Ongoing climate change can shift organism phenology in ways that vary depending on species, habitats, and climate factors studied. To probe for large-scale patterns in associated phenological change, we use 70,709 observations from six decades of systematic monitoring across the former Soviet Union. Among 110 phenological events related to plants, birds, insects, amphibians and fungi, we find a mosaic of change, defying simple predictions of earlier springs, later falls and stronger changes at higher latitudes and elevations. Site mean temperature emerged as a strong predictor of local phenology, but the magnitude and direction of change varied with trophic level and the relative timing of an event. Beyond temperature-associated variation, we uncover high variation among both sites and years, with some sites being characterized by disproportionately long seasons and others by short ones. Our findings emphasize concerns regarding ecosystem integrity and highlight the difficulty of predicting climate change outcomes.

Main text

Climate change is restructuring biodiversity across the globe[1]. Among key responses to spatial and seasonal changes in ambient temperature are changes in phenology[2,3] – i.e. changes in season-related life cycle events. At mid- to high latitudes in the northern hemisphere, spring events are generally occurring earlier, whereas autumn events are occurring later, mostly due to rising temperatures[2,4]. Overall, responses are expected to be faster and more pronounced the higher the latitude or elevation, that is, the lower the average temperatures[5–7].

Despite rough consensus regarding these general trends and expectations, there are substantial differences in the observed magnitude and direction of phenological responses to climate change among individual species[8–10], different taxonomic groups and trophic levels[3,11,12]. Where spring

9

208 phenology in terrestrial areas has advanced by a global average of 2.3 to 2.8 days/decade[2,8,13], some

209 studies have suggested changes as fast as 30 days per decade[14]. Higher rates of advance are possibly

210 associated with lower trophic levels[3,12], as perhaps reflecting not only different sensitivity to

211 different drivers among trophic layers, but also different responses in terms of physiological

212 development[3]. Another factor which may accelerate phenological advance relates to the mean

213 timing of an event within the season: spring-time events may be advancing at higher rates than

214 autumn events[15]. On top of species-specific variation, there is also considerable site-specific

215 variation in phenological advance[16]. Such variation among sites and populations may arise from a

216 combination of factors, including changes in temperature and other climatic variables, population

217 sizes, genetic differences, phenotypic plasticity, and land use[16,17].

218 A general reason for variability in phenological responses is that patterns of climate change vary

219 substantially across the globe. As the climate of different regions and biomes are changing in

220 somewhat different ways[5], uniform responses to climate change are hardly to be expected. Regional

221 variation in climate change concern patterns in e.g. overall warming, precipitation and in the

222 seasonal distribution of change[6]. Thus, changes in phenology can be expected to track local changes

223 in the timing of abiotic or climatically-driven events, within the constraints set by the utilization of

224 and sensitivity to cues of the regional species assemblage[18–20]. Such local and regional variation in

225 drivers[19,21,22] and sensitivity towards them[18,20] can be reflected in spatiotemporal variation in

226 phenological shifts[4,8,15,23,24]. While the few studies analyzing geographically extensive datasets on

227 phenology have observed spatial variation in temporal trends of phenological responses (e.g. [25,26])

228 and their main abiotic drivers[5,27–29], the question remains whether patterns of change and response

229 follow major environmental gradients in latitude, photoperiod or temperature[15,16,30].

230 **Spatially extensive, long-term data across northern Eurasia**

231   Evaluating to what extent shifts in phenological events vary over space[31], with their annual

232   timing[3,11,12] or with trophic level[16,32] requires consistently sampled, community-wide data which are

233   both long-term and spatially extensive[3,12,16,32]. Such data may also give insights on whether local

234   phenology is influenced by biotic interactions beyond abiotic cues[7,33,34]. Unfortunately, systematic

235   community-wide data sets are still uncommon, hampering progress in understanding large-scale

236   taxonomic and geographic patterns in phenological change[35]. The few existing exceptions (e.g.

237   [2,4,8,15,36,37]) are built on sparse data and/or combining individual studies using variable methods

238   (e.g.[38]). However, for such data, both noise and bias may affect the overall pattern detected.

239   Regarding seasonality, most datasets come with a particular bias, since much more interest has been

240   invested in spring- than in autumn-time events[2,4,39]. This is a problem, since where data are

241   available, phenological events occurring during different times of the year have oftentimes been

242   found to shift differently[40].

243   Here, we draw on a uniquely comprehensive, long-term database established using uniform

244   protocols across northern Eurasia[41–43]. As this monitoring effort encompassed the timing of multiple

245   seasonal events as characterizing both climatic variation and a wealth of taxa (plants, birds, insects,

246   amphibians, reptiles and fungi; Fig. 1), it allows us to quantify large-scale patterns in phenological

247   responses over six decades. Specifically, we ask: 1) Has the timing of different phenological events

248   shifted similarly across this vast geographic range, measured in terms of the rate and direction

249   (advance or delay) of change?; 2) To what extent does variation in the rate and direction of change

250   follow major biogeographic gradients, such as latitude, photoperiod, temperature or chilling-degree-

251   days?; 3) To what extent can variation in the rate and direction of change be linked to the relative

252   seasonal timing of the event (early versus late), or to the species' trophic level?; and 4) To what

253   extent does variation in the timing of different events covary locally in ways not attributable to

254   overall patterns, suggesting an effect of biotic interactions (and/or joint responses to unmeasured

255 variables)? When combined, these questions allow us to characterize how different components of

256 the ecosystem have shifted their phenologies over the last few decades of climate change, which

257 environmental gradients can explain variation on a large spatial scale, and whether events occurring

258 during different parts of the season or for different taxa keep pace with each other.

259 To quantify phenological shifts across events, trophic levels and environmental gradients, we fitted

260 a joint species distribution model[41] treating the dates of the phenological events as the multivariate

261 response variable. To capture linear shifts in the timing of events, we included year as a fixed

262 covariate, and to account for phenology varying with environmental or spatial gradients, we

263 included the linear effect of four environmental descriptors of each study site (i.e., mean annual

264 temperature, mean annual chilling sum, photoperiod, or latitude), with a separate model fitted for

265 each descriptor (see below). Additionally, in order to quantify to what extent shifts in phenology

266 differ along the environmental gradient, we included an interaction term between year and the

267 environmental descriptor. Variation among sites beyond that explained by the environmental

268 descriptor was captured by including site as a random factor, and similarly year-to-year variation

269 beyond any linear trend was modelled by including year as a random factor. All events were

270 grouped into abiotic (n=28; e.g. the transition of daily average temperatures above a given

271 threshold, the melt of snow cover, or the breakup of ice on a given water body; Table S1) versus

272 biotic events (n= 82; e.g. the first occurrence of a fungus species, the onset of blooming in a plant

273 species, or the end of leaf fall for a tree species; Table S1), with the latter further split according to

274 the species trophic level, yielding five "trophic levels" (producers, n=54; primary consumers, n=4;

275 secondary consumers, n=22; and saprotrophs, n=2; Fig. 1; Table S1). To evaluate how the

276 multivariate response (i.e. dates of the phenological events) varies within year for each trophic

277 level, we further included as explanatory variables the trophic level, the mean timing of the event

278 across all sites, and their interaction. Since we treated the phenological events as the "species" of

our joint species distribution model, we treated their characteristics (i.e. the trophic level or the

mean timing of the event) as its "traits", just as one would model e.g. the body size or feeding guild

of a species as its traits[41,43]. Thus, the explanatory variables were allowed to affect how the events

respond to the fixed effects of year, the environmental descriptor (i.e., mean annual temperature,

mean annual chilling sum, photoperiod, or latitude), and their interaction[5,6,8]. The periodic nature of

seasons over time was captured by including the mean timing of the event as the linear effects of its

cosine and sine transformations (see Methods for more details).

To examine the impact of different descriptors of climatic conditions at each site, we fitted four

alternatives models to the data. Each model was identical in structure, but used an alternative

climatic descriptor of the sampling sites. The specific metrics used were (1) the mean annual

temperature in each study location, (2) the mean annual chilling sum (sum of degree days for those

days for which the temperature is below zero), (3) the photoperiod (measured as the difference

between the longest and shortest days of the year), and (4) the latitude of the site, with data sources

for (1)–(3) identified in the Methods section. We fitted four separate models, rather than including

all drivers into a single model, because all four drivers are highly correlated. Thus, their

simultaneous inclusion in a single model would be of limited added value (in terms of variation

"accounted for"), whereas it would compromise the interpretability of the results.

