specimens, and the results of the experimental testing**

Beam	Age of Beam at Testing (months)	$f'_c$ (MPa)	Fire Exposure	Ultimate Residual Strength (kN)	Ratio of Residual Strength to Original Strength as Determined by FEA	Spalled Volume Percentage
<b>B1</b>	16	106	SF1	129	.77	3.2
<b>B2</b>	107	103	SF2	112	.57	1.5
<b>B3</b>	8	106	LF1	-	-	7.0
<b>B4</b>	108	106	LF2	102	.43	3.3

**Figure 3.10: Air temperature inside furnace for each heating regime. SF stands for “short design fire,” LF stands for “long and severe” design fire. ASTM E119 curve shown for reference (used with permission from Wiley, reprinted from [56])**

All of the beams were found to have a significantly reduced ultimate capacity compared to their capacity before heating (as determined by the finite element model). The researchers suggested that the residual capacities of B2 and B4 were much lower than B1 because the beams were subjected to a rapid cooling phase during heating and were stored for a week after cooling. It is worth noting, however, that these beams were also much older than B1, and it is unclear if this could affect the results. Although the ultimate capacities of all the beams were reduced, each still had a greater ultimate capacity than the capacity of the beams at room temperature predicted by the provisions of ACI 318, which was 94.5 kN.

### **3.1.5. Choi et al. (2013) – Reinforced Concrete Beams in Flexure**

A 2013 study by Choi et al. analyzed the residual flexural strength of reinforced concrete beams, focusing on the effects of spalling and temperature distribution within

the members [53]. In total, twelve reinforced concrete beam specimens were prepared which were each 250 mm in width, 400 mm in depth, and 4700 mm in length. Two different concrete strengths (NSC and HSC), two different concrete cover amounts, and three different heating durations were used. Each beam was reinforced with 3- $\phi$ 22 mm bars on the bottom and 2- $\phi$ 22 mm bars on the top, with a tested ultimate strength of 439 MPa. Of the twelve beams, four were not heated and used as controls. The beams which were heated were subjected to a 40% service load during heating. To measure the temperatures within the specimens during heating, each beam was outfitted with three thermocouples at the midspan, located at 50 mm, 200 mm, and 350 mm from the bottom of the beam, denoted as “Low,” “Mid,” and “High,” respectively.

Eight of the beams were heated in a furnace according to the ISO 834 fire curve, while being subjected to a 40% service load. Only the bottom and the two sides of the beams were heated. As would be expected, the NSC beams with the 40 mm cover experienced about 10% higher temperatures on average at the “Low” thermocouple than the NSC beams with 500 mm cover. The temperature at the “Low” thermocouples is significant as it is near the longitudinal reinforcement, which could negatively affect the flexural capacity of the beam if heated to very high temperatures. The temperature distributions for the HSC beams were also measured. For the HSC beams, the effect of the cover thickness on the temperatures at the “Low” thermocouple is not applicable since extensive spalling was reported in the HSC beams.

After heating and prior to the load testing, the beams were visually inspected. For the NSC beams, extensive cracking and loss of the concrete cover in some instances were

noted, but significant spalling was not observed. On the other hand, the HSC beams experienced significant spalling.

After cooling, the beams were loaded to failure in a four-point bending test. The most notable finding is that the HSC beams lost significantly more strength after heating than the NSC beams, possibly due to the greater extent of spalling. None of the NSC beams lost more than 10% of their strength, whereas one of the HSC beams lost nearly 50% of its strength compared to the control. The NSC beams with 50 mm cover fared slightly better than the NSC beams with 40 mm cover, possibly due to the protection offered by the increased cover thickness. The HSC beams with the 50 mm cover performed worse than the HSC beams with 40 mm cover.

Ultimately, the results suggest that spalling resulting in the reduction of concrete in the compression zone and exposure of tension reinforcement may have a significant effect on the residual strength of reinforced concrete members. Though the recorded temperatures near the longitudinal rebar were low enough that they likely did not experience any reduction in residual strength, the loss of concrete in compressive region of the HSC beams as shown in Figure 3.15 may have contributed to the significant loss of residual strength of the HSC beams.

### **3.1.6. Summary of the Effects of Fire Exposure on the Residual Strength of Structural Members**

Table 3.4 summarizes several existing studies on the residual strength of concrete members, including those presented in this section. Not all of these studies are directly relevant to concrete tunnel structures, but general observations from these studies can still be valuable for assessing the residual strength of structural elements in tunnels.

The residual strength reductions observed in existing studies varied greatly. In some cases, ultimate strength losses of 5-10% were observed, while in other cases residual strength losses up to nearly 60% were observed. Based on the wide variety of specimen dimensions and types, materials, and heating regimes used in the studies, it is difficult to directly specify the specific factors which govern the residual strength loss; however, some general conclusions can still be drawn. For one, greater lengths of exposure to heat generally result in greater residual strength losses. Furthermore, spalling seems to result in greater strength losses compared to when spalling does not occur. This can potentially be explained by the fact that spalling can expose reinforcing steel in the tension zone of flexural members to direct heat, which can result in residual strength loss of the steel. In multiple studies, it was found that specimens made with high-strength concrete are more likely to experience spalling, which is significant given that the use of high-strength concrete in tunnel structures is prevalent.

Note that these findings of these existing studies are compared to the findings of residual strength testing performed as part of this work in Section 7.7.

**Table 3.4: Summary of studies on the residual strength of reinforced concrete members**

Study	Specimens Tested	# Specimens	Exposure Temperature(s)	Exposure Time(s)	Strength Results
El-Hawary et al. (1995) (29)	Reinforced Concrete Beams	4	650°C	0, 30, 60, 120 minutes	0 min: 100% Flexural capacity 30 min: 88.2% 60 min: 80.7% 120 min: 61.3%

## **CHAPTER 4**

### **EXISTING POST-FIRE INSPECTION METHODS FOR CONCRETE STRUCTURES**

The post-fire inspection of tunnels poses several challenges [64]. For one, the possibility of long fire durations and high temperatures means that the level of damage can range from minor surface damage to damage requiring extensive repairs. Furthermore, a wide variety of materials and structural elements may be present in tunnels, requiring the inspector to understand how fire may affect each component and material. Lastly, the inspector may be under pressure to decide if a tunnel is safe to be reopened as quickly as possible, due to the high economic and societal cost of traffic disruption.

There are several documents which describe existing techniques for the post-fire assessment of concrete structures [8], [41], [65], [66]. Many of these techniques are aimed at evaluating the residual strength of structures after fire. From reviewing the literature, three main categories of inspection techniques emerge:

- visual inspection methods,
- non-destructive testing methods,
- laboratory testing methods.

Generally speaking, visual methods and non-destructive testing approaches are most suitable for rapid inspections, since laboratory methods may take weeks to perform. On the other hand, laboratory methods may give a more accurate and thorough assessment of the residual capacity of the structure.

## **4.1. Visual Inspection Methods**

While current visual methods are not currently suitable for directly determining the residual strength of structural components, they can give the inspector valuable information about the maximum temperatures reached in certain areas of the structure during the fire and give a general sense of the severity of the damage.

### **4.1.1. Examination of Debris Materials**

An important step in post-fire assessment of concrete structures is estimating the temperatures reached at certain areas of the structure, since the residual strength of steel and concrete largely depend on the maximum temperature to which they were exposed [6], [7]. Examining the residual condition of debris and non-structural materials, such as melting of metals or charring of plastics, can reveal the upper and lower bounds of temperature exposure in different areas of the structure [8], [41]. Table A6.1 in *Appraisal of Existing Structures* lists the visual condition of many common building materials after exposure to certain temperatures [41], such as aluminum and PVC.

Researchers at the United States Nuclear Regulatory Commission employed this method after the 2007 Newhall Pass tunnel fire in California to develop a map of the maximum and minimum temperatures reached along the length of the fire in the tunnel [67].

The researchers visually examined the condition of various metallic material samples from five burned vehicles in the tunnel, such as aluminum brackets and steel framing, and estimated the upper and lower temperatures bounds by observing whether the samples were melted, partially melted, or not melted.

**Figure 4.1: Picture taken during the fire event (left), after the fire event (right) (reprinted from [67])**

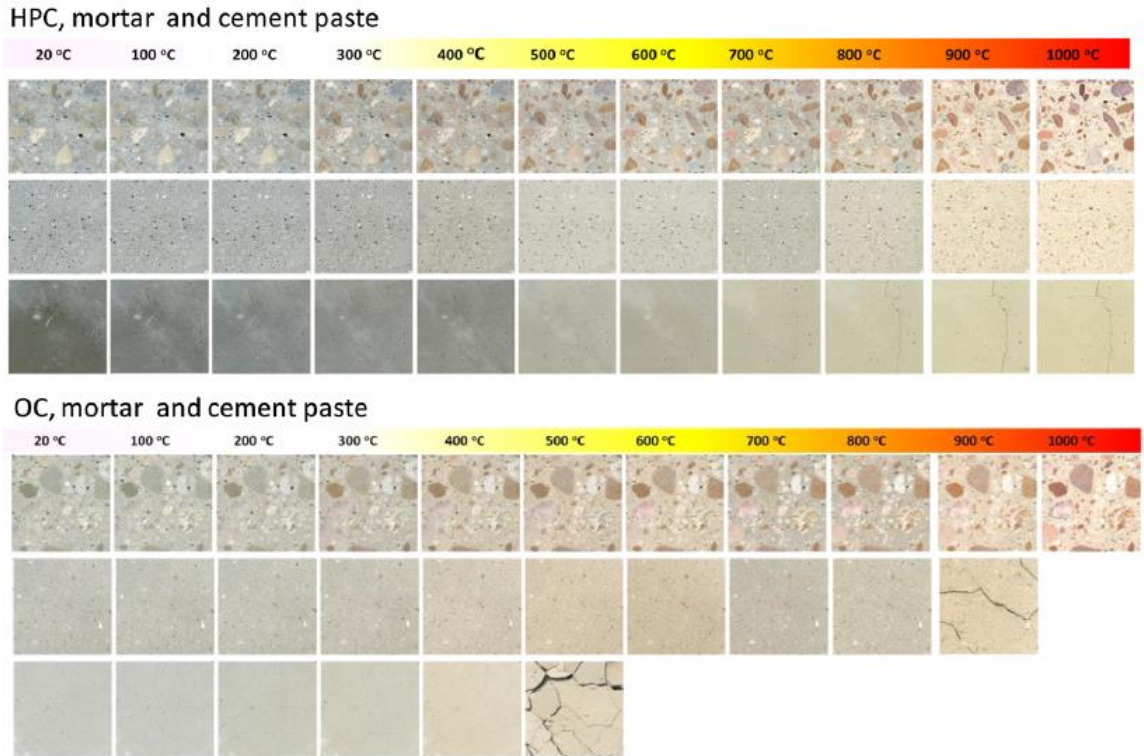

**Figure 4.2: Melted aluminum alloy on wheel of truck (reprinted from [67])**

Differential scanning calorimetry (DSC) was used to precisely determine the melting points of the various samples, since the addition of alloying substances can alter the melting points of pure metals. However, the data provided in the study shows that melting points determined using the DSC process were within  $\pm 100^{\circ}\text{C}$  of the melting points shown in Table A6.1 in *Appraisal of Existing Structures*. In addition to this method, the researchers also used hardness tests and microstructure analysis for some of the samples. Ultimately, a map of the temperature bounds at the physical location of each of the five burned vehicles was developed based on the materials analysis.

#### 4.1.2. Concrete Color Change due to Heat

The color of concrete may change when exposed to high temperatures such as in a fire, due to physical and chemical processes which occur during heating. These processes can affect the color of both the aggregate and the cement matrix. It is generally agreed that concrete mixtures containing siliceous aggregates (quartz, flint) will develop a red/pink color in the range of 300–600°C, due to the dehydration and oxidation of iron compounds in the aggregate. In addition, the cement matrix can change to a whitish-grey color in the range of 600-900°C, and a “buff” color from 900-1000°C [68], [69]. The red/pink color change in concretes containing siliceous aggregates is quite useful, as concrete is generally said to have a marked reduction in residual compressive strength when heated to above 300°C [11]. Therefore, red/pink concrete present in a fire-damaged structure should be treated as being potentially damaged and investigated further. Some have recommended using a chisel or hand drill to determine the depth of red/pink concrete and taking the depth of red/pink concrete as the depth of the 300°C isotherm in the concrete, which indicates the depth of damaged concrete [65], [69].

One study produced high-quality images of heated concrete, mortar, and cement paste at a series of temperatures ranging from 20-1000°C [68], which help show the progression of the color in concrete as it is heated to progressively higher temperatures. The study used both a normal-strength and a high-strength concrete containing CEM II/A-V 42,5 R cement, and natural riverbed aggregates. The color progression is shown in Figure 4.3.

**Figure 4.3: Color change of high performance and ordinary concrete, mortar and cement paste heated to temperatures from 100-1000°C (reprinted from [68])**

Another study tested four different concrete mixtures, each with a different type of aggregate: (i) siliceous gravel, (ii) crushed limestone, (iii) crushed granite, (iv), Lytag, a proprietary lightweight aggregate [69]. It was found that the mixture with siliceous gravel had the greatest color change, while the color change in the mixtures with other aggregates was less noticeable. Furthermore, a transient heat analysis was conducted on some specimens in which the specimens were heated only on one side. Figure 4.4 shows a cut and polished specimen subjected to this heating regime.

**Figure 4.4: Concrete specimen heated on left face (transient heat analysis)  
(Reprinted from *Construction and Building Materials*, Vol. 15, No. 1, Assessment of  
fire damaged concrete using colour image analysis, 2001, with permission from  
Elsevier [69])**

Several studies, including those mentioned above, have attempted to systematically analyze the changes in color in concrete which occur due to heating [68] [69] [70] [71]. This is typically done by digitally processing the images and quantifying changes using the red, blue, green (RGB) scale, or the hue, saturation, and intensity (HIS) scale. Unfortunately, processing the images can be a lengthy endeavor, and the lighting conditions can have a major impact on the results.

This approach comes with some important limitations. For one, while the red/pink color change in concretes with siliceous aggregates has been widely observed, studies of heated concretes with other aggregates such as limestone, granite, and Lytag have shown a much less significant color change [69]. In some cases, the color may not change at all. Furthermore, concrete can develop a red/pink color due to the natural process of carbonation, which occurs as the concrete ages. For this reason, it is important to compare concrete that is suspected of being damaged with concrete in parts of the

structure that are known not to be affected, either visually or by using phenolphthalein to determine the carbonation depth, a technique which is described in Section 4.2.3 [65].

#### 4.1.3. General Visual Damage Classification

Concrete and reinforced concrete members can experience many permanent, visible changes when exposed to high temperatures. Color changes, cracking, and spalling have been widely reported in fire-damaged concrete, and the extent and severity of these phenomena can be used to give a first indication of the residual condition of the concrete. A visual damage classification scheme for fire-damaged concrete is shown in Figure 4.5.

Class of damage	Features observed					
	Finishes	Colour	Crazing	Spalling	Reinforcement	Cracks/deflection
0 (Decoration required)	Unaffected	Normal	None	None	None exposed	None
1 (Superficial repair required)	Some peeling	Normal	Slight	Minor	None exposed	None
2 (General repair required)	Substantial loss	Pink/red *	Moderate	Localised	Up to 25% exposed	None
3 (Principal repair required)	Total loss	Pink/red * Whitish grey **	Extensive	Considerable	Up to 50% exposed	Minor/ None
4 (Major repair required)	Destroyed	Whitish grey **	Surface lost	Almost total	Up to 50% exposed	Major/ Distorted
<b>Notes</b>						
* Pink/red discolouration is due to oxidation of ferric salts in aggregates and is not always present and seldom in calcareous aggregate.						
** White-grey discolouration due to calcination of calcareous components of cement matrix and (where present) calcareous or flint aggregate.						

**Figure 4.5: Visual damage classification scheme for fire-damaged concrete (Republished with permission of Institution of Civil Engineers, from Forensic engineering of fire-damaged structures, J. Ingham, Vol. 162, No. 5, 2009; permission conveyed through Copyright Clearance Center, Inc.**

[11])

The general visual condition of the structure can also be used to assess its residual condition after a fire. An example visual damage classification chart for buildings can be found in Table A6.3 in *Appraisal of Existing Structures* [41]. It is typically recommended to verify that the classification schemes are appropriate for the structure being

considered, and that they are combined with other inspection techniques such as non-destructive testing or laboratory testing.

#### 4.2. On-Site Non/Partially Destructive Testing Methods

While visual methods are useful for quickly assessing the general condition of a structure after fire event, it is sometimes necessary to estimate the residual strength of structural members more directly. There are a wide variety of non-destructive and partially destructive testing methods which have been used and recommended for the assessing the residual strength of concrete [8], [12], [64], [65]. Figure 4.6 shows a list common non-destructive and partially destructive techniques for assessing fire-damaged structures. Figure 4.7 shows a more exhaustive list of non-destructive and partially destructive inspection tools, specifically for tunnel linings.

Test location	Test type	Test method	Structural material		
			Concrete	Steel (including reinforcement)	Masonry
On-site	Non-destructive	Visual inspection	✓	✓	✓
		Endoscope survey			✓

#### 4.2.1. Rebound Hammer

The rebound hammer is one of the most widely used non-destructive testing techniques for fire-damaged structures, owing to its low cost and ease of use [65]. Furthermore, several studies have investigated the use of the rebound hammer for assessing fire-damaged concrete [70] [71] [72] [73] [74] [75] [76] [77]. Standard procedures for performing the rebound test are described in ASTM C805-18 [78]. To operate the rebound hammer, the narrow end of the hammer, known as the plunger, is pressed into the concrete until a spring-loaded mass is released. The mass impacts the concrete and rebounds, and the rebound number is determined either by the ratio of the rebound travel distance of the mass to the initial travel distance of the mass, or the ratio of the rebound velocity to the initial velocity [79]. The amount of energy absorbed by the

concrete on impact, which is expressed by the rebound number, is related to the strength and stiffness of the concrete. Generally, stronger, stiffer concrete will result in a higher rebound number, while weaker, less stiff concrete will result in a lower rebound number. In the case of non-fire-damaged concrete, the rebound hammer can be used to estimate compressive strength, provided that a correlation between the compressive strength and the rebound number for the particular concrete mix has been determined. It has been noted, however, that the rebound number is highly variable, and can be affected by many factors. Moisture/water content, aggregate size, carbonation, and surface texture of the concrete are some of the most influential factors that can affect the rebound number [66]. The accuracy of the rebound hammer in measuring the in-place compressive strength of non-fire-damaged concrete has been estimated to range from +/- 25-40%.