How phenology is shifting across a continent

All models provided adequate descriptions of the data, as evidenced by a high mean explanatory

power: averaged over the events R^2 was 74% for the model with latitude and 75% for all other

models. We note that the reason why all models had similarly high explanatory power was that the

part of the site-specific variation not explained by the climatic descriptor of the site was captured by

the random effect of the site. The proportion of explained variation attributed to the climatic

descriptor was 36% for the mean annual temperature of the site, 24% for the chilling sum, 27% for

13

303   the photoperiod, and 28% for the latitude (Extended Data Fig 2). Because mean annual temperature

304   was the best predictor in the sense of explaining the most variation, we report the results of that

305   model in the main text. All four models yielded qualitatively consistent results (Extended Data Figs.

306   1-8).

307   The explanatory power was greater for spring events than for autumn events, except for abiotic

308   events (see Table S1) where it was consistently high (Fig. 2a for the model with mean temperature;

309   Extended Data Figure 1 for other models). Averaged over the different events, 36.0% of the

310   explained variance was attributed to the site mean temperature, 2.8% to the linear effect of year and

311   its interaction with the temperature, 41.5% to the random effect of the site (i.e. variation among

312   sites not explained by mean temperature), 13.4% to the random effect of the year (i.e. variation

313   among years not explained by linear trends), and 6.4% to the random effect of the sample (i.e.

314   synchronous variation at the level of site-year combinations; Fig. 2b).

315   Spring events tend to occur earlier and autumn events tend to occur later at warmer (typically lower

316   latitude or elevation) sites, creating a longer activity period or growing season, as reflected by a

317   strong negative effect of temperature on spring event timing and strong positive effect for autumn

318   event timing (Fig. 3a, b). For a large proportion (54%) of all events, we found strong statistical

319   support (at least 95% posterior probability) for a shift towards an earlier date, whereas fewer events

320   (10%) showed strong statistical support for a shift towards a later date (Fig. 3a). As examples of

321   events shifting towards an earlier date, we find the break of ice cover, the first blooming of many

322   plants (from Tussilago, *Tussilago farfara*, to the Lily of the valley, *Convallaria majalis*), the first

323   flight of bumblebees, *Bombus*, and the first occurrence of a range of bird species (ranging from the

324   swift *Apus apus* to the crane *Grus grus*). Among events shifting towards a later date, we find the

325   formation of snow and ice cover, the timing of autumn colours and leaf fall in several trees (from

326   aspen *Populus tremula* to birch *Betula pendula*), and – perhaps oddly enough – the spring-time

327   awakening of the brown bear, *Ursus arctos*. Specifically, spring events showed the strongest shift

328   towards earlier dates, whereas autumn events showed the strongest shifts towards later dates (Fig.

329   3c). This was particularly evident for primary producers, which overall showed stronger shifts in

330   both directions; i.e. plants advanced early or delayed late events faster than did higher trophic

331   levels. By comparison, the abiotic events showed even stronger shifts in both directions for both

332   temperature and year effects. Thus, abiotic change, consumers and producers slide apart as springs

333   shift earlier and autumns later.

334   Additionally, shifts were more positive at warmer sites for some events (18% showed strong

335   statistical support; Fig. 3d), but more negative for others (15%; Fig. 3d), with no clear pattern over

336   time or across trophic levels. Among those events that showed a strong statistical support for an

337   overall shift to earlier, 17% showed a strong statistical support for shifting to earlier especially in

338   cold sites and 16% in warm sites (Fig. 3e). Among those events that showed a strong statistical

339   support for an overall shift to later, 11% showed a strong statistical support for shifting to later

340   especially in cold sites and 22% in warm sites (Fig. 3e). As concrete examples of events which have

341   actually shifted later at cold sites but earlier at warm sites, we find the first spring rain, the onset of

342   blooming in Scots pine (*Pinus sylvestris*) and Marsh Labrador tea (*Rhododendron tomentosum*, syn.

343   *Ledum palustre*), and the first song of the skylark (*Alauda arvensis*). Among events shifting earlier

344   at cold sites but later at warm sites, we find e.g. the arrival of the rook (*Corvus frugilegus*), and the

345   ripening of blueberry (*Vaccinium myrtillus*) and lingonberry (*Vaccinium vitis-idaea*).

346   The random effect of site was positively associated both within spring and within autumn events,

347   but negatively associated between spring and autumn events (Fig. 4a); i.e., at any given site, spring

348   events tended to occur particularly early while all autumn events particularly late, or vice versa,

349   after accounting for the effect of site mean temperature. This pattern remained qualitatively

350   unchanged when replacing mean temperature with other environmental descriptors (mean chilling

351   sums, photoperiod or latitude; see Extended Data Fig. 6). Thus, summer – in the sense of the

352   biologically active period – tends to be particularly long at some sites and particularly short at other

353   sites, a pattern which is only partly captured by simple environmental gradients (for potential

354   explanations, see below). The random effect of year was positively correlated among events overall,

355   but especially among spring events, meaning that some years are characterized by early spring

356   phenology and others by late spring phenology across all events and trophic levels (Fig. 4b).

357   Perhaps most interestingly, though, the random effect at the level of the sampling unit (i.e. the site-

358   by-year combination) showed positive association among most phenological events. Thus, a large

359   majority of all phenological events within a given site in a given year tended to be consistently

360   "early" or "late" to an extent unexplicable by the effect of the year as such (Fig. 4c) – a pattern

361   suggesting that some other factor may be orchestrating the relative timing of events at the level of

362   the local community.

363   **Striking variation over space, species and trophic levels**

364   Our results highlight considerable spatial, seasonal and trophic heterogeneity in the magnitude and

365   direction of shifts in phenological timing. While much of the large-scale variation can be attributed

366   to a simple environmental gradient, phenological responses to ongoing climate change can

367   idiosyncratically cause advance or delay over time within regions, and among sites and trophic

368   levels. The strong effect of site beyond the effect of mean temperature (as shown by the overall

369   partitioning of variance in our model; Figs. 2 and Extended Data Fig. 2) importantly qualifies the

370   expectation of a strong and general pattern of phenology change along latitudinal or other

371   environmental gradients [17]. Yet, it is consistent with our previous work[17] showing that phenological

372   plasticity is constrained by local differentiation in reaction norms to temperature cues[44], i.e., by

373   local adaptation (see also[18,45]). Under such a scenario, we would indeed expect site-specific

374   variation in phenology beyond patterns attributable to average temperature or its change over time.

375   However, it is worth noting that different abiotic events (such as snowmelt, ice formation and ice

376   break) likewise vary differently with mean temperature, change differently over time, and remain

377   cross-correlated even when temperature has been accounted for (Figs. 3, 4). In other words, early

378   sites tend to remain early, and late sites tend to remain late, both with respect to the biotic and

379   abiotic components of the local ecosystems. Most interestingly, the overall timing of events tends to

380   be more synchronized than suggested by the overall effect of year. The strong dominance of

381   positive residual associations between event-pairs at the random sample level (Figs. 4c and

382   Extended Data Fig. 8) implies that an early date of one given event is associated with an earlier date

383   in another *beyond* the advance expected by the overall earliness of the year. Residual covariance at

384   this level could potentially be interpreted as a sign of a synchronizing effect of biotic interactions

385   among species. In doing so, we should naturally exercise the same caution as whenever statistically

386   observed associations are interpreted as biotic interactions[41,43]. It is also worth noting that beyond

387   biotic interactions, this result is likely to partly reflect the synchronizing effect of abiotic conditions

388   which affect multiple events, as well as the fact that different phenophases within one and the same

389   species are interconnected with each other (e.g a migratory bird species cannot breed without first

390   arriving, so the timing of breeding is constrained by the timing of arriving). Regarding the latter

391   type of dependencies, we note that while we scored two or more separate phenological events in

392   several species (Supplementary Information, Table S1), such repeated measures concerned far too

393   few species to account for the vast predominance of positive residual associations observed overall.