Due to the inherent unreliability of the rebound hammer, and the fact that performing a calibration for the particular concrete mix in an existing structure is often impractical, it is generally recommended that the rebound hammer only be used to delineate damaged areas in a fire-damaged structure, rather than to estimate the compressive strength of fire-damaged concrete [8], [65]. It has been suggested that the rebound hammer can be used to detect areas of concrete where 30-50% of strength has been lost. The poor sensitivity of the rebound hammer to low levels of damage can be explained by the dehydration of the concrete that occurs when it is heated. Drier concrete is known to register higher rebound numbers than concrete saturated with water. As a result, the decreasing value of the rebound number that might otherwise occur due to thermal damage is offset by the simultaneous dehydration of the concrete; hence, the rebound number will only begin to diminish after significant loss of compressive strength

has occurred [8]. In spite of this limitation, an attempt has been made to create a curve that correlates the rebound number to the strength of fire-damaged concrete [73].

Several studies have quantified the decrease in rebound number that occurs based on maximum exposure temperature and decrease in compressive strength. In one study, rebound hammer tests were conducted on concrete cubes made with siliceous aggregates and ordinary Portland cement which had been heated and cooled [70]. The cubes were heated to a uniform temperature throughout, up to a maximum temperature of 600°C. Some of the cubes were tested immediately after cooling; others were stored in water or air for 28 days. All the cubes were then subjected to tests with the rebound hammer.

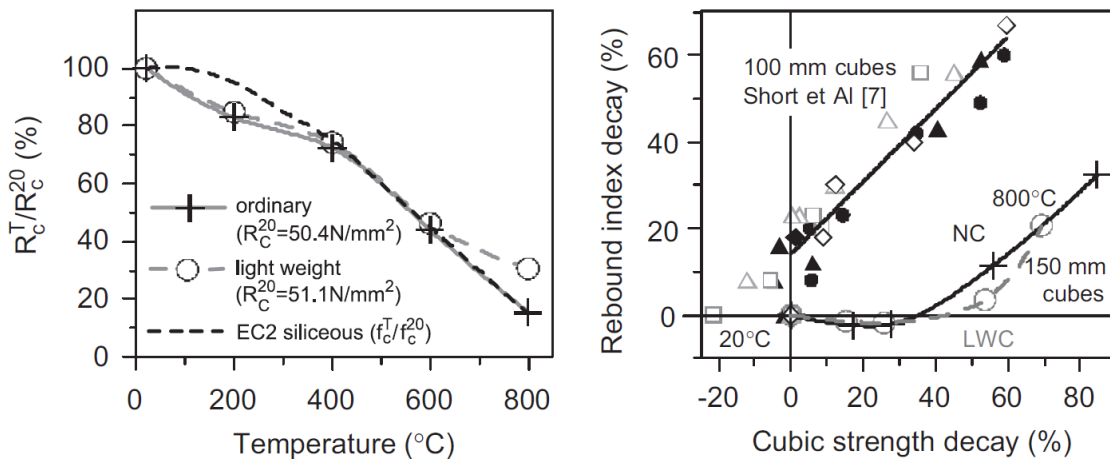

From the data, the researchers proposed a criterion to help determine whether a region of concrete has been damaged based on the rebound number:

$$\begin{array}{ll} \text{RI}_T / \text{RI}_{20^\circ\text{C}} > 0.85 & : \text{concrete element is superficially damaged only} \\ 0.85 \geq \text{RI}_T / \text{RI}_{20^\circ\text{C}} & : \text{concrete element should be further investigated} \end{array}$$

Though it was not described how this criterion was determined, a relative rebound ratio of 0.85 appears to coincide roughly with exposure to temperatures of 300°C, which has been stated as the temperature at which concrete begins to lose significant compressive strength [11].

In another study, two batches of concrete cubes were created: a normal-weight concrete made with siliceous aggregates, and a light-weight concrete made with expanded clay coarse aggregate and siliceous sand [71]. Some cubes were not heated to serve as a control, and the rest of the cubes were subjected to a slow heating and cooling cycle to achieve “uniform damage” throughout the cubes, to maximum temperatures of 200°C, 400°C, 600°C, 800°C. After cooling, the rebound numbers measured from the

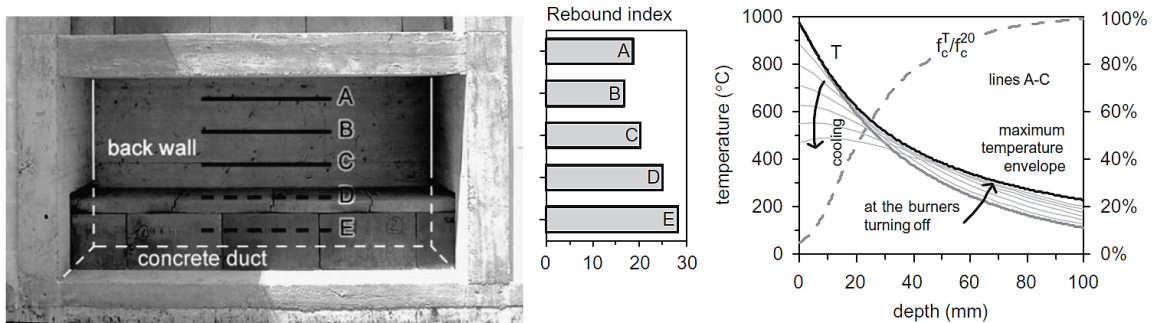

cubes were recorded, and the cubes were subjected to compression tests to measure the corresponding compressive strengths. On the left, Figure 4.8 shows the ratio of the compressive strengths of the cubes at each temperature to the strength of the unheated cubes (the strength decay ratio). On the right, Figure 4.8 shows the ratio of the rebound index of the heated cubes to the rebound index of the unheated cubes plotted against strength decay of the concrete, which includes data from this study and data from another similar study at Aston University (Short et al. 2001).

**Figure 4.8: Relative residual strength of cubes from compression tests (left), relative rebound index of cubes plotted against the compressive strength decay ratio (right) (Reprinted from Fire Safety Journal, Vol. 42, No. 6-7, New NDT techniques for the assessment of fire-damaged concrete structures, 2007, with permission from Elsevier [71])**

This same study also demonstrated the ability of the rebound hammer to delineate areas damaged by fire with a separate experimental setup [71]. In this part of the study, a concrete wall partially protected by a concrete duct (at left in Figure 4.9) was subjected to 90 minutes of the ISO 834 fire curve. Since concrete has excellent thermal insulation properties [2], the duct would greatly reduce the temperature which the protected part of the wall experienced. After cooling, rebound tests were performed at various heights along the wall (lines A-E). The rebound index results are shown in Figure 4.9 at center.

In addition, the temperatures recorded at lines A-E and the corresponding compressive strength decreases ( $f_c^T/f_c^{20}$ ) are shown at right. The rebound numbers are significantly lower at the exposed parts of the wall as compared to the protected part of the wall, supporting the idea that the rebound hammer can delineate areas of concrete damaged by fire.

**Figure 4.9: Concrete wall partially blocked by a concrete duct (left), the average rebound indices measured at each line (center), the recorded temperature and corresponding compressive strength decay at lines A-C on the wall (right) (Reprinted from Fire Safety Journal, Vol. 42, No. 6-7, New NDT techniques for the assessment of fire-damaged concrete structures, 2007, with permission from Elsevier [71])**

Though the previously mentioned studies provide a lot of useful data on the relationship of fire exposure, loss of compressive strength, and the change in the rebound number of concrete, all were conducted under controlled laboratory conditions, which may not completely reflect the in-situ conditions of a structure after a real fire. In a case study of a six-story reinforced concrete office building in Islamabad, Pakistan that experienced a severe fire, several different NDT techniques, including the rebound hammer, were used to assess the condition of the concrete in the building [75]. The rebound hammer test was performed at several locations in the building, and at each test location, a concrete core was extracted to perform compressive strength tests (Figure 4.10). This allowed the researchers to correlate the rebound number to the measured compressive strength of the concrete.

**Figure 4.10: Extraction of concrete cores for compressive strength tests (Reprinted from Case Studies in Construction Materials, Vol. 11, Structural health assessment of fire damaged building using non-destructive testing and micro-graphical forensic analysis: A case study, 2019, with permission from Elsevier [75])**

The rebound number data is shown in Figure 4.11. The red, dashed line shows the rebound number and the corresponding measured compressive strength. The blue, solid line ostensibly shows the compressive strength estimated by a typical correlation curve or perhaps the manufacturer's provided correlation curve, but the line is not fully described in the study.

Overall, the rebound number clearly decreases as the measured compressive strength decreases, but a nonlinear manner. The data indicates a high sensitivity to the initial decreases in strength, which contrasts with the findings of other researchers [71]. One notable limitation of this analysis method is that it is unclear how the non-uniform damage gradient along the concrete would affect the results of the compression tests.

**Figure 4.11: The measured core strength of the concrete vs. the rebound number (dashed line), and the compressive strength estimated by the rebound number (Reprinted from Case Studies in Construction Materials, Vol. 11, Structural health assessment of fire damaged building using non-destructive testing and micro-graphical forensic analysis: A case study, 2019, with permission from Elsevier [75])**

#### 4.2.2. Pullout Tests

The pullout test is another commonly used method for estimating the compressive strength of concrete; it has also been proposed to be used for the case of fire-damaged concrete [64], [77], [79]. Standard procedures for performing the pullout test are described in ASTM C900-19 [80]. Two types of pullout tests exist: those that are cast into the concrete, and those that are post-installed into hardened concrete. For post-fire inspection, post-installed tests are the only feasible type, such as the commercially available cut and pull-out (CAPO) test. The post-installed test is conducted in four steps, as shown in Figure 4.12:

1. a 45 mm deep, 18.4 mm diameter hole is drilled perpendicular to the surface of the concrete, and part of the hole is routed to 25 mm at a depth of 25 mm in the initial hole.
2. The metal expandable insert is inserted into the hole.
3. The bottom of the insert is expanded.
4. The bearing ring and hydraulic loading system are installed, and the insert is subjected to an increasing tensile force until failure of the concrete occurs, which extracts a cone-shaped piece of concrete. The maximum pullout force is recorded.

**Figure 4.12: Schematic showing the procedure of conducting a post-installed pullout test [Reprinted, with permission, from ASTM C900-19, Standard Test Method for Pullout Strength of Hardened Concrete, copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428. A copy of the complete standard may be obtained from ASTM International, [www.astm.org](http://www.astm.org)] [80]**

Though the specific failure mechanism governing the ultimate pullout force is

debated [79], the pullout force has been shown to have an excellent correlation with

compressive strength [66]. Though ASTM C900-19 states that a calibration of the pullout force to the compressive strength must be performed for each new concrete mixture, the excellent correlation between pullout force and compressive strength in the literature has led many researchers to suggest that a single strength-pullout force correlation curve is applicable for all normal-density concrete mixtures, except for mixtures with a maximum aggregate size exceeding 40 mm [66]. Figure 4.13 shows the results from several studies on the relationship between cube, core, cylinder compressive strength and pullout force. In Figure 4.13, the Lok Test is commercial pullout test system in which the inserts are cast in place, whereas the CAPO test is a system which uses post-installed inserts. Cast in place and post-installed inserts have been shown to give comparable results [79].

**Figure 4.13: Compressive strength - pullout force correlations from several studies [used with permission from Germann Instruments, Inc]**

One study assessed the efficacy of the pullout test, specifically the CAPO test, for estimating the compressive strength of fire-damaged concrete [81]. In the first part of the study, two sets of ordinary Portland cement concrete cubes, an “ordinary” set and lightweight set, were cast. The cubes were then subjected to a slow heating and cooling cycle to achieve “uniform damage” throughout the cubes, to maximum temperatures of

200°C, 400°C, 600°C, 800°C. After cooling, CAPO tests were performed on the cubes to determine the change in pullout force due to heating. Additionally, compressive strength tests were performed on the cubes to measure the corresponding compressive strength decrease.

Though the number of data points was limited, the method was shown to have a good sensitivity to the reduction in compressive strength caused by heat, with the pullout force varying nearly linearly with the concrete strength decay. Though this data is informative, concrete is rarely damaged in a uniform manner in real fire scenarios [2]; fire-damaged concrete usually has a damage gradient which can vary along the surface and depth of the concrete. To address this, two concrete panels (one with ordinary concrete and one with lightweight concrete) heated only on one side were also subjected to the CAPO test. Three CAPO tests were conducted on each panel. According to the researcher, the CAPO test results seem to give an indication of the condition of the concrete very near the surface (5-10 mm), based on the other pullout force results from the cube tests. The CAPO test is somewhat time-consuming compared to other NDT techniques, taking about a half hour per test, which may not be acceptable in certain circumstances.

#### **4.2.3. Carbonation Tests**

The carbonation test is a quick, simple test which can be used to approximate the depth of damage in a concrete member. As concrete is heated, several reversible and irreversible chemical reactions can occur, as shown in Table 2.1. In the range of 450-500°C, portlandite (a.k.a.  $\text{Ca(OH)}_2$ , calcium hydroxide) will undergo dehydroxylation, meaning that the calcium hydroxide begins decomposing in this temperature range [11].

Since portlandite exists in saturated solution in concrete pores, the pH of concrete will decrease when exposed to temperatures above 450-500°C. Therefore, assessing the pH along the depth of the concrete can indicate the depth of concrete which has been exposed to at least 450-500°C. The depth of dehydroxylation of the portlandite is often referred to as the carbonation depth, as it will be referred to hereafter.

The pH indicator phenolphthalein is typically used to assess the pH of fire-damaged concrete in a process known as the carbonation test [8], [72], [82], [83]. A few methods have been used to apply phenolphthalein or pH indicators to fire-damaged concrete. Some have sprayed phenolphthalein solution directly onto the concrete in situ [12], [82]. This may require chiseling a certain depth of the concrete to observe the depth of color change from colorless to pink. Others have applied phenolphthalein to concrete powder or concrete cores extracted from the structure [72], [84]. The depth of carbonation is typically assumed to be the depth in the concrete at which the phenolphthalein indicator transitions from colorless to pink. One important note when conducting the carbonation test is that carbonation can occur in structures due to natural processes such as aging [65], [84]. As a result, the carbonation depth of parts of the structure suspected to be damaged must be compared with parts of the structure known not to be damaged.

One study evaluated fire-damaged concrete using the Carbontest® kit, a commercially available kit that was developed and patented by the researcher [72]. The Carbontest® device, shown in Figure 4.14, collects the concrete powder that results from drilling with an ordinary hand drill and keeps the powder sorted in terms of the order of

extraction. A separate study by the same author showed that the device was effective in keeping the powder sorted by order of extraction [84].

**Figure 4.14: A schematic of the Carbontest® device (left), and the Carbontest® device in use (right) [used with permission from ASCE, this material may be downloaded for personal use only. Any other uses requires prior permission of the American Society of Civil Engineers] [84]**

In the study, a 135 mm thick rectangular concrete panel was heated on only one side, up to a maximum surface temperature of 840°C on the heated side. The temperature profile within the panel during the test was estimated using three embedded thermocouples. After cooling, the five Carbontest® tubes were filled with powder by drilling into the panel with a hand drill. The tubes were then filled with a phenolphthalein solution.

From the depth of the colorless part of the concrete powder in the tubes, the carbonation depth of the panel was estimated to be 26 mm, considering that a scale factor of 2:1 between the length of the powder sample and the length of original hole must be applied for a 10 mm drill bit. This result was plotted along with the estimated temperature profile, which showed that the maximum depth of carbonation (the carbonation front) coincided with a maximum temperature of 450°C. These test results suggest that the carbonation test can be used to determine the approximate depth of the 450°C isotherm in

the concrete. For reference, the residual strength of concrete which reaches temperature of 450°C is about 50-60% of the original strength.

Another study presented in [12] analyzed the carbonation depth in several buildings exposed to fire of different intensities. For each building, the fire damage was categorized as “none,” “medium,” or “severe.” The carbonation depths were determined by spraying the concrete with phenolphthalein and observing the depth into the concrete at which the phenolphthalein transitioned from colorless to pink. A plot of the measured carbonation depths is shown in Figure 4.15.

**Figure 4.15: Carbonation depths in buildings exposed to fire, measured 3-4 years after the fires (Reprinted from Fire Safety Journal, Vol. 16, No. 4, Repairability of fire-damaged structures, 1990, with permission from Elsevier [12])**

#### 4.2.4. Penetration Resistance Tests

Another non-destructive testing method which has been suggested for use with fire-damaged concrete is the penetration resistance test, often known as the commercial testing system Windsor Probe [8], [64], [65], [79]. The test is performed by firing a metal probe into hardened concrete using a probe gun with a standardized powder cartridge and

measuring the depth of penetration of the probe or the length of the exposed probe (Figure 4.16). Like the rebound hammer, the penetration resistance test is a hardness tester, and while no theoretical relationship between penetration depth and compressive strength has been established, empirical relationships can be determined [79]. Generally, the penetration depth is inversely related to the compressive strength of the concrete.