394   Thus, the pattern observed may be seen as suggestive, but clearly inconclusive of evidence for an

395   imprint of biotic interactions on community-level phenology[7,33,34].

396   Overall, strong phenological shifts over time occur not in lieu of but on top of the imprints of

397   environmental gradients of mean temperature, photoperiod and latitude[5,6,8]. That is, strong added

398   imprints of site on local phenology change might stem from spatial variation in additional factors

17

399   varying more idiosyncratically in space, rather than as smooth gradients. Species respond to

400   multiple climatic dimensions over time[46,47], and the effects of climate on phenology may further

401   vary with habitat[48], urbanization[49,50], and precipitation[5,6]. Thus, an anthropogenic-induced shift in

402   the macroclimate[4,5,15,32], potentially leading to large-scale environmental changes along latitudes[51]

403   or other geographical gradients, may be further modified by the local changes that species are

404   responding to customized by the local conditions that they have adapted to. Such added impacts

405   could limit the scope for space-for-time substitutions[16], and leads us to warn against uncritical

406   extrapolation of trends observed among sites, trophic levels, or from one region to another[5].

407   As proposed by Burrows et al.[17,52], the observed patterns of shifts in phenology should be compared

408   to patterns in the velocity and seasonal shift of climate change. In this context, we note that our

409   current data include both abiotic climate-related events and biotic responses, with the former

410   shifting more than the latter. These disparities between the rates of change in the abiotic

411   environment and species responses match previous observations that current phenological plasticity

412   is not keeping pace with variation in climatic conditions[3,17,18,22,53–56]. Mismatches between the

413   velocity of climate change and realised seasonal shifts may help identify regions of concern, e.g.

414   where phenology change is lagging behind species thermal niches.

415   **Ecosystem integrity imperilled yet understudied**

416   Our findings emphasize concerns regarding ecosystem integrity, as the velocity of change in space

417   and time differed between interacting trophic levels. Combined with different responses among

418   events over different parts of the season, this variation can lead to temporal mismatches between

419   species[1,11,56] and potentially affect community structure and persistence. Importantly, a shift in the

420   timing of an event related to one life-stage may propagate to another, but our current dataset holds

421   limited resolution towards resolving such knock-on effects. To establish whether the stability and

422   persistence of natural systems is ultimately affected by the loss of phenological synchrony at one

423 stage, or within food webs, we need a much-improved understanding of the interplay between

424 spatial, trophic, species- and event-specific patterns in phenological responses (e.g. [35]).

425 Accumulated negative effects of rapid seasonal shifts across many species may threaten

426 biodiversity[14,57,58]. Surprisingly enough, our current findings suggest that phenological shifts during

427 the last few decades may differ between warmer and colder locations across our study area. In this

428 context, we stress that our estimates concern absolute, not relative, rates of change. Counter-

429 weighing the interpretation of stronger shifts at warmer (thus more southern or lower elevations)

430 sites is the fact that phenology is naturally constrained by the overall length of the season. At high

431 latitudes, i.e. in colder regions, a shift of a few days may amount to a considerable part of the full

432 growing season. As polar areas warm at faster rates, resident organisms might lose major parts of

433 their phenological niches [21]. In contrast, areas of slower seasonal shifts, and smaller relative shifts,

434 may be important repositories for both biodiversity and ecosystem integrity[5]. Our current study

435 provides a first attempt in this direction, and will hopefully inspire more work to come.

561

Methods

563   We used data from Ovaskainen et al.[59], who compiled dates of phenological events (for concrete

564   examples, see Supplementary Information, Table T1.1) systematically recorded for multiple

565   taxonomic groups in 471 localities across the Russian Federation, Ukraine, Uzbekistan, Belarus and

566   Kyrgyzstan. In addition, the database includes dates on climatic events recorded at each locality

567   (e.g., ice formation and first day of snowfall). The data were curated by EarthCape[60] and published

568   on Zenodo[59]. From this set, we selected events for which there were at least 100 data points in total,

569   and at least 10 data points from at least 10 sites. Further, we only included sites that were at least 25

570   km apart, and sampling units for which there were at least 10 events recorded. All anthropogenic

571   events, such as dates for sowing and harvest, were excluded from this analysis. This process yielded

572   70,709 phenological observations for 110 events across 113 locations (Fig. 1). The data included 52

573   taxa and four types of meteorological events (Supplementary Info, Table S1.1), and covered the

574   period between 1960-2017 (earlier records were excluded), spanning 43.08°–67.82° latitude and

575   21.15°–136.15° longitude.

576   The sampling units consist of (site, year) pairs. We denote by y_{ij} the date on which the

577   phenological event j took place in sampling unit i. These are combined in the data matrix $\mathbf{Y} = \{y_{ij}\}$

578   with $j = 1, \dots, n_s = 110$ events recorded in $i = 1, \dots, n_y = 2789$ sampling units. The data consist

579   of 70,709 dates, so that 77% of the entries in the **Y** matrix are missing (NA) due to not all events

580   being recorded in all sites and in all years. To these data, we fitted Hierarchical Modeling of

581   Species Communities (HMSC) models[41,43]. HMSC is a multivariate Bayesian generalized linear

582   mixed modelling framework, which allowed us to account for both correlation among the

23

583 phenological events included in the models, as well as for the spatio-temporal structure of the study

584 design[41–43]. Additionally, HMSC allows including trait information to inform species-level

585 responses to model covariates[41] – in our case, event-level responses. Here, we summarize our

586 rationale and inference, while an in-depth description of the HMSC model fitted is provided in

587 Supplementary Information, Text S2.

588 As predictors related to each sampling unit i, we included the linear effect of year of the sampling,

589 aimed to capture temporal shifts in phenology which are the main focus of this study. To account

590 for phenological variation due to climatic conditions, as well as to capture any systematic variation

591 in the phenological shifts as a function of climatic conditions, we also included a variable

592 describing the overall (not year-specific) climatic conditions at each study site, and its interaction

593 with the linear effect of year. As climatic descriptor, we considered four alternatives variables based

594 on [29], who identified the three most important factors controlling phenology in primary producers as

595 the degree of winter chilling, photoperiod (day length relative to night length), and temperature. We

596 thus derived descriptors of spatial variation in each of these three variables, and showed that our

597 main results were upheld across each (Extended Data Figs. 1-8). Specifically, these were (1) the

598 mean annual temperature, (2) the mean annual chilling sum (calculated as the sum of degree days

599 for those days for which the temperature is below zero), and (3) the photoperiod measured as the

600 difference between the longest and shortest days of the year, for each site. In addition, we

601 considered (4) the absolute latitude of the site, as a standard descriptor of space as such in both

602 phenological[61] and other biogeographic analyses[62]. We note that photoperiod is a function of

603 latitude, but that the two are non-linearly related to each other. For this reason, we included latitude

604 *per se* as a separate, potential climatic descriptor. To compute the mean annual temperature and the

605 mean annual chilling sum, we used the ERA5-Land data (representing the period 1979-2019)[63,64].

606 To calculate the photoperiod, we used the daylength function of the R-package geosphere[65].

607　To examine how the shifts and their dependency on the climatic conditions co-varied among

608　different types of phenological events, we also included event-level predictors (i.e., species traits in

609　the HMSC framework): (1) the mean timing of each event (calculated as the mean day of the year

610　over the entire data set); and (2) the trophic level of the species for which the phenological event

611　was recorded (classified as producers, primary consumers, secondary consumers, and saprotophs, or

612　abiotic events). To account for the periodic nature of seasons over time, we included the mean

613　timing of each event as the linear effect of its cosine and sine transformations. To account for the

614　nature of the study design and to evaluate co-variation among the phenological events, we included

615　three random effects for the site, the year, and the sampling unit (i.e. year-site pairs). All of these

616　were modelled at the community-level, using the latent variable approach of HMSC[41,43]. This

617　allowed us to assess the relationships among phenological events that could not be explained by

618　responses to the main covariates, and for each of the three random effect levels included in our

619　models. For a more technical description of the HMSC model, we refer the reader to [41–43].

620　We fitted the models with package Hmsc[42] in R[66] assuming the default prior distributions (see[42,43]).

621　We performed posterior sampling for four Markov Chain Monte Carlo (MCMC) chains, each of

622　which we sampled for 375,000 iterations, out of which we discarded the first 125,000 as a transient

623　and thinned the remaining by 1000, thus yielding 250 samples per chain and 1000 samples in total.

624　To evaluate MCMC convergence, we examined the distributions of the potential scale reduction

625　factor over the parameters related to the fixed effects (β –parameters) and the random effects (Ω-

626　parameters), equivalent to the Gelman-Rubin statistic[67].

627　Overall, we note that our aim is to quantify spatial variation in the rates (slope) of phenological

628　change over time, not to identify the specific drivers of the timing of each individual event. To

629　emphasize this point, we stress that we regressed phenological timing on year and on descriptors of

630　each site's position in physical (latitude) or environmental space (average temperature, average sum

631 of chilling degree days or photoperiod), not on year-to-year variation in some specific driver. What

632 our analyses show is thus that trophic level and seasonal timing of an event affect how it has shifted

633 over time, and that the rate of shift is further affected by its position along the biogeographic

634 gradient, whereas the exact descriptor of this gradient has little impact on the results (Extended Data

635 Figs. 1–8).

Competing Interests

698 The authors declare no competing interests.

699

700
701
Figure 1. Illustration of the study design and the extent of data. Individual panels show **top-left**: the amount of phenological data per year included in the study; **top and middle**: the spatial provenance of data of each type; and **bottom**: mean annual temperature for each sampling location. All events were classified into four trophic levels according to the organism expressing the event: primary producers (plants), primary consumers (herbivorous insects), secondary consumers (predatory insects, amphibians, birds, mammals), and saprotrophs (fungi, as commonly feeding on the remains of multiple other levels).

709

710
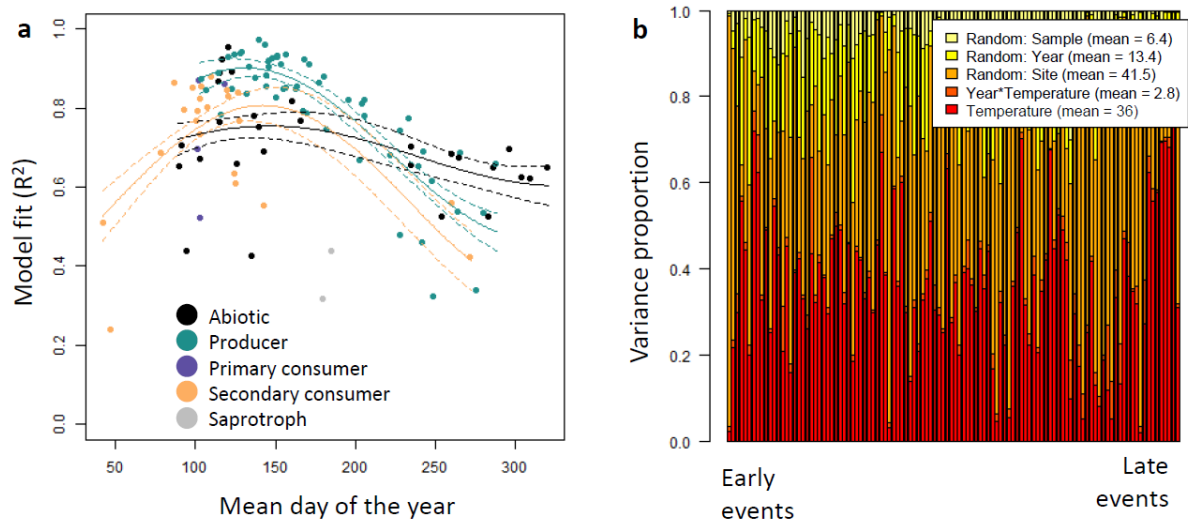

Figure 2. **Explanatory power (a) and variance partitioning (b) of the HMSC-model with mean**

annual temperature as explanatory variable. **a,** Degree of determination (R^2) as a function of the

timing of the event (mean day of the year when the event occurs) and of the trophic level of the

organism expressing the event (shown by curves in different colours). Here, curves show second-

order models fitted to groups with at least 5 events; continuous lines show mean model prediction

and dashed lines ±1 standard error. **b,** Partitioning of the overall variance of the data into the

different model components. Here, individual events have been sorted from the earliest to the latest

(left to right along abscissa).

719
Figure 3. **Responses of the events to the fixed effects of mean temperature and year**. **a**, Cases

for which the response is positive (red) or negative (blue) with at least 95% posterior probability,

with the events ordered according to their mean date (increasing from top to bottom). The

covariates year and temperature have been normalized to have zero mean, so the main effect of the

year relates to a site with average temperature, and the main effect of temperature relates to data

points collected at the middle of the study period. **b**, **c**, **d** Dependency of event-specific responses

on phenological timing (mean day of the year when the event occurs) and on the trophic level of the

organism expressing the event (shown by curves in different colours for those groups with at least 5

events). **e**, Dependency of the response to year x temperature on the response to year. The four

quadrats correspond to events that have shifted to earlier especially at cold sites (EC), shifted to

earlier especially at warm sites (EW), shifted to later especially at cold sites (LC), and shifted to

later especially at warm sites (LW). Filled symbols indicate cases that are either positive or negative

with at least 95% posterior probability. For the effect of year, we show responses in days per year,

so that a value of -0.2 represents a shift of two days earlier per decade. For the effect of

31

735   temperature, the unit is days per degree Celsius, so that a value of -4 means that the event takes

736   place 8 days earlier in a location with mean temperature 4°C compared to a location with mean

737   temperature of 2°C.

738
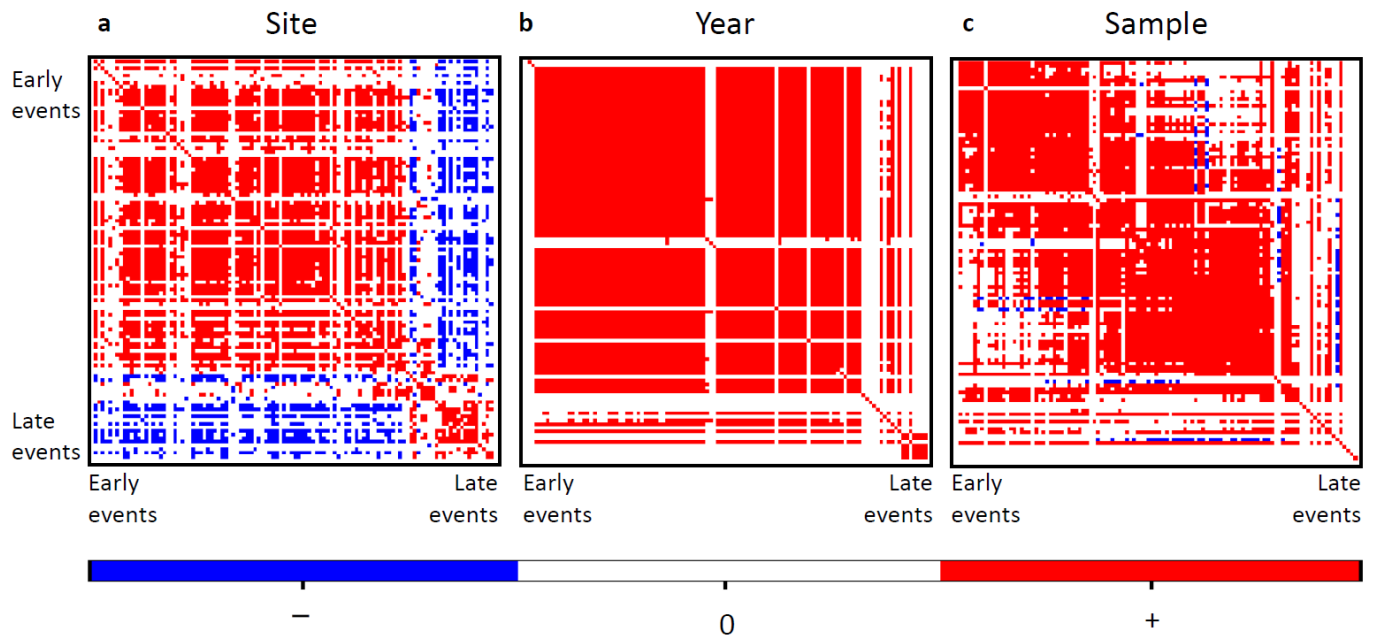

Figure 4. **Residual associations among events related to random effects. a,b,c** Associations at