Manufacturers typically provide calibration tables to relate the penetration depth to compressive strength, and the tables may include variables such as aggregate hardness to adjust the penetration depth/strength relationship. These tables may not give accurate results in all cases, and both ASTM C803-18 and ACI 228.1R recommend developing a penetration depth/strength correlation for each concrete mixture and testing kit; however, penetration resistance tests can still be used to delineate zones of poor quality concrete without using a calibration curve by comparing relative penetration depth values.

**Figure 4.16: Area that is damaged by the insertion of the metal probe [authorized reprint from ACI 228.1R-19, Jan. 2019 Edition] [79]**

To the knowledge of the researchers, no calibrations curves for penetration resistance exist for fire-damaged concrete. It has been suggested that penetration resistance tests can be used to determine areas of concrete damaged by fire. Furthermore, *fib* suggests that the relative strength profile along the depth of the concrete could be

established by performing the test on the surface of concrete cut/chiseled to various depths [8].

#### **4.2.5. Ultrasonic Pulse Velocity (UPV)**

The behavior of various types of waves (mechanical, acoustic, electromagnetic, etc.) as they travel through concrete mediums has been studied and used as a means of assessing the condition concrete in situ [66]. So-called ultrasonic methods are a popular choice for assessing the residual condition of concrete after fire events, as they can delineate areas of concrete damaged by fire. A wide variety of techniques fall under the category of ultrasonic methods; therefore, only the most common method, ultrasonic pulse velocity, will be described here. Ultrasonic pulse velocity tests are performed by monitoring the transmission of elastic waves through concrete. The parameters that can be observed are the velocity of the elastic waves, as well as the attenuation of the elastic waves, although this parameter is much more difficult to study [66].

The elastic waves are generated in the concrete by an emitter transducer, which vibrates at its resonant frequency when sent short pulses of high-voltage electricity. These pulses are detected by a receiver transducer placed nearby [79], and the time of transmission is determined by a device containing a timer which is connected to both transducers. From this, the pulse velocity,  $C$ , can be determined by the equation  $C = L/t$ , where  $L$  = distance travelled, and  $t$  is time. A generalized schematic of this system is shown in Figure 4.17.

**Figure 4.17: Diagram showing the principle of the ultrasonic pulse velocity test [authorized reprint from ACI 228.1R-19, Jan. 2019 Edition] [79]**

Figure 4.17 shows the UPV technique applied by direct transmission through the concrete medium. Since this is not always possible depending on the geometry of the member and its location in the structure, it is also possible to use semi-direct transmission, and indirect transmission. All three transmission types are shown in Figure 4.18.

Fig. 2.4 Direct transmission ultrasonic testing

Fig. 2.5 Semi direct transmission ultrasonic testing

Fig. 2.6 Indirect transmission ultrasonic testing

**Figure 4.18: Transmission types which can be used for the ultrasonic pulse velocity test (Reprinted by permission from Springer Nature: RILEM (Non-destructive assessment of concrete structures: reliability and limits of single and combined techniques), [COPYRIGHT 2012] [66])**

The pulse velocity through concrete can be affected by many factors, including aggregate size and type, concrete mixture proportions, moisture content, concrete age, cracks or voids, and the amount and orientation of reinforcing steel, among other factors [66], [79]. Owing to these complications, and the requirement of special equipment for the tests, UPV tests must be performed by a qualified technician [66].

For example, one study sought to estimate the thickness of the damaged layer in a concrete wall that was heated only on one side according to the ISO 834 fire curve [71]. The concrete panel, shown in Figure 4.19, was 200 mm thick.

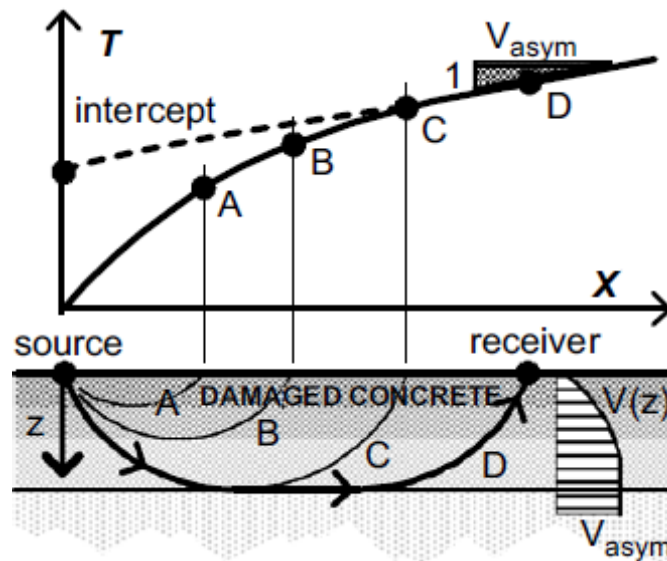

**Figure 4.19: Concrete wall heated only on one side (Reprinted from Fire Safety Journal, Vol. 42, No. 6-7, New NDT techniques for the assessment of fire-damaged concrete structures, 2007, with permission from Elsevier [71])**

After heating, UPV tests were performed along lines B and C, using the indirect method of transmission. The emitter transducer was held in the same location, while the receiver transducer was gradually moved farther away from emitter. The pulse velocity in concrete generally decreases with increasing damage. As a result, due to the damage gradient present in concrete after a fire, it can be assumed that the elastic wave speed will increase with increasing depth into the concrete, until an undamaged layer has been

reached. When a pulse is sent, the path of the wave that arrives first will be the one that strikes the best compromise between the shorter travel distance of the surface layers, and the fast travel speeds of the deeper layers, as shown in Figure 4.20. When distance reaches a certain point, the velocity will converge on the asymptotic velocity value, which is the velocity of the pulses through undamaged concrete. The X-T plot shown in Figure 4.20 have also been used to analyze data in other studies [85].

An interpretation of the X-T graph produced indicated that the damage thickness was approximately 100 mm. Temperature measurements during heating of the panel indicated that the concrete at 100 mm depth reached a maximum temperature of 250°C, which is very close to the temperature at which concrete begins losing significant compressive strength (300°C) [11].

**Figure 4.20: Schematic showing the fastest path for the pulse, along with an X-T curve where X is the distance between the transducers, and T is the time of transmission (Reprinted from Fire Safety Journal, Vol. 42, No. 6-7, New NDT techniques for the assessment of fire-damaged concrete structures, 2007, with permission from Elsevier [71])**

#### **4.2.6. Other Non-Destructive Testing Methods**

Several other non-destructive methods have been implemented in post-fire inspections of structures; however, these methods require a specialist to perform. Some of these methods were used for the structural inspections after the famous 1999 Mont Blanc tunnel fire. A summary of these specialty non-destructive testing methods will be provided here.

The seismic refraction analysis method was used after the Mont Blanc tunnel fire to delineate damaged zones of the concrete. Similar to the ultrasonic pulse velocity (UPV) method, this technique uses the propagation of elastic waves to determine the subsurface conditions of the concrete. Unlike the UPV method, which generates the elastic waves by transducers, waves are generated by a steel ball hit against a steel anvil glued to the concrete surface. The refraction patterns of the elastic waves can be measured by a seismograph, and subsequently used to analyze the condition of the concrete [85].

Another method used after the Mont Blanc tunnel fire is the ground-penetrating radar technique. For this technique, the time of travel for electromagnetic impulses through concrete is measured. Since the waves are reflected at interfaces of materials with different properties, such as the layers of varying damage in concrete exposed to fire, the depth of damaged concrete can be determined [85].

Other techniques which have been proposed in academic studies include crack pattern mapping, crack density measurements, drilling resistance tests [64].

### **4.3. Laboratory Testing Techniques**

In some cases, when visual inspections and non-destructive testing techniques are not sufficient, or a greater deal of confidence in the post-fire inspection is desired, laboratory testing methods are an excellent, proven option.

#### **4.3.1. Petrographic Analysis**

Petrographic analysis is a widely used technique for the assessment of fire-damaged concrete structures. Standard procedures for performing petrographic analysis of concrete are described in ASTM C856 [86]. To perform a petrographic analysis, cores of concrete must be extracted from the structure and sent to a laboratory with a qualified petrographer. The cores are first inspected with a low-power microscope to observe any changes in obvious changes in color or cracking. Afterwards, the cores are sliced into thin sections, which are then analyzed with a high-power microscope. Analysis of the cores can allow temperature contours to be drawn based on the chemical and physical reactions which occurred during heating, such as the transition from  $\alpha$ -quartz to  $\beta$ -quartz at 600°C. As such, while a petrographic examination will not directly measure mechanical properties, it can be used to estimate the depth of damage in concrete exposed to fire [87].

**Figure 4.21: A photomicrograph of a concrete sample showing red discoloration of a flint aggregate particle near the outer surface of the concrete, indicating heating from 300-600°C (Reprinted from Materials Characterization, Vol. 60, J. Ingham, Application of Petrographic Examination Techniques to the Assessment of Fire-Damaged Concrete and Masonry Structures, Pg. 700-709, Copyright 2009, with permission from Elsevier) [87]**

For example, one study demonstrated the use of petrographic analysis for the post-fire assessment of concrete in a ten-story reinforced concrete building which was damaged in a fire. Over a hundred concrete cores were taken from the structure and analyzed to determine both the extent of damage as well as the likely depth of damage in the concrete. Figure 4.21 shows an example of red discoloration of flint aggregates in the concrete, a phenomenon which can also sometimes be observed macroscopically in the concrete. This change in color indicates heating between 300-600°C. Figure 4.22 shows discoloration of the cement matrix when exposed to cross-polarized light, which indicates heating up to 500°C. Overall, from this analysis it was determined that while a large portion of the structure suffered fire damage, most areas of concrete did not experience temperatures greater than 600°C, and repair of the structure was recommended rather than demolition. Residual strength tests on reinforcing steel

samples taken from the structure confirmed that minimal loss of strength in the steel had occurred.

**Figure 4.22: A photomicrograph of a concrete sample with a yellow-beige color in the cement matrix, indicating heating up to 500°C (Reprinted from Materials Characterization, Vol. 60, J. Ingham, Application of Petrographic Examination Techniques to the Assessment of Fire-Damaged Concrete and Masonry Structures, Pg. 700-709, Copyright 2009, with permission from Elsevier) [87]**

#### **4.3.2. Chemical Analysis**

Another well-known technique for assessing fire-damaged concrete is chemical analysis. For this technique, concrete must be chiseled along the damaged surface, producing samples for each “layer” of the concrete. The samples are then heated, evaporating the water, which allows the amount of combined water in the samples to be determined. Since the degree of dehydration of the cement paste is related to the temperature experienced, the temperature gradient in the concrete can be estimated [12].

### **4.3.3. Other Laboratory Methods**

Other methods, which mainly used in academic research, include X-ray diffraction analysis, thermoluminescence tests, thermo-gravimetric analysis (TGA), differential thermal analysis (DTA), and derivative thermo-gravimetric analysis (TMA) [8], [12], [64].

### **4.4. Summary of Existing Inspection Methods for Fire-Damaged Structures**

Three main methods of inspection are available: visual, non-destructive, and laboratory methods. Visual methods are generally quickest, but least accurate. Laboratory methods are generally the most-time consuming, but the most accurate. Non-destructive techniques are of medium quickness and accuracy.

Visual methods can be used to gain a general sense of the extent of damage and to identify the bounds of damage. Several methods have been developed largely based on previous experiences with real fires in building structures. Damage classification charts can be used to rate the condition of certain areas of a structure, either based on the general visual condition, or the condition of more specific items such as the concrete. In addition, the visual condition of other non-structural materials, such as aluminum and PVC, can be used to estimate the temperatures reached in various parts of the structure, which can help determine if and where further non-destructive or laboratory tests will be needed.

A variety of potential non-destructive testing methods are available for assessing the post-fire condition of concrete, and some methods can even provide estimates of residual strength loss. The two most popular methods at present, the rebound hammer and

ultrasonic pulse velocity, can both delineate areas of damaged concrete, but are generally considered unsuitable for estimating residual strength. The pullout method and penetration resistance method both have excellent predictive capabilities for the strength of non-fire-damaged concrete; however, limited studies are available on their ability to predict strength loss in fire-damaged concrete. Additional studies should be conducted on these methods with respect to fire damaged concrete to see if they may be suitable. The penetration resistance is particularly promising, given that it can be conducted much faster than the pullout test, which takes about half an hour per test.

Lastly, the most common laboratory testing method used is petrographic analysis. This method can determine the depth of damage in concrete by observing microscopic changes in color and structure. While it is very accurate, these kinds of tests are expensive and time-consuming, and can only give the condition of the concrete at very specific points in the structure. Furthermore, a specialist is required to perform these types of tests.

Further research should focus on developing and improving visual and non-destructive testing techniques, as these methods have the potential to be quicker and more flexible than existing laboratory methods.

## CHAPTER 5

### REPAIR TECHNIQUES FOR FIRE-DAMAGED CONCRETE STRUCTURES

#### 5.1. Overview

After the fire event and initial inspection, it must be determined if repairs to the affected structure are necessary. Due to concrete's excellent thermal insulation properties, even heavily damaged structures can usually be repaired [12]. Repair actions can range from aesthetic restoration to the replacement of damaged members. Several reports provide recommendations for the design and implementation of repairs in fire-damaged concrete structures [8], [12], [65]. In general, the following steps should be taken to repair a structure after a fire event:

1. Perform a detailed post-fire inspection and determine the extent and magnitude of damage
2. Design repairs (if necessary)
3. Implement repairs (if necessary)

This section details the inspection process necessary to decide on the appropriate repairs and presents common repair methods and their implementation.

#### 5.2. Evaluation/Classification of Damage

Although a quicker inspection will likely be performed immediately after a fire event to determine whether a structure poses any immediate safety hazards, a more detailed inspection should follow at a later time to decide what repairs, if any, are needed. The purpose of the detailed inspection is to determine the level of damage at various

locations of the structure affected by fire, which will inform the repair actions needed for each area. The International Federation for Structural Concrete (*fib*) recommends the following steps for a detailed post-fire inspection [8]:

1. Collect data about the fire event and its effect on the structure
2. Examine the damage due to the fire and the extinguishing efforts
3. Classify the severity of the damage
4. Identify and select repair methods

Data collected about the fire event should include the time history of the fire and the location history of the fire. This could be ascertained from eyewitnesses such as first responders, or from surveillance footage. Another option is to examine the visual condition of structural and non-structural materials such as steel or plastics in various areas of the structure. Materials which have melted, charred, or suffered other effects from heat exposure can indicate maximum temperature reached during the fire at certain locations in the structure. This technique is described in greater detail in Section 4.1.1. The classification of damage is usually performed by splitting up the affected area into zones and classifying the damage level in each zone using predetermined damage “classes.” *fib* suggests using the visual classification chart from Table A6.3 in *Appraisal of Existing Structures* to classify damage levels, but classifications could also be based on the results of non-destructive tests or laboratory analysis of samples from the structure. The most common non-destructive testing methods for post-fire inspections are the rebound hammer and ultrasonic pulse velocity methods, as both can be quickly implemented over large areas. Non-destructive methods, however, are highly variable and often cannot

directly measure residual mechanical properties of materials, such as the residual strength of concrete. If a more precise characterization of the condition of these materials is desired, samples of concrete and steel suspected to be damaged may be sent to a laboratory for more precise analysis such as petrographic examination, compression tests, or tensile tests. After the damage classification has been performed, the appropriate repair actions need to be determined for each location, which is described in the next section

### **5.3. Common Repair Techniques**

Once the damage has been thoroughly assessed, appropriate repairs should be designed and implemented. Common repair methods include [8], [12]:

- Cleaning and aesthetic restoration
- Repair of concrete surfaces with mortar or resins
- Repair of concrete members and restoration of the original shape with sprayed concrete or flowable concrete
- Strengthening of members by addition of reinforcing steel or fiber-reinforced polymers (FRP)
- Complete replacement of selected elements

When designing a repair for a member, the cost of repair versus the cost of replacement should first be considered. Though fire-damaged elements can often be repaired, certain elements, such as those with prestressing steel, may be too difficult or too expensive to repair. In general, the objectives of a repair are to restore the load-bearing capacity and fire resistance of the member, restore the original shape of the member, and protect the reinforcement from corrosion over the remainder of its lifetime

[12]. Example calculations for assessing the strength of fire-damaged and repaired members can be found in Appendix B of *Assessment, design, and repair of fire-damaged structures* [65].

For reinforced concrete, the main steps in the repair process are to remove damaged concrete, to replace the concrete to restore the member to its original size, and to replace or supplement weakened reinforcement. It is generally recommended that all concrete which experienced temperatures above 300°C be removed. The 300°C isotherm in the concrete can sometimes be determined by observing the depth of pink discoloration in some concretes or can be determined by laboratory analysis on core samples collected from the structure [8], [65]. In some cases, such as when buckling of reinforcement has occurred (Figure 5.1), additional concrete may need to be removed from behind the reinforcement to ensure that the concrete replacement material can fully surround the reinforcement. Damaged concrete can be removed by hammer and chisel, by powered breaking tools, or by high-pressure water jets. Removal of concrete with a hammer and chisel is only practical when the damage area is small. If extensive areas of concrete have been damaged, powered breaking tools or high-pressure water jets are more suitable [65].

**Figure 5.1: Buckled reinforcing bars in the underside of a slab [used with permission from The Concrete Society] [65]**

Sprayed concrete (e.g., shotcrete) or flowable concrete are both popular options for replacing concrete. Some of the advantages of sprayed concrete over flowable concrete are that no formwork is needed, and it can be much easier to apply in many circumstances. On the other hand, flowable concrete may be a better option where large amounts of concrete need to be replaced, or the reinforcement is very dense, which could result in air voids if sprayable concrete were used. The advantages and disadvantages of sprayed concrete compared flowable concrete for concrete replacement are summarized in Figure 5.2 [65].