the level of the site (**a**), the year (**b**) and the sample (site×year; **c**) The events have been ordered

according to their mean date (increasing from left to right, and from top to bottom), and estimates of

events associations are measured by residual correlation. Shown in colour are associations showing

a positive (red) or negative (blue) association with at least 95% posterior probability, with

remaining cases indicated in white.
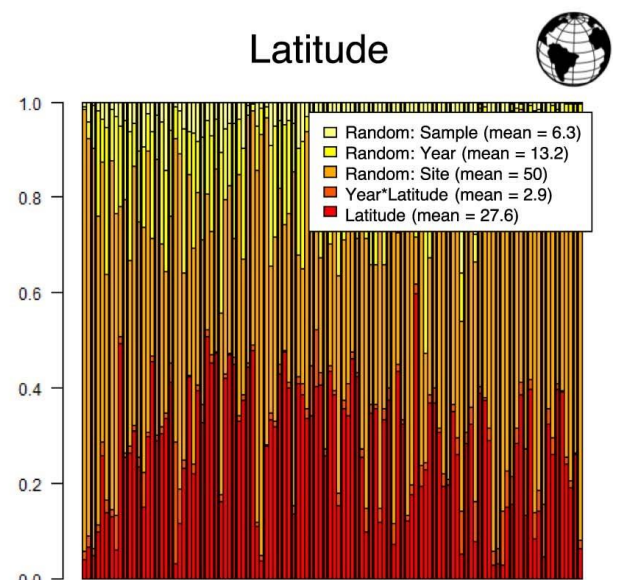

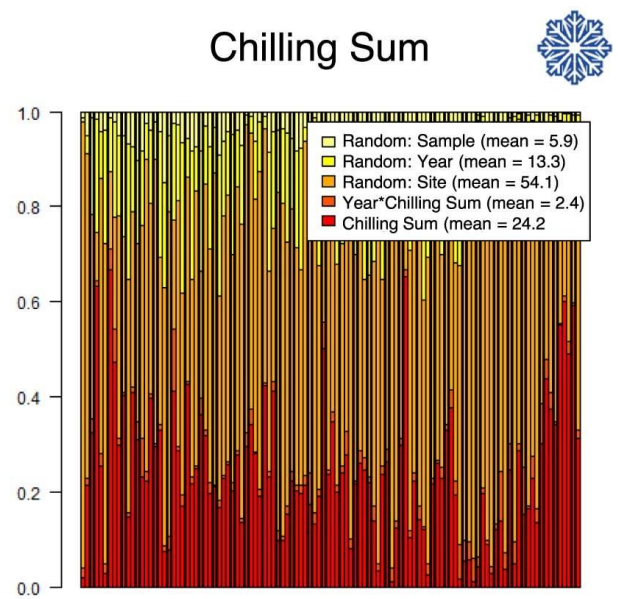

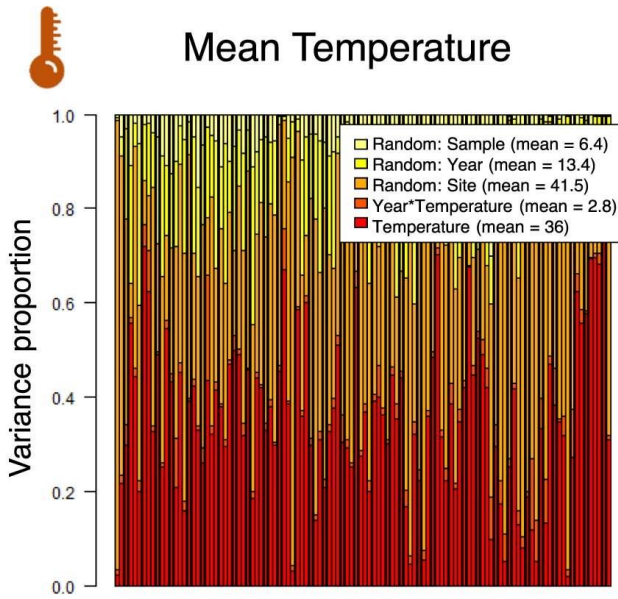

Extended Data Fig. 1: Variance partitioning of alternative HMSC-models. Plots show the partitioning of the overall variance of the data into the model components identified in the figure legend. Individual panels show results for models with identical structure but using alternative climatic descriptors of the sampling sites; note that the top-left panel corresponds to Fig. 2b of the main text. Silhouettes adapted from https://thenounproject.com.

754
Extended Data Fig. 2: Explanatory power of alternative HMSC-models. Plots show the degree

of determination (R2) as a function of the timing of the event (mean day of the year when the event

occurs) and the trophic level of the organism expressing the event (different colours). Curves show

second-order models fitted to groups with at least 5 events; continuous lines show mean model

prediction and dashed lines ± one standard error. Individual panels show results for models with

identical structure but using alternative climatic descriptors of the sampling sites; note that the top-

761   left panel corresponds to Fig. 2a of the main text. Silhouettes adapted from

762   https://thenounproject.com.

763
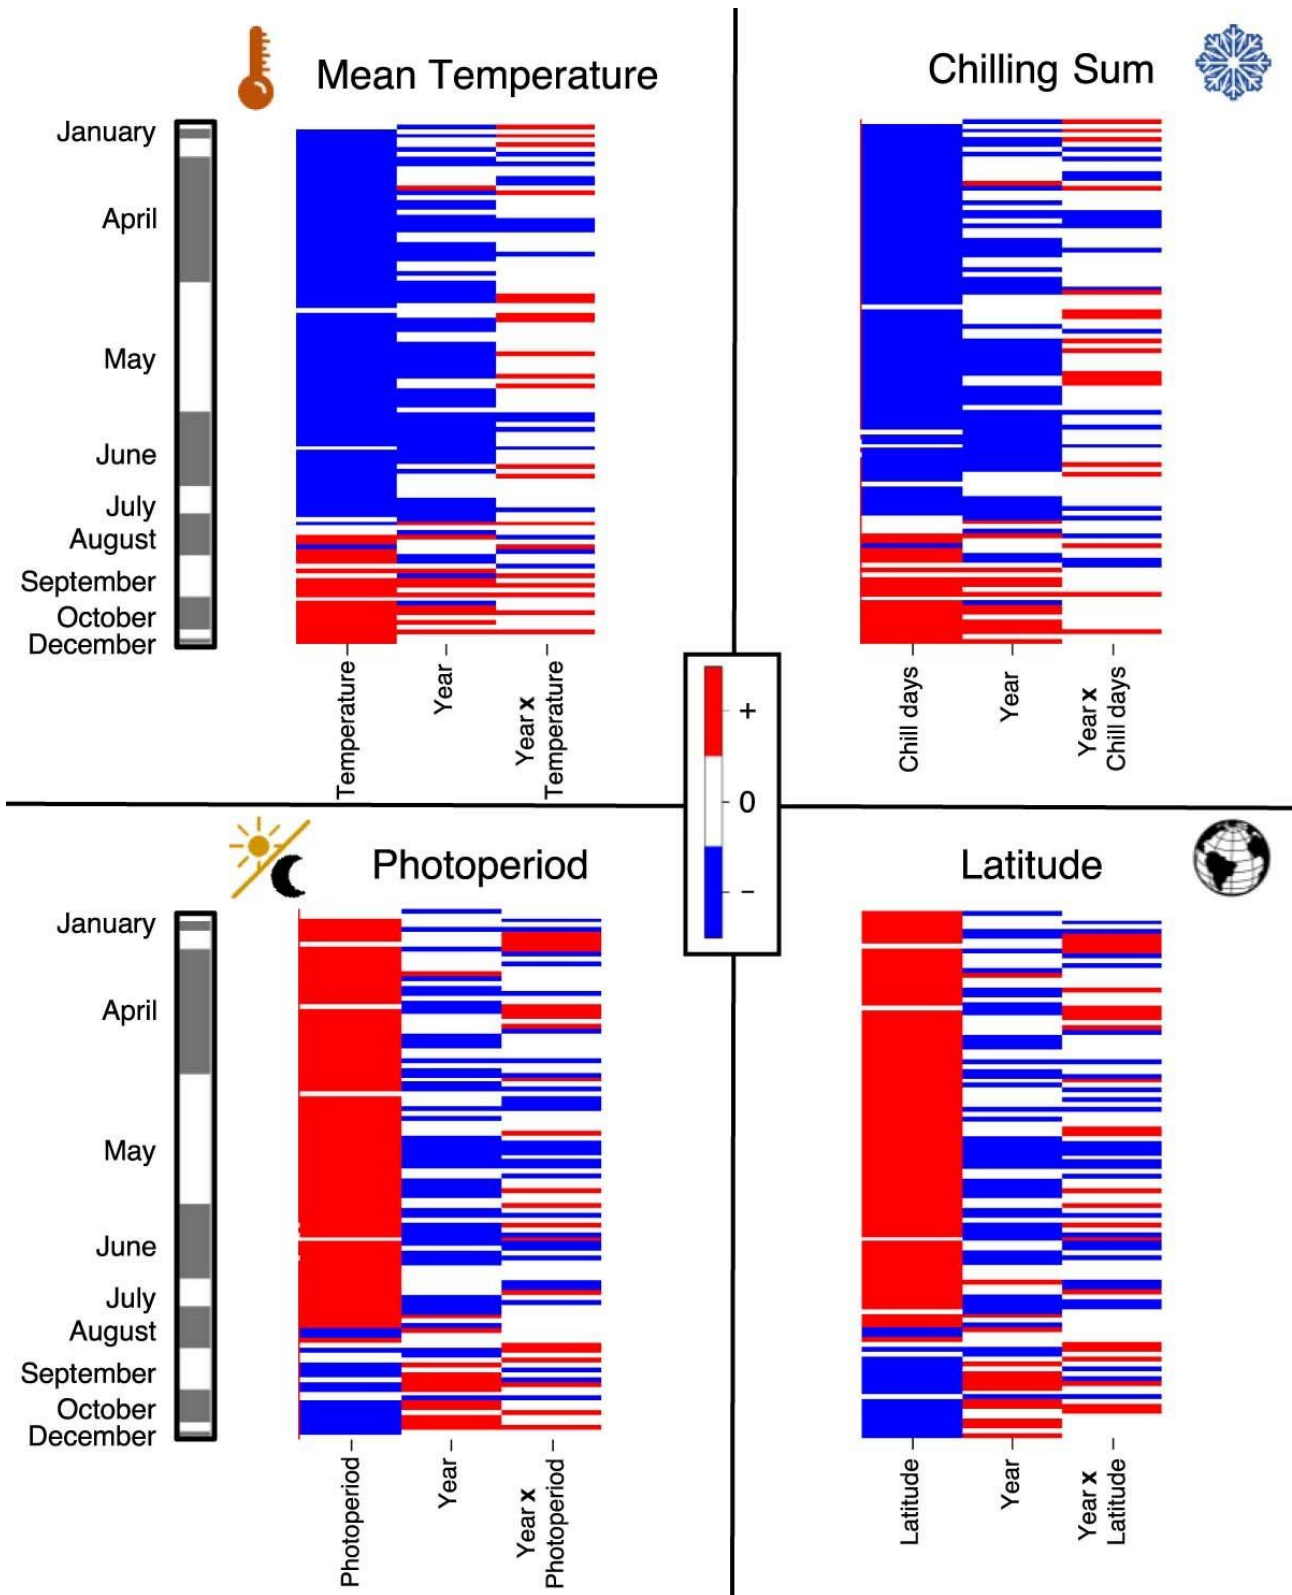

Extended Data Fig. 3: The sign of responses of phenological events to the fixed effects

included in the HMSC model. Plots show cases for which the response is positive (red) or

767 negative (blue) with at least 95% posterior probability. Events have been ordered according to their

768 mean date (increasing from top to bottom). The covariates have been normalized to have zero mean,

769 so that the main effect of the climatic descriptor relates to a data point collected at the middle of the

770 study period, and the main effect of the year relates to a site with an average value of the climatic

771 descriptor. Individual panels show results for models with identical structure but using alternative

772 climatic descriptors of the sampling sites; note that the top-left panel corresponds to Fig. 3a of the

773 main text. Silhouettes adapted from https://thenounproject.com.

774
Extended Data Fig. 4: Dependency of event-specific responses on phenological timing and on the trophic level of the organism expressing the event. Individual sections show results for models with identical structure but using alternative climatic descriptors of the sampling sites; note that the top-left section corresponds to Fig. 3b–e of the main text. Within each section, that is for each model, individual panels show the dependency of event-specific responses on phenological

781   timing (mean day of the year when the event occurs) and on the trophic level of the organism

782   expressing the event (shown by curves in different colours for those groups with at least 5 events).

783   The covariates have been normalized to have zero mean, so that the main effect of the climatic

784   descriptor relates to a data point collected at the middle of the study period, and the main effect of

785   the year relates to a site with an average value of the climatic descriptor. In the bottom-right figure

786   within each quadrat, we show the dependency of the response to year $\times$ temperature on the response

787   to year; here, the four quadrats within the panel correspond to events that have shifted to earlier

788   especially at cold sites (EC), shifted to earlier especially at warm sites (EW), shifted to later

789   especially at cold sites (LC), and shifted to later especially at warm sites (LW). Filled symbols

790   indicate cases that are either positive or negative with at least 95% posterior probability. Silhouettes

791   adapted from https://thenounproject.com.