<b>Advantages</b>	<b>Disadvantages</b>
No formwork required Rapid placing Dense, homogeneous, high quality concrete Reduction in access requirements Good bond to substrate and between layers Reduced thermal stresses when placed in several layers Suitable for use of soffits where it may be difficult to get concrete to flow into a shutter	Specialists required for design and application Variable concrete quality (mainly with dry process) High material costs (pre-bagged materials, wastage) Poor encasement behind dense concentrations of reinforcement

**Figure 5.2: Pros and cons of sprayed concrete for replacing fire-damaged concrete [used with permission from The Concrete Society] [65]**

For more minor damage, concrete can be replaced with mortar applied with a trowel. Unlike for sprayed or flowable concrete, bonding aids must be applied to the substrate before application of the mortar to create a sufficient bond between the existing concrete and the mortar. Resins have also been used to repair lightly damaged areas of concrete, though the performance of these materials under heat exposure is not well known [8], [65].

After the replacement of the concrete with sprayable concrete, flowable concrete, mortars, or resins, the bond between the substrate and repair material should be assessed by a pull-off test [8]. The pull-off test is performed attaching a circular disc to the repair

material with an adhesive such as epoxy and pulling on the disc until failure. A typical pull-out test setup is shown in Figure 5.3.

**Figure 5.3: Pull-out test setup [Reprinted, with permission, from ASTM C1583-20, Standard Test Method for Tensile Strength of Concrete Surfaces and the Bond Strength or Tensile Strength of Concrete Repair and Overlay Materials by Direct Tension (Pull-off Method), copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428. A copy of the complete standard may be obtained from ASTM International, [www.astm.org](http://www.astm.org)] [88]**

As shown in Figure 5.4, 4 different failure modes may occur during the pull-off test. As a result, only when failure between the repair material and substrate occurs should the pull-off load value be taken as the bond strength. Further details for application of the pull-off test for assessing bond between repair materials and existing concrete are described in ASTM C1583-20. To ensure a sufficient bond, *fib* recommends a mean value of  $1.5 \text{ N/mm}^2$  for a series of pull-off tests, and minimum value of  $1.0 \text{ N/mm}^2$  for any one test in the series.

In addition to concrete, reinforcing steel may also need to be replaced or supplemented after a fire if the residual strength of the steel has decreased. The residual strength of steel can be determined via tensile tests on specimens collected from the structure, or by in-situ hardness tests. Reinforcement can be added by lapping with the

existing reinforcement, but it must be ensured that the required anchorage length is provided. Sleeve and wedge couplers can be used to attach bars in compression bars, while tension couplers can be used to attach bars in tension [8].

**Figure 5.4: Possible failure modes during the pull-off test [Reprinted, with permission, from ASTM C1583-20, Standard Test Method for Tensile Strength of Concrete Surfaces and the Bond Strength or Tensile Strength of Concrete Repair and Overlay Materials by Direct Tension (Pull-off Method), copyright ASTM International, 100 Barr Harbor Drive, West Conshohocken, PA 19428. A copy of the complete standard may be obtained from ASTM International, [www.astm.org](http://www.astm.org)] [88]**

Another repair option for damaged members are fiber composite materials (FRPs), specifically carbon fiber reinforced polymers (CFRPs) and glass fiber reinforced polymers (GFRPs). FRP materials have a high tensile strength, making them suitable for areas such as the positive flexure zones of beams and slabs. The FRP material, such as FRP plates, are bonded to the damaged member with an adhesive to bolster the strength of the member. These types of repair materials must be applied to sound, undamaged concrete to ensure a good bond to the substrate (the existing concrete) [65], [89].

## **5.4. Case Studies in Repair of Fire-Damaged Structures**

### **5.4.1. Overview**

In this section, two case studies of repairs of fire-damaged structures and members will be presented, which showcase some of the repair methods discussed in the previous section. The first case study details the repair process of the Tauern Tunnel after a 1999 fire, and the second describes the repair of a fire-damaged prestressed roof girder which was repaired and subjected to load testing to assess its residual strength after repair. Additional case studies can be found in Appendix A of *Assessment, Design, and Repair of Fire-Damaged Concrete Structures* [65].

### **5.4.2. Tauern Tunnel, Austria**

A 2001 paper by Leitner [90] reviewed the repair of the Tauern Tunnel after a 1999 fire. The Tauern Tunnel, located Salzburg, Austria, experienced a severe fire event on May 29, 1999 after a truck crashed into stopped vehicles and caught fire. Damage to the tunnel was extensive, and remedial work took three months to complete and cost about \$6.5 million (US).

The cross-section of the tunnel originally consisted of an outer lining of shotcrete and bolts, and an inner lining of unreinforced concrete. The tunnel also featured a transverse ventilation system separated from the roadway by a 150 mm thick cast-in-place reinforced concrete ceiling, which was partially supported by ceiling suspenders and partially supported by the sidewall. A cross-section of the tunnel is shown in Figure 5.5.

**Figure 5.5: Cross-section of the Tauern Tunnel before the 1999 fire (Reprinted from *Tunnelling and Underground Space Technology*, Vol. 16, No. 3, *The fire catastrophe in the Tauern Tunnel: experience and conclusions for the Austrian guidelines, 2001*, with permission from Elsevier [90])**

The fire damage included extensive and deep (up to 400 mm) spalling of the sidewall, spalling/cracking of the ceiling concrete, damage to the ceiling reinforcement, and damage to the pavement and electrical housings.

The sidewall was repaired by removing the damaged concrete, adding rebar, and applying shotcrete. First, 50 mm of the sidewall concrete was removed with high-pressure water jets to remove damaged concrete and create a suitable surface for applying the shotcrete. Next, holes were drilled into the existing concrete and rebar were inserted into the holes to help attach the existing concrete to the soon to be applied shotcrete layer (Figure 5.6). Wire mesh was also installed along the sidewall. After the rebar and wire mesh were installed, shotcrete was applied to the sidewall. A cross-section presenting the details of the repairs to the sidewall are shown in Figure 5.7.

**Figure 5.6: Rebar to connect existing concrete to shotcrete layer (Reprinted from Tunnelling and Underground Space Technology, Vol. 16, No. 3, The fire catastrophe in the Tauern Tunnel: experience and conclusions for the Austrian guidelines, 2001, with permission from Elsevier [90])**

**Figure 5.7: Schematic of repairs for the sidewall (Reprinted from Tunnelling and Underground Space Technology, Vol. 16, No. 3, The fire catastrophe in the Tauern Tunnel: experience and conclusions for the Austrian guidelines, 2001, with permission from Elsevier [90])**

Due to the extensive damage to the ceiling, it was decided to replace 300 meters of the damaged cast-in-place ceiling with precast concrete panels, as shown in Figure 5.8. Furthermore, a rectangular concrete strip was added to the sidewall to support the ceiling. A schematic of the repairs is shown in Figure 5.9.

**Figure 5.8: Installation of precast ceiling panels (Reprinted from Tunnelling and Underground Space Technology, Vol. 16, No. 3, The fire catastrophe in the Tauern Tunnel: experience and conclusions for the Austrian guidelines, 2001, with permission from Elsevier [90])**

**Figure 5.9: Repairs of sidewall and ceiling (Reprinted from Tunnelling and Underground Space Technology, Vol. 16, No. 3, The fire catastrophe in the Tauern Tunnel: experience and conclusions for the Austrian guidelines, 2001, with permission from Elsevier [90])**

### 5.4.3. Full-Scale Fire Test of an Industrial Precast Hall

A case study of a repair of a fire-damaged pretensioned roof girder was presented in *Fire Design of Concrete Structures – Structural Behavior and Assessment* [8]. In 1974, an industrial warehouse made with precast elements was constructed for use in a full-scale fire test. The warehouse was 12 m x 18 m in plan and consisted of three portal frames. Wood was used as fuel, and the fire exposure of the building during the test was roughly equivalent to that of the ISO 834 fire curve.

After the fire test, one of the pretensioned roof girders was removed from the structure so that it could be repaired and subjected to a load test. The 18 m long roof girder had twelve 7-wire prestressing strands in the bottom flange, and two strands in the top flange, and the depth of the section varied along its span. As shown in Figure 5.10, the girder was badly damaged after the test. Extensive spalling exposed some of the shear stirrups and longitudinal rebar, and the concrete cover for the prestressing strands was missing in some areas.

To prepare the girder for the application of shotcrete, the surface of girder was cleaned, and damaged concrete was removed with a pneumatic hammer and a sandblaster. Shotcrete was then used to replace the damaged and spalled concrete, as shown in Figure 5.11. The midspan of the girder after the repairs is shown in Figure 5.12.

After the repair, the beam was subjected to a load test to assess its residual capacity. Four-point loads were applied to the beam (Figure 5.13) and gradually increased until failure. The beam was able to carry 2.45 times the design service load of the beam before failure; moreover, it was found to have an ultimate capacity of 1629

kN-m compared to the expected capacity of 1616 kN-m. Overall, the test showed that the fire-damaged beam could be satisfactorily restored using common repair techniques.

**Figure 5.10: Cross-section of pretensioned roof girder (left), pretensioned roof girder after the fire test (right) (Reproduced from fib Bulletin 46, page 129 - “Pretensioned roof girder – cross section and view after fire test,” with permission from the International Federation for Structural Concrete (fib) [8])**

**Figure 5.13: Load testing setup for the girder (Reproduced from fib Bulletin 46, page 131 - “Test setup” by Taerwe et al. 2006, with permission from the International Federation for Structural Concrete (fib) [8])**

## **5.5 Summary of Repair Methods for Fire-Damaged Concrete Structures**

Fire-damaged concrete structures and members can usually be repaired rather than replaced. For reinforced concrete, the main steps in the repair process are to remove damaged concrete, to replace the concrete to restore the member to its original size, and to replace or supplement weakened reinforcement. Concrete material is usually replaced by sprayable concrete (e.g., shotcrete) or flowable concrete when larger volumes of concrete must be replaced. Other innovative methods such as the repair of fire-damaged members with fiber-reinforced polymers (FRP) are becoming more common as well.

As proof of these ideas, the Tauern tunnel in Austria was successfully repaired after a tunnel fire event that resulted in severe damage. These repairs included replacement of damaged concrete and roadway items, and replacement of the damaged ceiling plenum structure.

## CHAPTER 6

# SURVEY OF THE POST-FIRE INSPECTION PRACTICES OF DEPARTMENTS OF TRANSPORTATION AND TRANSIT AUTHORITIES ACROSS THE US

### 6.1 Overview

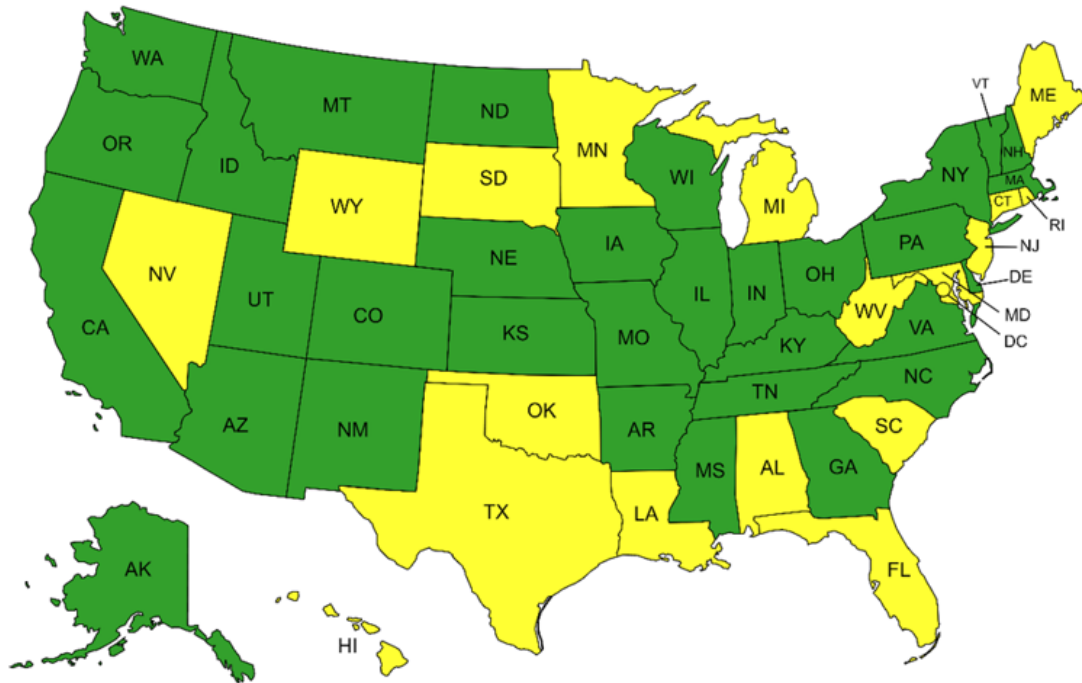

In addition to the review of existing literature on fire and structures presented in the previous sections, a survey of post-fire inspection protocols, standard practices after a fire, and fire research efforts of other state DOTs and transportation organizations was conducted. The purpose of this survey was to evaluate the common practices for post-fire inspections of tunnels among organizations across the United States, to gain an understanding of the concerns that other organizations have regarding fire, and to gather additional literature and knowledge on the subject. To conduct this survey, engineering personnel in these organizations were contacted via email and asked if they would be willing to discuss their experience and knowledge of post-fire inspections with the UMass research team. This section describes the inquiry process, provides brief summaries of each discussion with officials at these organizations, and presents the key findings from correspondence and discussions with these organizations.

### 6.2. Reaching Out to State DOTs and Transit Authorities

In total, all 50 state DOTs and 4 other transportation agencies were contacted via email (some states have other agencies aside from the state DOT which own tunnels, which is why they were included in the survey). Of those contacted, 32 state DOTs and 3 other transportation agencies replied, as shown in the map in Figure 6.1. Further details of the responses to the initial inquiry are presented in Figure 6.2. Though some

organizations stated that they owned no or few tunnels, or had minimal concerns about fire, several of these replies led to video conferences and email discussions between members of the organizations and the UMass team. To facilitate the discussions with the members of these organizations, a questionnaire was developed, and is included in Appendix A. The questions covered a wide range of subjects including organizations' standard post-fire inspection practices, personal accounts of post-fire inspection by organization members, and research efforts related to post-fire inspection or assessment of structures. During video conferences, these questions were typically asked one-by-one, which helped field consistent responses. Email discussions were less structured, but the questionnaire was used as a guide. The next section will show summaries of the most important points from each email correspondence and video conference.

**Figure 6.2: Summary of Responses to the Inquiry**

### **6.3. Summaries of Email Correspondences and Video Conferences with State DOTs and Transit Authorities**

Some organizations were willing to discuss their experience with post-fire inspections in more detail via video conferences. These video conferences were held in May-June 2020, and were based around the questionnaire included in Appendix A. In some cases, organizations were interested in participating in the survey, but video conferences were not practical or were deemed unnecessary; therefore, some discussions were conducted over email. This section will summarize the key discussion points and insights from the video conferences and email correspondences with the organizations.

### **6.3.1. Summaries of Email Correspondences**

**Arkansas DOT** (correspondence with Chad Adams, P.E., District Four Engineer)

- Arkansas DOT only owns one tunnel
- The tunnel has not experienced any fires
- Their post-fire protocol is the same inspection procedure as for their routine inspections, based on the FHWA National Tunnel Inspection Standards (NTIS)

**Kentucky DOT** (correspondence with Joshua Rogers, P.E., TE Branch Manager)

- Kentucky DOT owns 8 tunnels, one of which is complex with ventilation
- Have had few fires in their tunnels
- In the case of a fire, the post-fire inspection would be an element-level inspection in accordance with following documents: FHWA Specifications for the National Tunnel Inventory (SNTI), FHWA Tunnel Operations, Inspection, and Evaluation Manual (TOMIE), and an inspection manual specifically for Kentucky's tunnels

**Missouri DOT** (correspondence with David Koenig, Bridge Management Engineer)

- Missouri DOT only operates one tunnel
- David did not recall any recent fire incidents

**New York DOT** (correspondence with James Flynn, P.E., Deputy Chief Engineer of Structures)

- New York DOT only owns one tunnel
- The tunnel does not have any history of fires

**Ohio DOT** (correspondence with Brandon Collet, P.E., Structures Planning Engineer)

- Ohio DOT owns 1 tunnel, which is a cast-in-place cut and cover tunnel
- Brandon did not recall any significant fire events in the tunnel

**Port Authority of New York and New Jersey** (correspondence with Steven Vecchione, P.E., Manager – Structural Integrity)

- The Port Authority owns 4 tunnels, which are all complex with ventilation systems
- Frequently experience tunnel fires, but none in the last 13 years have resulted in structural damage
- Port Authority employees conduct post-fire inspections

**Tennessee DOT** (correspondence with Thomas Quinn, P.E., Assistant Director of Structures Division)

- Tennessee DOT owns 9 tunnels. 1 is bare rock cut, 2 are complex with ventilation, and 6 are concrete lined bored tunnels
- No fire incidents have occurred in the tunnels
- In the case of a fire, the bridge inspection protocol would be used, which entails visual inspection, rock hammer soundings, and the extraction and analysis of cores, if needed
- Tennessee DOT employees generally conduct the inspections, but private consultants are used in some cases
- The inspection process is not standardized; instead, it is up to the discretion of the inspector

### **6.3.2. Summaries of Video Conferences**

#### **Alaska DOT** (discussion with Gordon Burton, Facilities Manager)

- Alaska DOT has 1 tunnel, which is a bored and rock-lined tunnel
- Have experienced 2 locomotive fires, neither of which resulted in damage
- In the case of a fire, the post-fire inspection protocol for bridges would be used for the tunnel
- Use private consultants for detailed inspections after the fire
- Main structural concerns for the tunnel after a fire are the condition of the rock liner and the geotechnical mesh over the rock
- Inspection procedures are based on FHWA's TOMIE

#### **Caltrans** (discussion with Vassil Simeonov, Ph.D., Supervising Bridge Engineer)

- Most notable tunnel fire event was the 1982 Caldecott Tunnel fire
- No specific post-fire protocol is used, but the inspection would consist of looking for discolored concrete and testing the concrete with a rock hammer
- Caltrans does not use private consultants for inspections, only state inspectors
- Major structural concerns post-fire are plenum structures (hung ceiling slabs), and any equipment suspended above the traffic
- Caltrans' Materials Engineering and Testing Services (METS) lab conducts all research for the organization

#### **Colorado DOT** (discussion with Tyler Weldon, P.E., State Maintenance Engineer)

- Colorado tunnels have a wide variety of constructions: cast-in-place tunnels, rock and shotcrete-lined tunnels, and cut and cover tunnels
- Two recent fires have occurred: a 2019 car fire, and a 1998 RV fire, neither of which resulted in structural damage
- For post-fire inspections, state inspectors follow the FHWA National Tunnel Inspections Standards (NTIS). Private consultants are also on-call to perform an inspection after a fire event
- Biggest structural concern post-fire are the ceiling panels, and any equipment suspended above traffic that could fall
- Recommended looking at the NCHRP report on highway bridge fire hazard assessment

**FHWA** (discussion with Stephen Bartha, P.E., Structural Engineer)

- Stephen used to work for MassDOT, and has conducted several post-fire inspections for bridges
- The post-fire inspection consisted of general inspection of concrete condition (spalling, cracking, etc.), and identifying any areas of pink/red concrete, which can indicate fire damage
- Visual guides would be very helpful for an inspector during post-fire inspections

**Illinois DOT** (discussion with Sarah Wilson, P.E., Bridge Maintenance Engineer)

- Illinois has 3 tunnels, 2 of which are exit/entrance ramps for another roadway
- Illinois has not experienced any tunnel fires, but have experienced bridge fires

- No written protocols for the post-fire inspection are used. Visual inspection is focused on locating any possible distortion or warping in the steel members (Illinois' bridges are mostly constructed of steel)
- Main concerns after a fire are the condition of steel beams and any loose concrete which could injure motorists

**Massachusetts DOT** (discussion with John Czach, Tunnel Maintenance Engineer, and Joe Rigney, Former Tunnel Engineer)

- Several minor/intermediate fires have occurred in the last decade
- None of the fires resulted in any structural concerns
- The prestressed concrete plenum panels were singled out as the biggest concern if a major fire were to occur

**Massachusetts Bay Transportation Authority** (discussion with Joe Guyder, P.E., Director of Civil Infrastructure, and Brian Mellen, P.E., Manager of Civil Engineering)

- Several minor debris fires have occurred, but no major fires
- MBTA has a tunnel inspection guide, but it does not contain any information for post-fire inspections
- Would use the post-fire inspection information in FWHA's TOMIE if a major fire occurred

**North Carolina DOT** (discussion with Gichuru Muchane, P.E., Assistant State Structures Engineer)

- North Carolina has not experienced any tunnel fires
- Bridge inspectors would conduct a post-fire inspection. No specific protocol for tunnel fires is in place, but inspectors are trained in accordance with the NBIS bridge inspection protocols
- Most significant concern after a fire would be the condition of overhead lighting
- North Carolina DOT conducted some research to determine the residual capacity of steel girders exposed to fire

**Nebraska DOT** (discussion with Fouad Jaber, P.E., Assistant State Bridge Engineer)

- Nebraska does not have any tunnels
- Have had two recent major bridge fires
- The post-fire inspection of the bridges consisted of petrographic analysis of cores, and LIDAR to determine straightness of girders

**Oregon DOT** (discussion with Albert Nako, P.E., Seismic Standards Engineer)

- Oregon has few tunnels, all of which are less than 1100' in length
- Albert did not recall any bridge or tunnel fires in the last 17 years

**Pennsylvania DOT** (discussion with Lou Ruzzi, P.E., District Bridge Engineer, and Ben DeVore, P.E., Tunnel Maintenance Engineer)

- Frequently experience car fires in their tunnels. One fire in the early 2000s was quite large, and resulted in damage to wall tiles

- No specific post-fire inspection protocol exists; rather, the typical tunnel inspection protocol is followed
- Major structural concerns after a fire include suspended ceiling panels and portals of the tunnel
- Pennsylvania conducted research with Lehigh University to develop a visual inspection protocol for their bridges

**Virginia DOT** (discussion with Prasad Nallapaneni, P.E., Assistant State Structure and Bridge Engineer)

- A tunnel fire in 2016 resulted in damage to the tunnel tiling
- No post-fire inspection protocol is followed, inspection procedure is at the discretion of the inspector

#### **6.4. Findings of Survey**

This section presents the results of the survey of post-fire inspection practices of state DOTs and transit organizations. In total, of the 35 organizations which responded to the initial inquiry, 19 organizations took part in the survey via video conferences or email correspondence (Figure 6.2). Note that the FHWA does not own tunnels, and the discussion with FHWA was focused on understanding the federal guidelines for inspections. For reference, per the FHWA National Tunnel Inventory data as of June 2020, the number of tunnels owned by each DOT which participated in the survey is shown:

- California (Caltrans) – 62 state-owned tunnels
- Massachusetts – 45 state-owned tunnels
- Colorado DOT – 20 state-owned tunnels
- Virginia DOT – 11 state-owned tunnels
- Oregon DOT – 9 state-owned tunnels
- Pennsylvania DOT – 8 state-owned tunnels
- Tennessee DOT – 7 state-owned tunnels
- Kentucky DOT – 4 state-owned tunnels
- North Carolina DOT – 4 state-owned tunnels
- Illinois DOT – 3 state-owned tunnels
- Alaska DOT – 2 state-owned tunnels
- New York DOT – 1 state-owned tunnel
- Ohio DOT – 1 state-owned tunnel
- Arkansas DOT – 1 state-owned tunnel
- Missouri DOT – 0 state-owned tunnels
- Nebraska DOT – 0 state-owned tunnels

Of the 12 states with the most state-owned tunnels in the United States, 7 participated in the survey. Data about the number of tunnels owned by the MBTA and the Port Authority of New York and New Jersey was not readily available. Missouri DOT does not own any tunnels but does have jurisdiction of the maintenance of a tunnel in the state. Nebraska also does not have any tunnels, and as such the discussion with them focused on their experiences with bridge fires.

The survey was focused on identifying each organization's experiences with tunnel fires and their procedures for post-fire inspections. A summary of the organizations' responses to these questions is shown in Table 6.1. A wide variety of responses were received. For instance, of the 16 organizations with tunnels, 9 reported having experienced tunnel fires. Most of the reported fires were small and did not cause significant damage. It is also worth noting that most of the organizations that reported experiences with tunnel fires were those that owned the most tunnels.

Of the 16 organizations, 4 reported using a written document for their post-fire tunnel inspection procedures. All 4 of these organizations stated that they conduct their post-fire tunnel inspections in accordance with guidelines specified under the *National Tunnel Inspection Standards (NTIS)*. Furthermore, Kentucky DOT stated that they referred to the FHWA document *Tunnel Operations, Maintenance, Inspection, and Evaluation (TOMIE) Manual* for their post-fire inspections. *TOMIE* contains a brief section on post-fire inspections, which explains how to assess damage based in visual techniques including examining the condition of debris material (melting, charring, etc.), and identifying color changes in concrete that occur due to heat. None of the organizations surveyed indicated that they had any sort of custom post-fire protocol for their specific tunnels. The other organizations that did not use written protocols stated that inspection would be performed at the discretion of the inspectors. The organizations typically said that evaluations consisted of visual inspection and inspection of concrete with a rock hammer. Only a few reported experiences with non-destructive or laboratory testing, which was usually conducted by private consultants.

Of the organizations that did not use a post-fire protocol for their tunnels, several reported that, if a major tunnel fire were to occur, they would use their protocols for assessing the condition of bridges after fire to assess their tunnels. Moreover, many organizations stated that they would call on their bridge inspectors to conduct a post-fire inspection of a tunnel. This is a significant point, as many states which did not report having tunnel fires reported numerous bridge fire incidents. The Colorado DOT noted that the National Cooperative Highway Research Program (NCHRP) 2013 Highway Bridge Fire Hazard Assessment report contains information on the effect of fire on structural materials and contains information on post-fire assessment of bridges.

Most organizations reported using private consultants for the post-fire evaluations of their tunnels or bridges, including Stantec, Mott MacDonald, and Hardesty & Hanover. In most cases, consultants were called in after an initial inspection by personnel from the DOT or transportation agency to conduct a more thorough investigation. Some of these organizations stated that they have private consultants on-call in case of the urgent need for a post-fire inspection.

Another question posed to several organizations assessed their main concerns for their tunnels after a fire, noting that tunnel constructions can vary widely. The organizations with complex tunnels all reported being concerned about the residual strength of ceiling/plenum panels, and about the condition any overhead fixtures such as lighting or fans which could fall into traffic. Furthermore, many organizations expressed concerns about loose concrete falling onto the roadway, either from the ceiling panels or the liner.

**Table 6.1: Summary of surveyed organizations’ experiences with tunnel fires and their post-fire inspection procedures**

<b>Organization</b>	<b>Has experienced tunnel fires?</b>	<b>Has a written post-fire protocol for tunnels?</b>	<b>Uses private consultants for post-fire inspection of tunnels or bridges?</b>
<b>Alaska DOT</b>	Yes	No	Yes
<b>Arkansas DOT</b>	No	Yes	Unknown
<b>Caltrans</b>	Yes	No	No
<b>Colorado DOT</b>	Yes	Yes	Yes
<b>Illinois DOT</b>	No	No	Yes
<b>Kentucky DOT</b>	No	Yes	Unknown
<b>Massachusetts DOT</b>	Yes	No	No
<b>MBTA</b>	Yes	No	No
<b>Missouri DOT</b>	No tunnels	Unknown	Unknown
<b>New York DOT</b>	No	Unknown	Unknown
<b>North Carolina DOT</b>	No	No	Yes
<b>Nebraska DOT</b>	No tunnels	No	No
<b>Ohio DOT</b>	No	Unknown	Unknown
<b>Oregon DOT</b>	No	Unknown	Unknown
<b>Pennsylvania DOT</b>	Yes	No	Yes
<b>Port Authority of NY and NJ</b>	Yes	Yes	Unknown
<b>Tennessee DOT</b>	No	No	Yes
<b>Virginia DOT</b>	Yes	No	Yes

Of the 16 organizations with tunnels, only Pennsylvania DOT reported conducting research related to the post-fire fire condition or evaluation of tunnels. A couple of states reported that they had conducted research on the post-fire condition of bridges.

## **6.5. Summary**

Most surveyed organizations do not have written protocol for post-fire tunnel inspections. Those who do use the guidelines within FHWA’s *Tunnel Operations, Maintenance, Inspection, and Evaluation (TOMIE) Manual*. However, while this manual does contain a section on post-fire inspections, very limited information is provided. This

section should be expanded to include residual strength curves for concrete and steel, and potential inspection methods, such as those presented in Chapter 4. Many organizations reported that, in the event of tunnel fire, they would employ the same inspection principles used for post-fire evaluations of their bridges to inspect the tunnel.

Given the commonalities of the constructions of many tunnels across the US, efforts to consolidate and develop knowledge of the post-fire inspection of tunnels specifically would greatly benefit many transportation agencies across the US. The survey revealed a lack of research efforts on the post-fire condition or assessment of tunnels, in spite of many organizations expressing interest in this type of research.

## CHAPTER 7

### EXPERIMENTAL TESTING AT UMASS AMHERST

#### 7.1. Overview and Purpose

This section describes the experimental testing conducted as part of this work. The scope included the setup of a radiant heating system, thermal and physical testing of specimens, and evaluation of results. The purpose of these tests was to determine the change in visual appearance of common tunnel materials subjected to heat damage, evaluate the effectiveness of two common non-destructive testing techniques, and determine the residual strength capacity of a common tunnel element after exposure to heat. Since the radiant heating system will be used for future heat testing at UMass, part of this section will cover best practices for using the heaters, and the capabilities and limitations of using this type of heating system.

Several types of specimens were heated to observe their residual condition, including: an aluminum wireway, tunnel tiling, unreinforced concrete, reinforced concrete slabs, and a prestressed concrete wall panel from a Massachusetts tunnel. Furthermore, after heating and cooling, residual strength tests were performed on the wall panel to determine the residual strength capacity of the panel after heating. Several of the transportation organizations surveyed as part of this work expressed concern about the potential post-fire condition of their plenum ceiling panels, which are used to create an exhaust air duct separate from the roadway. Their concerns stem from the fact that these panels are typically relatively thin (3-5”), and are directly over the roadway, meaning that they could potentially pose a safety hazard if damaged. The prestressed wall panel subjected to residual strength testing provides a decent representation of this type of

panel, and therefore the results of residual strength testing give a general sense of the resiliency of these types of members with respect to fire.

## 7.2. Heating Units and Setup

This section will the use of the radiant heating system, including different possible configurations of the heating setup, maximum temperatures achieved with each configuration, methods of insulating the test setup for maximum performance, and temperature monitoring using thermocouples.

### 7.2.1. Heat Source and Temperature Control/Recording

A system of three 16 in. by 12 in. Watlow ceramic 2030 style heaters with a high emissivity black surface coating (Figure 7.1) were used along with a Watlow F4T temperature controller (Figure 7.2) with data logging capacity for six thermocouples. Six type K thermocouples, 1/8 in. diameter by 12 in. length were used for collecting temperature data. One thermocouple was used to monitor each individual heater output, and the remaining three were used to monitor specimen temperatures. An example of recorded temperature data from one of the heat trials is shown in Figure 7.3.

**Figure 7.1: Watlow radiant heaters**

**Figure 7.2: Watlow F4T temperature controller**

**Figure 7.3: Example of recorded temperature data**

### **7.2.2. Configurations of Heaters for Heating Tests**

The heaters were mounted on a custom fabricated frame that could be easily attached to a portable wheel dolly for ease of heating of specimens (Figure 7.4). This allowed for the heating of several different types of specimens (e.g., aluminum, concrete

blocks, beams, etc.) using different configurations, such as those shown in Figure 7.5-  
Figure 7.7.

**Figure 7.4: Heaters on wheel dolly assembly**

**Figure 7.5: Heating chamber test setup**

**Figure 7.6: Heating of smaller specimen between two throwaway slabs**

**Figure 7.7: Direct heating of specimens**

Using these configurations, maximum concrete surface temperatures of 550°C-930°C were reached, depending on the size and geometry of the specimens. It was found that proximity to the heaters had a significant effect on the temperature of the specimen at any given location. Therefore, the best application of the heaters is the direct heating configuration, which allows for a more even heating of the specimens, and allows the highest temperatures to be reached. The heating chamber configuration may result in uneven heating of the specimens.

To protect the heating elements from damage, a protective shield was recommended by manufacturers. Two types were custom fabricated and evaluated at UMass Amherst. The first was a solid sheet metal shield of thin gauge sheet metal, while the second was a flat expanded metal sheet (Figure 7.8).

**Figure 7.8: Sheet metal shield (left), flat expanded metal shield (right)**

Initial testing showed that the solid sheet metal shields were much less effective at transferring heat to the specimens, producing significant disparities between temperature at the heating element and at the specimen surface. The expanded metal sheets provided more consistent heat transfer to specimens, allowing for higher maximum temperatures at the surface of the specimens. A potential concern regarding the open shield configuration is damage to the heating elements should specimens exhibit explosive spalling. As shown in Sections 7.4.4 and 7.5, two tests resulted in sudden spalling of beam specimens. The result was that the flat expanded metal sheet shield and thermocouple were pressed into the heating element. On both of these occasions, the heaters only experienced superficial damage, shown as the white areas where the coating has been damaged by the metal shield (Figure 7.9, left) and thermocouple (Figure 7.9, right), and the heating capabilities were not affected. Informal discussions with suppliers of Watlow heaters noted that damage to heaters has occurred using solid sheet metal shields during some heating and setup operations. The damage observed using the expanded metal sheet shield appears comparable. Based on these results, the flat expanded metal sheets are recommended for future testing.

As the heaters reached higher temperatures, both types of shield expanded and lost some stiffness, resulting in warping as shown in Figure 7.10. This did not affect any aspect of the heating regimen but would provide less protection against concrete spalling at extreme temperatures. Shields were intentionally connected such that deformations were outward to protect against contact with the heating elements.

**Figure 7.9: Damage to heater elements from shield (left), from thermocouple (right)**

**Figure 7.10: Deformation of shield**

### **7.2.3. Insulation Methods**

Initial trials using the heaters showed that there was significant loss of heat between the heaters and the concrete surface when no further insulation was provided. Thermal firebricks, a 1 in. thick insulation blanket and a 2 in. thick insulation blanket were obtained to improve insulation. A variety of setups were investigated to determine the impact on maximum attainable temperature and consistency in heating of specimens. It was determined that concrete specimen surface temperatures of up to 900°C could

consistently be obtained by minimizing the volume of air being heated and the loss of heat due to drafts. The optimal setup for maximum temperatures was as follows: specimens placed on or between concrete slabs with minimum distance between the heaters and the specimens, a layer of firebrick around the perimeter of the heaters, a 2” insulation blanket surrounding the firebrick and heaters, and the remaining gaps filled in with pieces of 1” insulation blanket. In order to position thermocouples, stands were provided on the outside of the insulation. This setup requires some openings in the insulation for the thermocouple body and/or wiring to enter the heated zone. The setup was varied for each test, depending on specimen size and temperature monitoring requirements. A typical setup is shown in Figure 7.11.