792
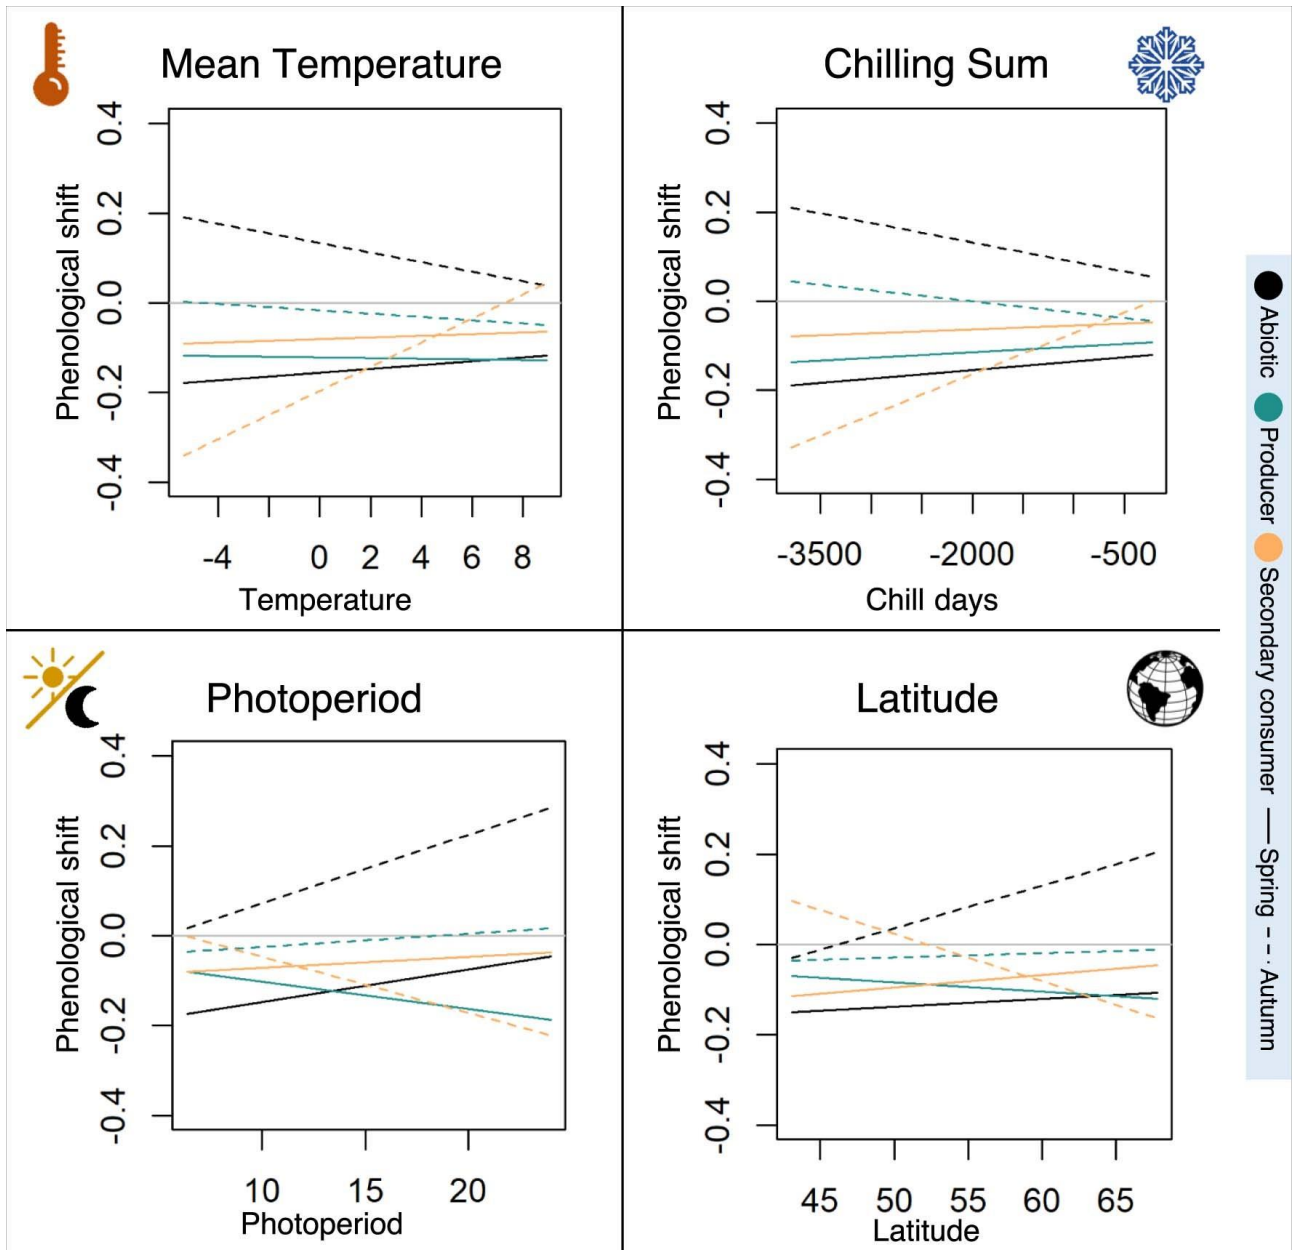

Extended Data Fig. 5: Estimated shift in the phenological timing of events occurring in the

spring versus autumn as functions of the average climate descriptors of the site. Plots show the

estimated shift in the phenological timing (days per year) among events occurring in the spring

(solid line, showing predictions for Day of Year (DOY) 100, that is April 10) versus autumn (dotted

line, showing DOY250, that is September 7), plotted against the average climate descriptors of the

site. The colours of the lines identify the trophic level of the organism expressing the event.

Silhouettes adapted from https://thenounproject.com.
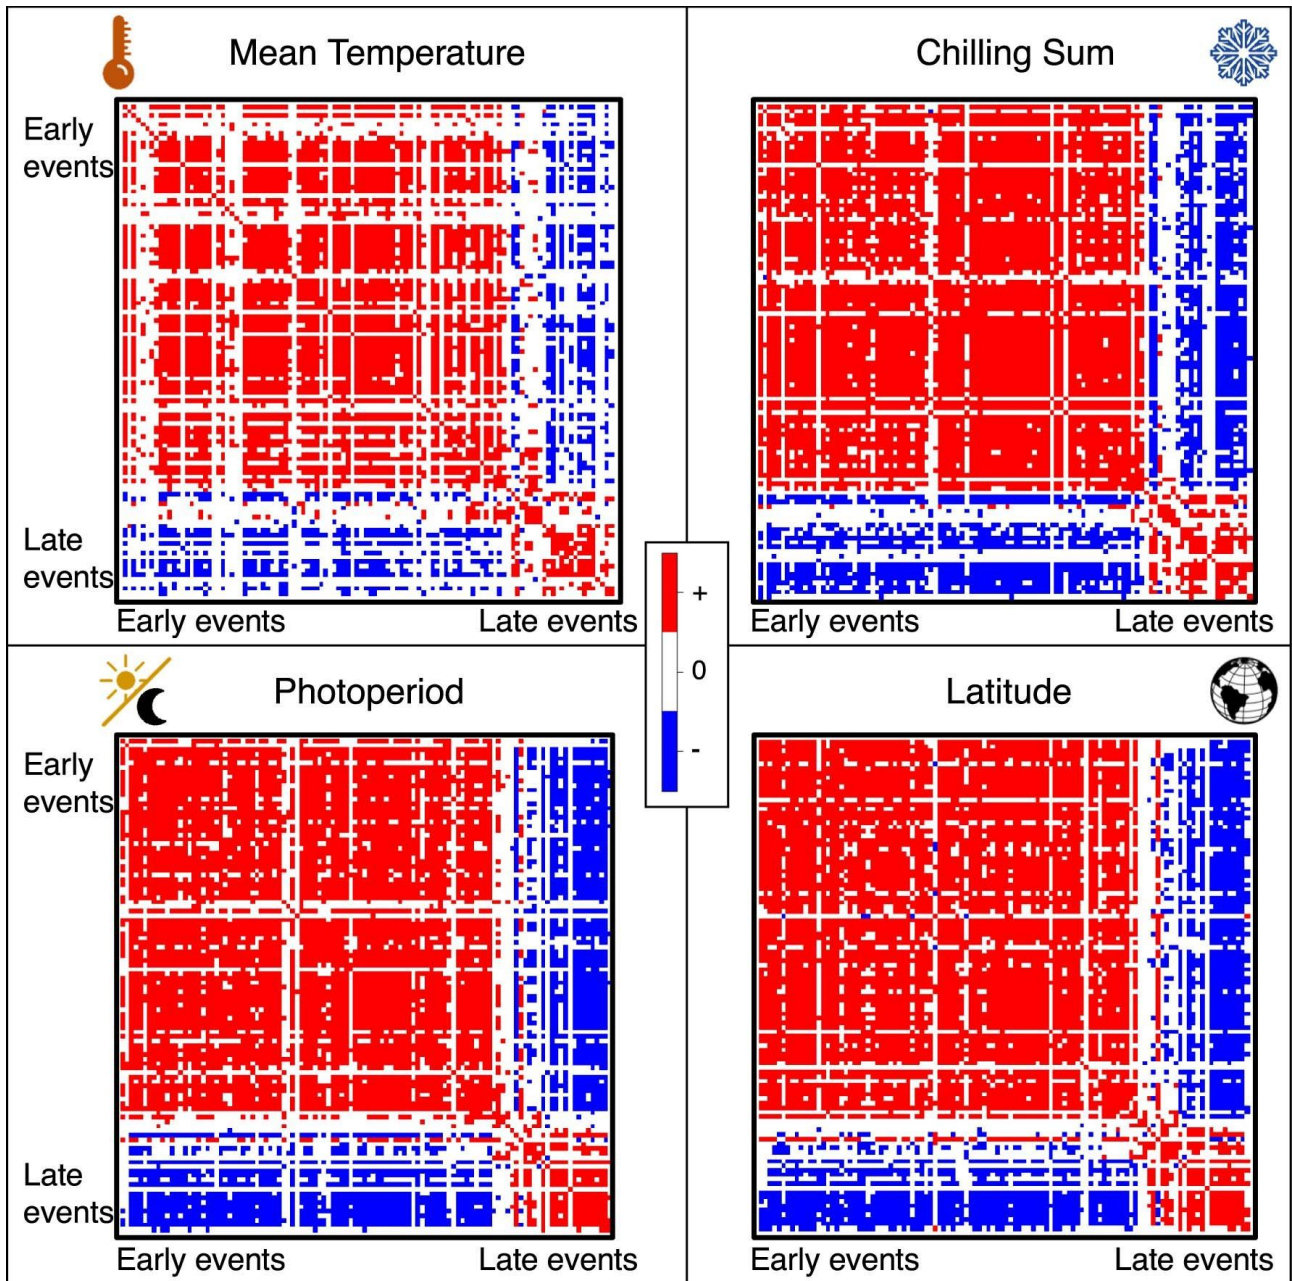