**Figure 7.11: Typical Insulation setup. Heating setup before adding any insulation (top), firebrick around heaters (bottom left), insulation around firebrick (bottom right)**

#### **7.2.4. Thermocouple Monitoring**

The thermocouple readings are critical to the thermal load being applied to the specimens. Initial testing noted that the load at the heating element source could vary significantly from the temperature of the air at the surface of the concrete, depending on the protective shield material used on the heater, robustness of the insulation, and other factors. The purpose of these tests is to determine the effects of temperature on the performance of materials such as wall and ceiling panels. This is independent of the heat source. For instance, a large fire farther away (closer to the ground for a ceiling panel or on the far side of the vehicle for a wall panel) may have a lesser effect than a moderate fire immediately adjacent to the panel. Of importance is determining the maximum temperature reached at the surface of the element and the resulting effects on damage and remaining capacity.

Thermocouples were used to monitor the air temperature at specimen surfaces. Thermocouple readings are taken at the tip of the metal casing. Initially there was some concern regarding the placement of these thermocouples to obtain an accurate reading of the concrete surface temperature. Figure 7.12 shows a test where one thermocouple was placed approximately 0.25 in. above the concrete surface, one was laid on the surface, and the third had the tip inserted directly against the edge of a drilled edge. All three thermocouples provided essentially identical readings (Figure 7.13), so thermocouples close to or touching the surface were used in all subsequent testing.

Additionally, some attempts were made to monitor internal concrete temperature by drilling from the side of the specimens and inserting the thermocouple. Side drilling may not be as effective, as insulating was difficult in the heating setup used, so heating of

the metal casing outside the specimen could transfer heat into the hole to the tip of the thermocouple, providing erroneous results. A better method would be to drill from the bottom of the specimen, which would require bending of the thermocouples to fit the desired location. While this would be possible for future tests, the thermocouples cannot be bent multiple times, so to preserve the instrumentation available this was not attempted. Readings taken in some preliminary tests indicated the feasibility measuring internal concrete temperatures. However, for the tests where residual load capacity was to be assessed, the researchers were concerned about potential for weakening the specimen at the hole locations, and thus only obtained surface temperature readings.

**Figure 7.12: Thermocouple readings**

**Figure 7.13: Temperature data from comparison of concrete surface temperature readings**

### **7.3. Specimens for Testing**

A single wall panel was provided to the laboratories at UMass Amherst for testing (Figure 7.14). The panel was removed from a Massachusetts tunnel during maintenance and had been stored. Additional information was not available. This panel was compared to construction document drawing sets for ceiling panels, and it was found that similar details and overall dimensions were used, with the wall panels not including details such as recesses for lighting and openings for anchorage. The inside face of the panel had a tile covering, with the remaining sides plain concrete. Staining was prevalent on the back (non-tile) face of the specimens of reddish or whitish hues. The panel thickness is 4 in. with tiled surface of grouted 8 in. square 0.25 in. thick clay tiles.

The research team took overall measurements and made estimates of expected reinforcement based on exposed reinforcement at damaged edges and inspection of inserts along the edges of the specimen. The expected reinforcement of these specimens from these evaluations is shown in Figure 7.15. These observations were used for initial recommendations for obtaining individual specimens from the panel, which were modified as needed during panel cutting. The intention of individual specimens was to obtain three comparable specimens for flexural testing that would be comparable to overall ceiling or wall panel behavior, and any additional remainder specimens for testing.

Witch Enterprises, Inc. were contracted to sawcut the panel into individual specimens. Initial cuts were made along the panel edges (approximately one tile from each edge and two tiles from the bottom of the wall panel, modified in the field to avoid reinforcement) to expose reinforcement. Inspection of the resulting exposed edges

confirmed reinforcing bar and prestressing strand locations. The top and bottom strips were cut into small specimens one or two tiles wide. Longitudinal cuts of 19 in. wide sections were made, centered on the three interior prestressing strands. Additionally, two strips of 9.75 in. were made to include only welded wire mesh reinforcement, further cut in half to make four identical specimens with minimal reinforcement. The remainders from the panel were retained to use for preliminary testing. This resulted in the following specimens (shown in Figure 7.16).

- Three primary beam specimens 19 in. by 96 in. with one prestressing strand and five longitudinal wires from the wire mesh reinforcement
- Three beam specimens 9.75 in. by 48.25 in. with wire mesh reinforcement only
- Ten single tile dimension specimens (8 in. by 8 in.) (some damaged)
- Six two tile dimension specimens (16 in. by 8 in.) (some damaged)
- Nine miscellaneous remainders, often one of a kind or pairs with one having significant spalling or inserts, some end sections with reinforcing steel and two prestressing strands, though these had pre-existing edge damage when delivered and therefore had no companion specimens of similar properties

**Figure 7.14: Panel as delivered**

**Figure 7.15: Panel dimensions and reinforcement**

**Figure 7.16: Specimens obtained from panel: Three primary beams (left), blocks, smaller beams, and miscellaneous (right)**

## 7.4. Initial Trials

For the initial testing, several different types of specimens were used: concrete specimens available in Gunness Laboratory (6 in. by 6 in. by 18 in. beam of undefined mixture properties and 22 in. by 34 in. by 6 in. slabs), individual block specimens from the wall panel (8 in. by 8 in. and 8 in. by 16 in.), an aluminum wireway provided by MassDOT, and beam specimens from wall panel the with only welded wire mesh reinforcement.

### 7.4.1. Heating of Small Plain Concrete Specimens

In an initial trial, a block-shaped concrete specimen to evaluate the thermal load potential of the heaters. The concrete mixtures and strengths were unknown, aside from having  $f'_c < 5 \text{ksi}$  (from student laboratory results). This specimen was heated to a maximum surface temperature of  $505^\circ\text{C}$  to  $560^\circ\text{C}$ , with temperature reduced once maximum temperatures were reached (Figure 7.17). There was no observed spalling or deterioration in the specimen (Figure 7.18).

**Figure 7.17: Sample test setup for heating plain concrete specimens**

**Figure 7.18: Plain concrete specimens: unheated (top), heated to surface temperatures up to 560°C (bottom)**

#### **7.4.2. Heating of Concrete Slabs**

Smaller specimens being heated were set on or between slabs that had been used for previous Gunness Laboratory testing. These specimens were 22 in. by 34 in. by 6 in. and had two layers of 4/4 – W2.9xW2.9 reinforcement. The concrete was provided by a local ready-mix plant to meet 4 ksi requirements. The 28-day cylinders strengths were  $f'_c = 4.8$  ksi.

These slabs were used in all testing to support specimens and seal the insulated heated zone at the bottom, protecting the laboratory floor from the heat. Therefore, only a section of each slab was exposed to heat, with the remainder outside the insulation and at ambient temperatures. These slabs were experienced surface temperatures that ranged from 300°C to 950°C for various time periods of thermal loading, and significant thermal gradients from within the insulated area to the ambient conditions outside. Two of the slabs were directly heated (Figure 7.19) and set aside after a known heat regimen and used to test the Carbontest® and rebound hammer test methods, reported in Section 7.6. No spalling occurred in any of the slab specimens. After heating to high temperatures,

there was hairline map cracking on many of the slabs (Figure 7.20) and a distinctly lighter coloration of the concrete (Figure 7.21).

**Figure 7.19: Concrete slab heating setup**

**Figure 7.20: Typical map cracking pattern for slabs after heating up to 930°C**

**Figure 7.21: Slab before heating (left), whitening after heating to surface temperatures up to 930°C (right)**

### **7.4.3. Heating of Panel Block Specimens and Aluminum Wireway**

The first specimens investigated from the tunnel wall panel were some of the smaller block-shaped specimens that were one or two tiles wide. Initial testing was conducted to determine potential effects of heating the tile or concrete side and investigate potential effects of heating on the panel concrete. The overall testing was shortened due to complications with noxious odors in the tests. No spalling was observed in any specimens, with air temperatures at the concrete surface reaching up to 790°C.

Figure 7.22 shows a test where two specimens were heated simultaneously, one with the tile facing upward and the other with the tile on the bottom against the concrete slab. As the specimens reached approximately 470°C, the testing was halted due to a noxious chemical odor from the specimens that spread through the laboratory and adjacent hallway. After cooling, inspection of the specimen with the tiles facing upward toward the heater showed a significant section of the grout between tiles and exposed on the edge had charred. This area of grout was easily sluffed off with a screwdriver (Figure 7.23). Subsequently, the researchers used a chipping hammer and hammer with chisel to break off the tile. When struck, the tiles in the vicinity of the charred grout broke off in small sections that separated near the grout line (Figure 7.24, bottom). In unheated specimens, the tiles and grout could not be separated from the concrete, instead breaking off in small sections that indicated no weak planes in the tile or grout (Figure 7.24, top).

**Figure 7.22: Specimens with tile side up (near) and tile side down (far)**

**Figure 7.23: Charring of grout material**

**Figure 7.24: Tile and grout removal by chipping hammer and chisel. Unheated specimen (top), specimen heated to 470°C with clean break at grout line (bottom)**

In a subsequent test, a block-shaped specimen with the tile facing upward and a section of the aluminum wireway were heated to temperatures of 400°C, 550°C, and 750°C, and held at each of these temperatures for an hour. At a temperature of approximately 350°C, smoke began billowing out of the heating chamber, which was confirmed to be from the grout when the heaters were removed to take a picture of the condition after maintaining a 400°C temperature for an hour. This smoking continued for about an hour before subsiding. Figure 7.25 shows pictures of the wireway and tile after maintaining temperature for an hour at 400°C, 550°C, and 750°C, respectively. Note that while the wireway appears grayish in the 400°C photo, these was due to backlighting; the wireway in actuality still had a white appearance. At 400°C, minor peeling of the coating on the wireway was noted, and the grout had turned a dark grayish/black color. At 550°C, significant peeling of the wireway coating was noted, and the grout had turned a light

whitish/gray color. At 750°C, the wireway had noticeably sagged, as shown in Figure 7.26, and the grout remained the same whitish/gray color as at 550°C. After the heaters were removed, a single hairline crack in the tile was observed, and additional smaller cracks could be seen forming during the first 5 minutes of cooling. The tile cracking pattern and aluminum wireway after heating and cooling are shown in Figure 7.27. After cooling, it was found that the grout had turned into a powder which could easily be scraped off with a screwdriver, as shown in Figure 7.28. Though attempts to pry the tile off the concrete were unsuccessful, it is postulated that the tiles can detach from the concrete during a fire due to the formation of cracks and the deterioration of the grout. Furthermore, it was noted that when water was poured on the hot tiles, the existing cracks grew and new cracks formed, indicating that water from fire suppression efforts could also contribute to the detachment of tiles from concrete after a fire event.

**Figure 7.25: Appearance of aluminum wireway and wall panel tile: before heating (top left), and after one hour at: 400°C (top right), 550°C (bottom left), 750°C (bottom right)**

**Figure 7.26: Sagging of aluminum wireway after heating**

**Figure 7.27: Closeup of tile and aluminum wireway after heating**

**Figure 7.28: Removal of grout with a screwdriver after heating**

Another block-shaped wall panel specimen was tested in a configuration where most of the specimen sides were flush against the concrete slabs, with only the top surface and approximately 2 in. of the sides exposed to the maximum heat during the test. This test was halted due to noxious chemical odors and some smoke at 790°C. As seen in Figure 7.29, the epoxy coating around the exposed reinforcing bar had melted and dripped down the side of the specimen. This was not observed in other specimens with similar exposed reinforcement. Nonetheless, most future testing was completed with the sides of specimens below the protective slab surface.

**Figure 7.29: Melting of epoxy reinforcement coating**

#### **7.4.4 Testing of Minimally Reinforced Beams Specimens**

The purpose of these tests was two-fold. First, these specimens were used to verify that the beam load testing setup was performing satisfactorily prior to the final beam tests. These tests would also provide data on the rupture capacity of heated specimens, though this has minimal design significance and would generally only be applicable to plain concrete members subject to flexure.

Three identical specimens were tested. One was not heated, to act as a comparison to the heated beams. The next was heated to 600°C. After 23 minutes at this temperature, the specimen suddenly spalled with significant loss of cross section (Figure 7.30, left). The specimen was cooled to room temperature and removed from the heater setup (Figure 7.30, right). In moving the specimen, a final portion of the cross section in the center of this photo became dislodged from the wire mesh, resulting in zero cross section remaining over a large portion of the specimen. This specimen has no flexural capacity by inspection, so was not tested further. The final specimen was also heated to 600°C and maintained at this temperature for approximately 180 minutes. This specimen showed no signs of spalling (Figure 7.31), though slight map cracking was observed on the heated face of the specimen.

The heating curves for the two specimens are shown in Figure 7.32. These specimens also had holes drilled from the side of the specimens to monitor temperatures within the concrete at depths of approximately 2 in. from the heated surface (location of wire mesh) and 1 in. from the heated surface. The intent was for these to be fully isolated from the heat chamber, although further testing would be required to verify that this

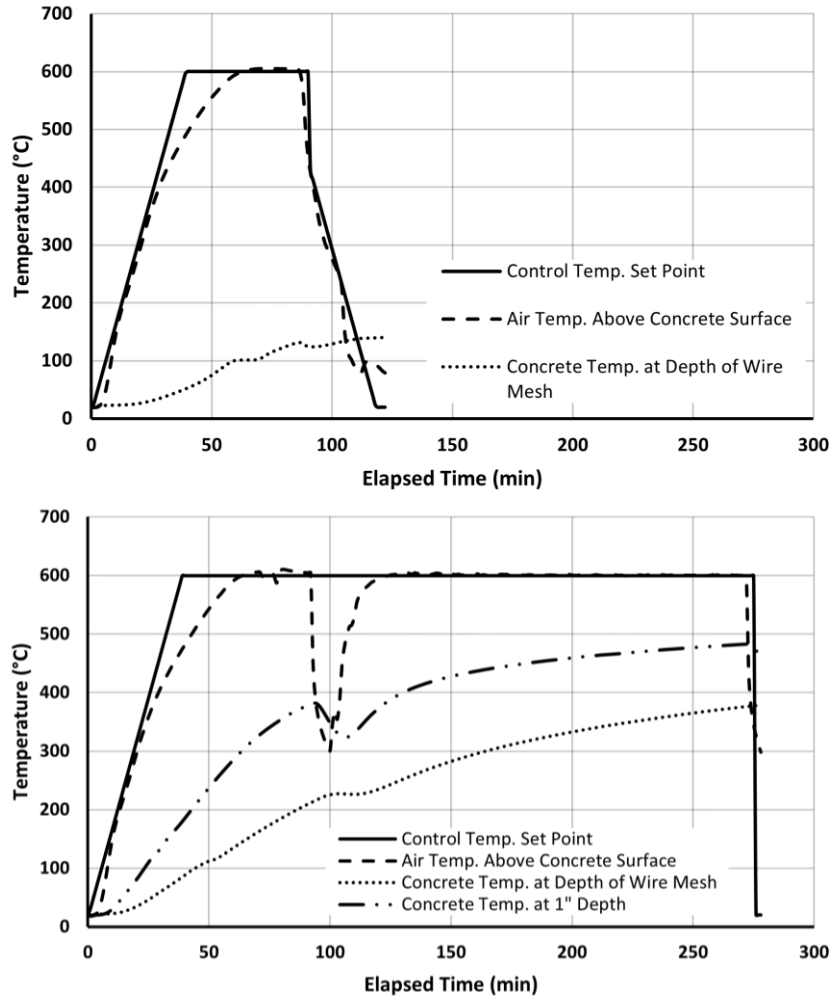

method accurately monitors concrete temperature and was not affected by hot air entering the drilled hole or heating the thermocouple casing. The monitored air temperature at the concrete surface at the center of the heated area was used to control the three heaters, while the control set point is the projected curve the heater output is intended to meet. For the intact specimen, the temperature drop occurred when insulating materials were removed to check for signs of spalling. The effects of cooling having less effects at depth can be clearly seen in the plot. The plots do not indicate why one specimen spalled and the other did not. The two specimens were then load tested in flexure to failure. Figure 7.33 shows a schematic of the test setup.

**Figure 7.30: Spalled minimally reinforced beam specimen after heating (left), after removal from setup (right)**

**Figure 7.31: Intact minimally reinforced beam specimen after heating**

**Figure 7.32: Heating curve temperature vs. time plots: spalled specimen (top), intact specimen (bottom)**

**Figure 7.33: Schematic of test setup for minimally reinforced beams**

The specimens were incrementally loaded until failure using manual control of load and displacement. This allowed for stopping at incremental load or displacement points to inspect the specimen and test apparatus.

Both specimens failed after propagation of a flexural crack in the constant moment region. Figure 7.34 presents photos of typical specimen failure. Figure 7.35 provides the applied load versus mid-span deflection plot for both specimens. For the control specimen, the maximum flexural capacity was reached at the cracking moment of the concrete tension fiber, though this would rarely be considered in design of members with reinforcement provided. After the cracking load was exceeded, the crack formed in the beam through approximately half of the depth and slowly progressed past the wire reinforcement and up to almost the tile prior to overall failure. The crack formed toward the left side of the specimen and therefore deflections at the left reading were approximately twice the centerline deflection shown, with the right gauge reading smaller values.

Results from the heated specimen load test were virtually identical to the control specimen load test, with the exception of the cracking moment. A crack similarly formed toward the left side of the specimen and therefore deflections at the left reading were approximately one and a half times the centerline deflection shown, with the right deflection gauge reading smaller values. The behavior of the load-deflection plot as well as maximum reinforced flexural capacity were nearly identical between the control and heated specimen. The only effect of heating on flexural capacity appeared to be to pre-crack the exposed face of the specimen with hairline cracks. This would not affect capacity if the concrete were heated in the tension region, and only affect capacity if in

the compression region by extending the zone of compression if the  $f'_c$  was lowered at the surface (resulting in a smaller moment arm between concrete in compression and steel in tension).

It is important to note that the force deflection curve past the initial concrete cracking (approximately 0.05 in.) would typically be considered for design of a reinforced member, as curing and aging will typically result in some cracking of concrete members, leading designers to neglect the concrete tensile strength. Therefore, the design capacity was not affected by the heating.

Post failure inspection of the ruptured specimens indicated changed concrete characteristics. This is shown in Figure 7.36, compared to the control specimen. There was a lighter band of approximately 0.25 in. to 0.375 in. extending from the heated surface of the concrete, with a darker band of approximately 0.50 in. to 0.75 in. above that layer. The darker section had the appearance of moist concrete. The thermal curve at 1 in. depth indicates that these areas reached temperatures of 450°C to 600°C.

**Figure 7.34: Photo of minimally reinforced beam specimens during load testing. Propagation of crack in control specimen during load application (top), after failure of heated specimen (bottom)**

## 7.5. Prestressed Beam Specimen Tests

The purpose of these tests was to compare the residual flexural capacity of wall panel samples after being subjected to heat to the load capacity of the wall panel samples before heating. Three specimens representative of ceiling and wall panels were tested. These included reinforcement of one prestressing strand and five longitudinal wires of the welded wire fabric, as shown in Figure 7.37.

**Figure 7.37: Beam cross section**

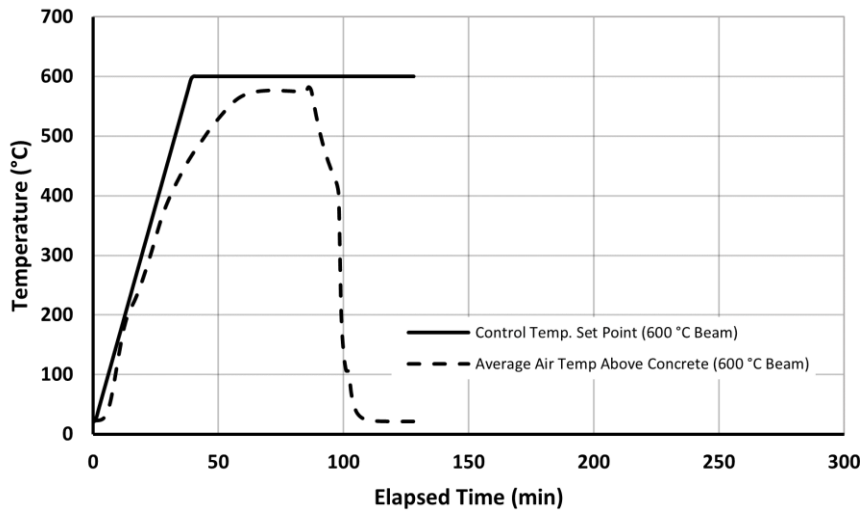

Three identical specimens were tested. The first was load tested without being heated, to serve as a reference. The next was heated to 600°C. After 27 minutes at this temperature the specimen suddenly spalled with significant loss of cross section (Figure 7.38) and the heaters were removed. The final specimen was heated to 300°C and this temperature maintained for 240 minutes. This specimen showed no signs of deterioration.

**Figure 7.38: Spalling of 600°C beam specimen prior to heating (left), post heating (right)**

The heating curves for the two specimens are shown in Figure 7.39. These specimens included three thermocouples to monitor air temperature at the concrete surface, under the center heater, and near the left and right of the insulated area. The left thermocouple was near a seam in the insulation intermittently used to observe the specimen. The monitored air temperature at the concrete surface at the center of the heated area was used to control the three heaters, where the control set point is the projected curve the heater output is intended to meet. In both specimens, the temperature to the left is lower than the other temperatures, and additional insulation would be required to provide a more consistent applied heat through the entire insulated area. However, the center thermocouple is expected to be representative of most of the heated area, as there were few seams in the insulation.

The three specimens were then load tested in flexure to failure. A schematic and photo of the test setup are shown in Figure 7.40 and Figure 7.41, respectively. The specimens were incrementally loaded until failure using a manual control of load and displacement. This allowed for stopping at incremental load or displacement points to inspect the specimen and test apparatus. The expected nominal moment of the specimens is  $M_n = 71.2$  kip-in., assuming  $f'_c = 7$  ksi for the concrete, tile, and grout,  $F_u = 90$  ksi for the welded wire ( $A_{sw} = 0.029\text{in}^2$ ) and  $F_u = 270$  ksi for the prestressing strand ( $A_{sp} = 0.085\text{in}^2$ ). For the test setup, this would correspond to an ultimate applied load at failure of  $P_u = 3.9$  kips.

**Figure 7.39: Heating curve temperature vs. time plots: spalled specimen (top), Intact specimen (bottom)**

**Figure 7.40: Test setup schematic for beam tests**

**Figure 7.41: Test setup photo for beam tests**

Photos of the specimens during testing are presented in Figure 7.41, Figure 7.42, and Figure 7.43. The applied load versus mid-span deflection plot for all three specimens are presented in Figure 7.44.

**Figure 7.42: Photo of control specimen after failure**

**Figure 7.43: Photos of 300°C intact specimen load testing. Multiple flexural cracks in constant moment region during load application (top and middle), after failure (bottom)**

**Figure 7.44: Photos of 600°C spalled specimen load testing. Prior to loading (top), propagation of crack during load application (middle), after failure (bottom)**

The specimens all failed within the constant moment region. All tiles remained intact and the final cracks were at or near grout lines. This indicates that the tile and grout were effective parts of the compression stress zone. Final cracks extended very close to the grout, further verifying the effectiveness of these components in compression. Load deflection plots showed no loss in strength in the heated specimens, but also an increase in ductility over the control, indicating that the heating process did not alter the internal

steel properties (note that the spalled specimen temperature load was discontinued as soon as spalling occurred).

The control specimen exhibited a typical reinforced concrete beam response, though the moment to cause concrete cracking was higher than expected (as in the small minimally reinforced beam specimens), indicated by the initial peak on the plot. After first cracking, there was a load drop. The specimen load capacity then increased along a less stiff path before reaching the peak load. The specimen heated to 300°C followed a similar initial path but had a gradual transition from the initial stiffness to the non-linear portion of the curve at a capacity slightly larger than the residual capacity of the control specimen after it cracked. It is conjectured that the heating induced some micro-cracking that slowly propagated with increasing moment, resulting in a smoother transition to the peak load capacity. The spalled specimen heated to 600°C showed immediate softening of the plot, as expected due to the significant damage and cracking in the concrete tension region. The specimen was able to continue loading to a peak load similar to the other two specimens.

It may not be intuitive that the highly damaged specimen had the most ductility and similar capacity. However, this specimen had an exposed length of prestressing strand, whereas the other specimens confined all significant non-linear deformations of the reinforcement to a specific crack location. Yielding occurring over a longer length of reinforcement results in a larger total reinforcement lengthening (strain remaining constant prior to necking). This would result in larger deformation of this damage beam during loading. Differences in total load capacity of all specimens are minimal, and in good agreement with the expected beam capacity before heating. Post failure inspection

of the specimen rupture planes showed no visible difference between the control and beam heated to 300°C (Figure 7.46).

**Figure 7.45: Load vs. deflection of tested specimens**

**Figure 7.46: Ruptured surface of 300°C heated specimen**

## 7.6. Non-destructive Testing Data

Carbontest® and rebound hammer tests were performed before and after heating in order to determine their effectiveness in post-fire inspection. These tests were initially

completed on slab specimens in the initial heating tests, and on some of the beam specimens.

### 7.6.1. Carbontest®

The Carbontest® was completed on one of the slab tests subjected to temperatures up to 900°C. Carbontest® was completed in the center of the heated zone and in the non-heated zone. At least two samples were collected from each region.

Results for the slab specimen are shown in Figure 7.47. According to the Carbontest® manual, concrete that remains colorless when a phenolphthalein solution is applied has been carbonated, while concrete that turns pink has not been carbonated. Carbonation can occur for several reasons, including heat exposure. With the heated powder being at the bottom of the tube, a minor difference in coloration was observed for the Carbontest® performed in the heated zone and the unheated zone. The test performed in the heated zone shows a lighter pink color at the bottom of the tube than the test performed in the unheated zone, which had a uniform pink color. There was not a distinct depth in the tube separating pink from colorless material. This preliminary test was therefore not conclusive, and further testing should be conducted to assess the viability of this method for determining the depth of carbonation in heated concrete.

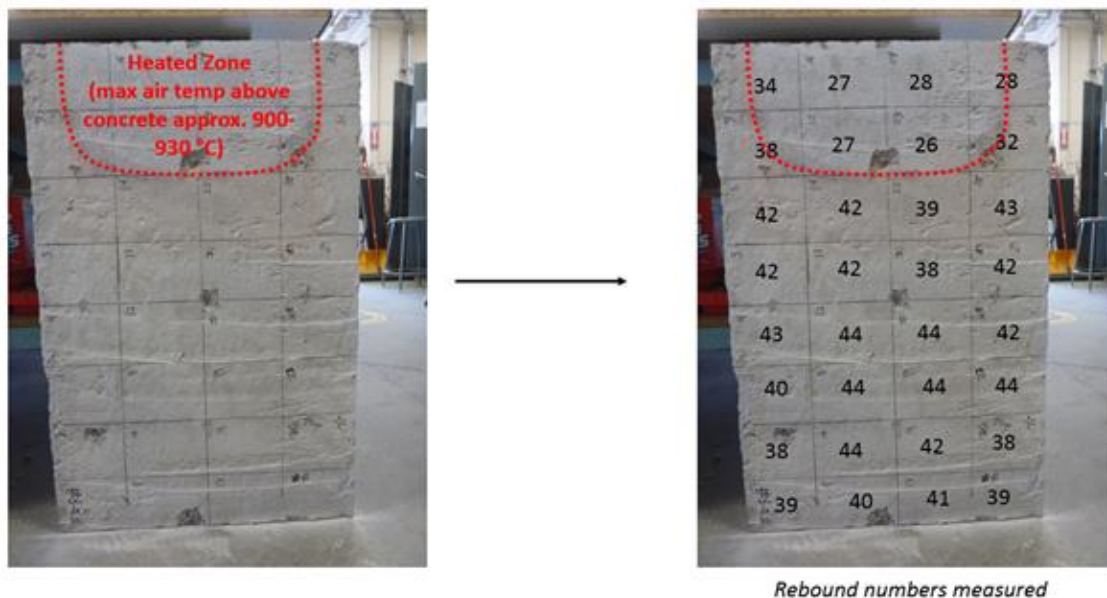

**Figure 7.47: Photo of slab Carbontest® tubes from: center of heated zone (left), unheated zone (right)**

## 7.6.2 Rebound Hammer

After heating, data was collected using the rebound hammer to determine the effectiveness of this tool in post-fire inspection. These tests were initially completed on slab specimens in the initial heating tests. Data was also collected prior to heating, and after failure, for the beam specimens.

Figure 7.48 presents slab specimen results. Results showed significantly lower readings (26-28) in the area of the slab that had been heated (area also visually appeared lighter in color) and consistent readings throughout the rest of the slab (38 to 44).

**Figure 7.48: Photo of 900°C slab rebound hammer and sample locations**

Figure 7.49, Figure 7.50, and Figure 7.51 show results from the final beam tests for the control, 300°C, and spalled 600°C specimens, respectively. Note that the heaters were centered on squares 12 and 13. For all specimens in their original condition the rebound numbers ranged from 25 to 57. This wide range can be attributed to debris that could not be removed, such as an unknown melted material staining the surface of the beams, and the presence of aggregate on the surface of the beams, which was noted to

result in highly inconsistent readings. Readings on the 300°C specimen were also collected after the specimen had cooled. As shown, there were no noticeable differences, with some numbers decreasing and others increasing by similar amounts, all within the range of scatter in the control and pre-heated specimens. Readings could not be taken post cooling on the spalled section of the 600°C heated specimen, but values outside the spalled area were relatively unchanged. Overall, the rebound hammer was not effective on the wall panel concrete due to initial variability in readings in the as delivered condition.

This beam was not heated

## 7.7 Conclusions

The three main objectives for the experimental heat testing are as follows:  
perform heating tests on various different specimens to determine the capabilities of the heater for future testing, document the visual changes in concrete specimens and tunnel

components after being subjected to heat, and perform residual strength tests on a wall panel removed from a Massachusetts tunnel.

The heating system was found to be capable of heating a variety of specimens of different shapes, including an aluminum wireway, concrete blocks, concrete slabs, and strips of a prestressed reinforced concrete wall panel. The heaters used in these experiments had a heating surface area measuring 36"x12", though this could easily be expanded given adequate space and electrical capacity. The heaters performed best when heating relatively flat specimens such as concrete slabs or the prestressed wall panel, as this allowed for the highest possible temperatures to be reached (up to 930°C), with an even distribution of heat across the surface of the specimen. Small specimens such as the aluminum wireway could also be heated quite evenly. Other types of specimens studied in this work such as the plain concrete blocks could be heated satisfactorily, but the heating may not be even among all faces of the member. The tests suggested that the surface temperature of the concrete can be effectively recorded by measuring the temperature of the air just above the surface of the concrete, assuming adequate insulation (thermal firebricks and fiberglass insulation blankets) is provided to prevent air drafts into the heating area. Measuring the surface temperature of concrete is important given that the strength degradation of concrete depends on the maximum temperature reached. Lastly, it was found that a metal grate constructed of expanded sheet steel could adequately protect the heaters from explosive spalling of the specimens.

During the course of the experiments, several important visual benchmarks for materials exposed to heat were observed. For one, the concrete slabs and prestressed wall panel concretes subjected to surface temperatures of 600-900°C showed significant

whitening, and the concrete slabs also showed map cracking after being exposed to surface temperatures of 900°C. Furthermore, a strip of the prestressed wall panel subjected to flexural tests after heat testing showed distinct bands of discoloration along the depth of the concrete up to 1” deep after being exposed to a surface temperature of 600°C for 4 hours. These temperatures generally match up with the temperatures at which whitish discoloration has been observed in concrete in literature (600-900°C) [69]. Interestingly, the reddish discoloration which can occur in some concretes was only observed in one of the specimens studied.

In terms of other visual effects, at 350-470°C, the tile grout on the prestressed wall panel gave off a noxious odor and became charred in appearance and brittle to the touch. At 550-750°C, the tile grout became whitish/grey in appearance and had powdery consistency and could be easily scraped up with a screwdriver. In one experiment, at temperature between 500-790°C, exposed epoxy reinforcement coating at a cut face of the prestressed wall panel melted, producing a noxious odor. Other specimens with cut epoxy coated wire mesh were heated to similar temperatures without any signs of melting. At 600-750°C, the paint coating on an aluminum wireway taken from a Massachusetts tunnel began to flake off, and significant sagging of the metal was observed.

Lastly, two strips of a the prestressed wall panel were heated, cooled to room temperature, and subjected to flexural tests to assess their residual flexural strength by comparing with an identical unheated strip of the panel. One of the strips was heated to a surface temperature of 600°C for 27 minutes before explosive spalling occurred, after which heating was stopped. Another strip was heated to a surface temperature of 300°C

for four hours. All three strips (unheated, 300°C, and 600°C) all had approximately the same strength capacity, suggesting that the heating was not great enough to damage the residual strength of the strips. It was found however, that the heated strips had a reduced stiffness compared to the unheated strip.

These results generally agree with those found in the literature. Several previous residual strength tests have found that the residual strength capacity of flexural members exposed to heat may not be significantly affected, depending on the level of exposure. The heating regimes used in this study (300°C for four hours and 600°C for less than thirty minutes) are lower than in many other residual strength studies, conferring confidence in these results. One point to note is that in this experiment, heating of the spalled specimen was halted after the explosive spalling event, while in a real fire heating would be likely to continue for some time after an explosive spalling event, as explosive spalling generally happens in the initial stages of a fire. As a result, the lack of loss of strength in the prestressed wall panel in this study which suffered spalling should not be taken to mean that spalled specimens in other cases may not lose significant flexural strength.

## **CHAPTER 8**

### **RECOMMENDATIONS FOR FUTURE WORK**

#### **8.1. Overview**

As mentioned previously, thus far more research efforts have been devoted to fire resistance design rather than the residual condition of structures. Furthermore, much of the available literature on the residual condition of structures is directed more at building structures than concrete tunnel structures. In general, further efforts must be made to consolidate existing knowledge of the effects of fire on the residual condition of concrete tunnel structures and post-fire assessment. Specific recommendations for each of the topics discussed in this work are provided in the following sections.

#### **8.2. Residual Strength of Concrete, Steel, and the Concrete/Steel Bond**

The residual strength of concrete after heat exposure is fairly well-characterized. Several structural code models for the residual strength of concrete are available in codes and experimental studies, covering a wide variety of concrete strengths and mixtures. The biggest remaining question is the effect of loading during heating on the residual strength. Other experiments have shown that concrete that is subjected to a working stress during heating has a higher strength at elevated temperature (in the hot state) than concrete that is not stressed during heating. The reasons for this are not entirely known, but it has been speculated that the presence of compressive load prevents the formation of cracks during heating, preserving some of the strength. It is not clear, however, if the presence of compressive stress during heating would also increase the residual strength of concrete

compared to concrete which is not stressed during heating. Additional experimental studies should be directed at this particular aspect of concrete residual strength.

Similarly, the residual strength of steel is well-studied, with models also available in structural codes and experimental studies. As with concrete, the effect of the presence of stress during heating on the residual strength is not well known, though a few studies have been conducted. These studies suggested that the presence of working stress has a negligible effect on the residual strength up to temperatures of 600°C. This point may be less significant than for concrete, given that many types of steel will rupture or fail when heated while being subjected to a working stress above 600°C.

Another less investigated aspect of the residual strength of steel is the loss of prestressing force in prestressing steel. Only one study was found which directly addressed this issue. This point is particularly pertinent for a post-fire evaluation, given that prestressing steel more susceptible to loss of strength than other types of steel, and the loss of prestressing force could not only further reduce the residual strength of a structural member, but could also have implications for the long-term durability of said members.

Lastly, though studies are available on the residual bond strength between concrete and steel, it is not entirely clear how useful this information is for a post-fire inspection. For one, it is not known what effect the loss of bond strength has on the potential loss of strength of an actual structural member. Existing experimental studies typically use development lengths well shorter than those required by code, meaning that the effects of bond strength loss may not be significant, given that code-prescribed bond lengths are intended to ensure yield failure of the steel well before bond failure would

occur. Additional studies with developments lengths similar to those required by code should be conducted to see if bond strength is a major concern for the post-fire condition of structural members, or if the yielding of steel is the controlling factor regardless. In addition, studies on the residual bond characteristics of epoxy-coated reinforcement should also be conducted to determine if this type of reinforcing is more susceptible to bond strength loss. This is especially important given that many existing tunnel structures have been constructed with epoxy-coated reinforcing.

### **8.3. Residual Strength of Structural Members**

Several existing studies have investigated the residual strength of reinforced concrete structural members. However, these studies have focused on members in building structures (beams, columns, and slabs), rather than members which may be present in tunnels. Though these findings are still useful, additional studies on members specific to tunnel structures would be very informative.

For example, many transit organizations across the United States which were surveyed as part of this work expressed concern about the condition of their ceiling ventilation structures after fire. These structures typically consist of 3-5” prestressed slabs hung to the tunnel lining above by steel hanger rods. The potential damage to overhead structures which could pose safety hazard to motorists, combined with the fact that the maximum gas temperature in tunnels fire often occurs at the ceiling, raise major concerns about the residual condition of these structures after fire. Additional studies into the residual strength of the relevant components (prestressed ceiling panels, hanger rods, mechanical anchors, epoxy anchors) should be conducted.

Particular focus should be given to the prestressed concrete panels common in ceiling ventilation structures. These panels are generally thin, reinforced with prestressing steel (which is highly susceptible to heat damage), and often contain inserts or cutouts to draw air from the roadway into the exhaust duct. The experimental tests conducted as part of this work suggest that the panels will likely not suffer a significant residual strength loss after small or moderately sized fires. More severe fire tests would help determine the true fire resilience of these panels.

#### **8.4. Post-Fire Inspection Techniques**

The literature search revealed a wide variety of post-fire inspection techniques, including visual, non-destructive, and laboratory methods. Visual and non-destructive techniques are generally much faster to perform than laboratory techniques, but are less accurate. In terms of non-destructive testing techniques, both the pullout method and Windsor Probe (penetration resistance) tests show particular promise for assessing the residual strength of concrete given their accuracy in assessing the strength of non-fire-damaged concrete, but little data is available on either method for the assessment of fire-damaged concrete. Additional studies should be conducted on both of these methods, especially the Windsor Probe, which can be performed much faster than the pullout method.

Another important point is that no viable in-situ non-destructive tests for the residual strength of steel were found. Although steel is generally less susceptible to heat damage than concrete, its strength may be more important in certain circumstances, such as damage to steel in the tension zone of flexural members.

Lastly, as part of this work, a rapid post-fire checklist was developed to aid inspectors in making safety determinations after a fire event. Noting the lack of existing post-fire inspection procedures for tunnels, a greater effort should be made among United States transit organizations to consolidate and develop knowledge about the post-fire condition of tunnel structures. The survey conducted also revealed a lack a research efforts in this area. Given the importance of tunnel structures for the infrastructure of many states, concerted research efforts between these organizations could greatly advance the current state of knowledge.

### **8.5. Post-Fire Repair**

In many circumstances, structures and structural members can be repaired even after severe fires. One study showed that a roof girder repaired with common techniques after a fire still had a greater flexural capacity than the design capacity. Additional studies should be conducted regarding the efficacy of typical post-fire repair techniques on the residual strength of structural members. Furthermore, additional information on the long-term health of fire-damaged members that have been repaired would be useful, as it is not known if repaired members have a similar expected service life to undamaged members.

## **CHAPTER 9**

### **CONCLUSIONS**

This work presented a literature review on the post-fire inspection of tunnels, and the findings from heat and load testing of some common tunnel elements. The purpose of the literature review was to gain an understanding of the effects of fire on the residual strength of tunnel structures and tunnel members, and to search for existing inspection methods and protocols for fire-damaged tunnels. The purpose of the experimental testing was to assess the capability of a radiant heating system for future experimental testing, and gain a preliminary understanding of the effects of heat on a few common tunnel elements. The key findings of this work are summarized in the following sections.

#### **9.1. Effect of Fire on the Residual Mechanical Properties of Concrete, Steel, and the Concrete/Steel Bond (from review of literature)**

A review of structural codes, standards, technical reports, and academic papers on the post-fire mechanical properties of concrete, steel, and the concrete/steel bond was conducted. This review focused on the residual strength and stiffness of concrete and steel after fire, as these properties can be related to the residual strength and stiffness of tunnel structures and structural members. The most significant findings can be summarized as follows:

- Concrete
  - The residual strength and stiffness of concrete after a fire are mainly dependent on the maximum temperature the concrete reaches during the fire.

- The residual strength and stiffness of concrete after heating and cooling begins to be negatively affected after experiencing temperatures of 200-300°C. After experiencing temperatures of 500°C, the residual strength is usually 40-60% of its original value.
- Concrete has excellent thermal insulation properties, meaning that typically only the regions of concrete near the exposed surface will be heated and damaged during a fire, while the inner regions of the concrete will be mostly unaffected.
- Thermal spalling can occur during heating, cooling, and after cooling, and can expose rebar and reduce the effective cross-sectional area of structural members.
- Steel
  - All types of steel lose a significant amount of strength and stiffness when at elevated temperatures (in the “hot” state) but regain some of that strength and stiffness loss upon cooling.
  - Different types of steel are affected more significantly by temperature exposure than others. After heating to 600°C and cooling, the residual yield strength of the 4 types of steels studied are as follows:
    - Hot rolled structural steel – 90-100% of original.
    - Hot rolled reinforcing steel – 80-100% of original.
    - Heat treated/cold worked steel – 70-100% of original.
    - Prestressing steel – 40-60% of original.

- Of the 4 types of steel studied, the post-fire condition of prestressing steel is most concerning, as it experiences the greatest strength losses, and can experience loss of prestressing force.
- Concrete and Steel Bond
  - The residual strength of the concrete/steel bond after heating and cooling from certain temperatures decreases to a similar or greater degree compared to the decrease in residual concrete compressive strength.
  - The residual bond strength is significantly affected by the thickness of the concrete cover. Rebar with a thinner cover generally has a lower residual bond strength than concrete with a thicker cover.
  - Existing bond strength studies use bond lengths well shorter than those required by code – additional studies with bond lengths per code requirements would clarify the role of bond strength loss in the residual strength of structural members.

## **9.2. Existing Experimental Studies on the Residual Strength of Reinforced Concrete Members (from review of literature)**

Five existing experimental studies on the residual strength of reinforced concrete members after fire exposure were presented. In each study, the members were heated, cooled, and loaded until failure. The most significant findings can be summarized as follows:

- Unlike studies on concrete, steel, and bond strength, studies on the residual strength of members do not use standardized test specimens (such as concrete cylinders), making direct comparisons among studies difficult.
- Greater lengths of exposure to heat generally result in greater residual strength losses after cooling.
- The residual strength reductions observed in the studies varied greatly. In some cases, ultimate strength reductions of 5-10% were observed, while in other cases residual strength reductions up to nearly 60% were observed. Based on the wide variety of specimen dimensions and types, materials, and heating regimes used in the studies, it is difficult to draw conclusions about the specific factors which govern the residual strength loss, aside from the fact that greater lengths of exposure to heat generally result in greater residual strength losses.
- Spalling seems to result in greater strength losses compared to when spalling does not occur.
- Specimens with high-strength concrete are more likely to experience spalling.

### **9.3. Existing Inspection Methods for Fire-Damaged Concrete Structures (from review of literature)**

A review of visual, non-destructive, and laboratory testing methods for the assessment of fire-damaged structures was conducted. The most significant findings can be summarized as follows:

- Visual Methods
  - The condition of non-structural materials such as aluminum can be used to estimate the temperature history within certain areas of a structure.

- Concrete can change to a pink color in the range of 300-600°C, which is useful since this temperature range coincides with onset of loss of residual compressive strength of concrete.
- Non-Destructive Testing Methods
  - From the review, the rebound hammer, Windsor probe, pull-out test, and carbonation test emerged as the best suited NDT methods for assessing fire-damaged concrete.
  - The rebound hammer is one of the most widely used non-destructive testing tools for post-fire inspections. It can be effectively used to delineate areas of concrete that have been damaged by fire.
  - The pull-out test has been shown to give excellent predictions of compressive strength in non-fire-damaged concrete. Limited test data with fire-damaged concrete suggests that it is also effective in measuring the residual compressive strength of the near-surface layers of concrete exposed to fire.
  - The penetration resistance test (Windsor probe) has also been shown to give good predictions of compressive strength in non-fire-damaged concrete. No studies could be found of its application to fire-damaged concrete.
  - The carbonation test has been shown to be able to determine the 450-500°C isotherm in fire-damaged concrete. Recently, a commercially available version of the test, Carbontest®, was developed.

- Laboratory Testing Methods
  - The most common method is petrographic analysis, which can determine the depth of damage in concrete exposed to heat or fire.

#### **9.4. Repair Methods for Fire-Damaged Concrete Structures (from review of literature)**

A review of technical reports and case studies was conducted to determine the feasibility of repairing fire-damaged concrete structures and structural members. The most significant findings can be summarized as follows:

- Fire-damaged concrete structures and members can usually be repaired rather than replaced.
- The main steps in the repair process of reinforced concrete are to remove damaged concrete, to replace the concrete to restore the member to its original size, and to replace or supplement weakened reinforcement.
- Concrete material is usually replaced by sprayable concrete (e.g., shotcrete) or flowable concrete in the case of significant damage.

#### **9.5. Survey of Post-Fire Inspection Practices Across State DOTs and Other Transportation Agencies**

A survey of post-fire inspection protocols, standard practices after a fire, and fire research efforts of other state DOTs and transportation organizations was conducted by contacting engineering personnel at these organizations and having discussions via video conference or email. The most significant findings of the survey are as follows:

- Most surveyed organizations do not have a written protocol for post-fire tunnel inspection. Those who do rely on the guidelines in FHWA's *Tunnel Operations, Maintenance, Inspection, and Evaluation (TOMIE) Manual*.
- 9 of the 16 surveyed organizations which owned tunnels reported experiencing tunnel fires, but most were not severe.
- Many organizations reported that, in the event of a tunnel fire, they would employ the same inspection principles used for post-fire evaluations of their bridges to inspect the tunnel.
- Many organizations have used private consultants to conduct post-fire evaluations of their tunnels and bridges.
- There is a general lack of research efforts related to the post-fire inspection of tunnels.

## **9.6. Experimental Testing at UMass Amherst**

Experimental testing was performed to evaluate the capabilities of a radiant heating system for future testing, and to gain some data on the effects of heat on the residual condition and strength of common tunnel materials. The most important findings are summarize below:

- The heating system can provide air temperature load at the surface of the concrete in excess of 900°C for ideal conditions. Higher temperatures may be possible with additional heaters.
- In the preliminary tests, several visually apparent deleterious effects of heat exposure were noted in the heated specimens that could be used in a post-fire

inspection. This included cracking of tiling and deterioration of grout, melting of reinforcement epoxy coating, spalling of concrete, red/white discoloration of concrete, map cracking of concrete, and distortion of an aluminum wireway. Further investigation is needed to verify the temperature at which these effects occur, and the level of structural damage they may indicate.

- Results from the NDT inspection methods investigated, Carbondent® and rebound hammer, were inconclusive; further investigation is needed to verify the feasibility and efficacy of these methods for use in a post-fire inspection.
- Spalling of wall panel concrete occurred in two specimens heated to 600°C within 30 minutes of reaching and maintaining this temperature. A third specimen heated to the same temperature showed no sign of spalling.
- Flexural tests on prestressed wall panels after heating and cooling to room temperature showed no change in the peak moment capacity. One specimen was heated to 300°C for four hours while the other was heated to 600°C for less than 30 minutes, at which point it experienced significant spalling. The spalled specimen still maintained the peak load of the other specimens and experienced more ductility but had less stiffness.

## APPENDIX A

### QUESTIONS FOR THE SURVEY OF POST-FIRE INSPECTION PRACTICES

- Has your organization experienced any notable tunnel fire events?
- Does your organization currently have a post-fire tunnel inspection protocol, or post-fire inspection protocol for other types of structures?
- If yes, what does this protocol entail (e.g., non-destructive testing, visual inspection, etc.)
- If yes, what is the basis these protocols (e.g., experimental testing, published standards, etc.)?
- Does your organization use private consultants to assess the condition of tunnels after fire events?
- Are there any particular post-fire structural concerns that your organization has in regard to the particular construction(s) of your tunnels?
- Has your organization conducted any fire tests on structural materials, members, or structures?
- If yes, would your organization be willing to share the testing results or the scope of these tests?
- Are you aware of any other research efforts or projects regarding post-fire tunnel inspections?
- Are you aware of any literature or documents on the subject?
- Are there any codes (regional, state, federal) regarding this issue?
- Have you personally conducted an inspection after a fire or seen a tunnel right after a fire?

- Do you have any contacts in other states or neighboring states?
- Do you know any other DOTs that may be interested in this sort of research?

## APPENDIX B

### DRAFT POST-FIRE INSPECTION CHECKLIST

DRAFT RAPID POST-FIRE TUNNEL INSPECTION CHECKLIST				
GENERAL INFORMATION				
INSPECTOR(S): _____	DATE/TIME: _____			
TUNNEL NAME: _____	TUNNEL STATION: _____

**ITEMIZED CHECKLIST**

**CONCRETE CEILING PANEL**

- PINK/RED/WHITENED CONCRETE YES  NO
- DROP IN REBOUND HAMMER READINGS VERSUS UN DAMAGED CONCRETE YES  NO
- CRACKS WIDTHS  $\geq 0.025"$  OVER PANEL YES  NO
- REINFORCING STEEL DAMAGE (MELTED EPOXY, DISTORTION, ETC) YES  NO
- NOTICEABLE MIDSPAN DEFLECTION YES  NO

**STEEL HANGER RODS**

- DISTORTION/PEELING OF PAINT OR GALV./DISCOLORATION YES  NO

**STEEL SUPPORT BEAMS/ANGLES**

- DISTORTION/ PEELING OF PAINT OR GALV. /DISCOLORATION/BUCKLING YES  NO

**SUPPORT ANCHORS**

- CREEP OR EXCESSIVE GAP YES  NO

**WALL PANEL**

- TILE LOSS YES  NO
- DAMAGE TO SUPPORTS/INSTABILITY YES  NO

**LIGHT FIXTURES**

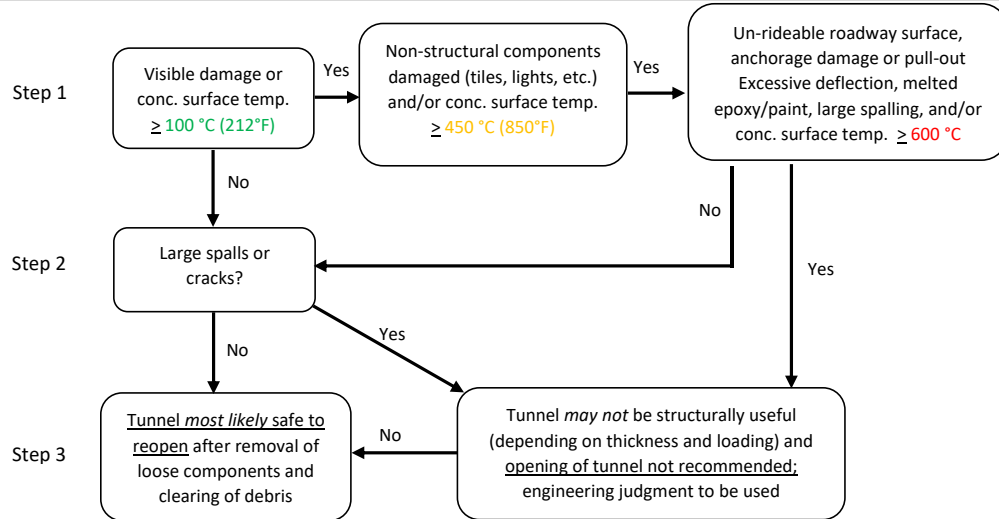

- MELTING OF LIGHT FIXTURE YES  NO
- MELTING/DEFORMATION OF ALUMINUM WIREWAY YES  NO
- UN-SOUND CONCRETE AROUND ANCHOR OR INSTABILITY YES  NO

**ROADWAY SURFACE**

- SLICK ROADWAY OR POTHOLES/SPALLS THAT IMPACT RIDING SURFACE YES  NO

**RECOMMENDED ACTION BASED ON VISUAL OBSERVATIONS AND RECORDED DATA**

NOTE: FLOWCHART IS INTENDED TO SERVE AS A **GUIDE** TO A POST-FIRE TUNNEL INSPECTION. HOWEVER, PROFESSIONAL JUDGMENT SHOULD BE USED IN AN ACTUAL INSPECTION

\*to assist estimating max. concrete temperature experienced, use attached reference guide

## REFERENCE GUIDE

**Disclaimer:** Many factors are to be considered in concrete strength reduction that should be considered as part of post-inspection review.

**Notes:** Surface temperatures may not always correlate with structural damage (such as explosive spalling from rapid/short-term temp. rises or the result of blast impact), however, large/deep cracking and structural damage could occur. Engineering judgment should be used.

### CONCRETE CONDITION STATE TABLE

Rating	Description
1	No damage/soot clearance only
2	Damaged tiles/small pop-outs, crack widths < 0.012"
3	Spalling with no exposed rebar, crack widths $\leq$ 0.025"
4	Exposed rebar, deep/wide cracking > 0.025"

### CONCRETE VS TEMPERATURE VISUAL GUIDE

Concrete discoloration at 600°C (1,112°F)