Extended Data Fig. 6: Residual associations among events related to the random effects of the site. Plots show the estimates of associations among events measured by residual correlation at the site level. The events have been ordered according to their mean date (increasing from left to right, and from top to bottom). Event-to-event association matrices identify pairs showing a positive (red) or negative (blue) association, shown only if association has either sign with at least 95% posterior

807   probability (the remaining cases are shown in white). Note that the top-left panel corresponds to

808   Fig. 4a of the main text. Silhouettes adapted from https://thenounproject.com.
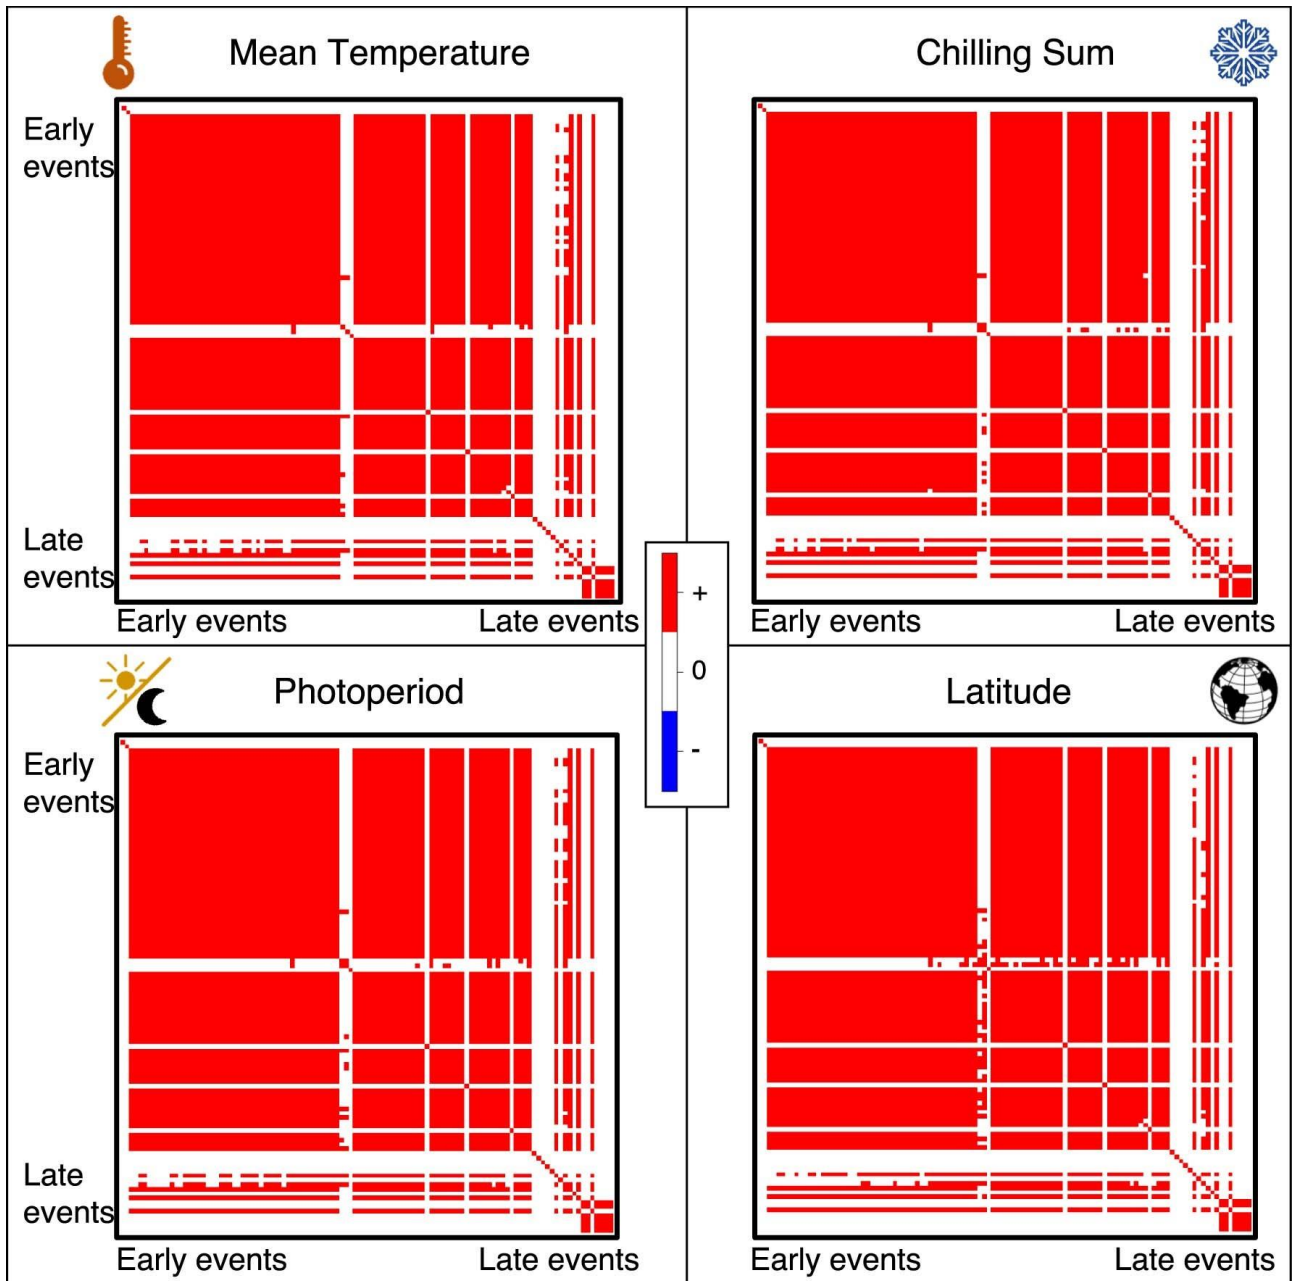

809

Extended Data Fig. 7: Residual associations among events related to the random effects of the year. Plots show the estimates of associations between events measured by residual correlation at the year level. The events have been ordered according to their mean date (increasing from left to right, and from top to bottom). Event-to-event association matrices identify pairs showing a positive (red) or negative (blue) association, shown only if association has either sign with at least 95%

816   posterior probability (the remaining cases are shown in white). Note that the top-left panel

817   corresponds to Fig. 4b of the main text. Silhouettes adapted from https://thenounproject.com.

818

Extended Data Fig. 8: Residual associations among events related to the random effects of the year-site pair. Plots show the estimates of associations among events measured by residual correlation at the level of samples, that is year×site combinations. The events have been ordered according to their mean date (increasing from left to right, and from top to bottom). Event-to-event association matrices identify pairs showing a positive (red) or negative (blue) association, shown only if association has either sign with at least 95% posterior probability (the remaining cases are

826   shown in white). Note that the top-left panel corresponds to Fig. 4c of the main text. Silhouettes

827   adapted from https://thenounproject.com.

Text S1. Classification of phenological events

All events were classified into four trophic levels according to the organism expressing the event: primary producers (plants), primary consumers (herbivorous insects) and secondary consumers (predatory insects, amphibians, birds, mammals). Saprotrophs (fungi) were included as a separate level, as commonly feeding on the remains of multiple other levels, and abiotic events as a separate category. Species classification was based on the basic biology of the juvenile stage. For holometaboulous organisms (such as insects undergoing full metamorphosis), the juvenile stage is typically the one consuming the most resources for growth, and the same applies for birds. Specifically, in classifying all birds as secondary consumers, we note that while some species may be mainly herbivorous as adults, their young are dependent on protein-rich arthropods for growth[1]. Since we expect breeding-time resources to be more decisive for these species' phenology than the needs of the adults, we have used the diet of the young for our trophic classification.

Table S1. Classification of events by taxonomic and trophic position

The table shows the identity of the species and events included in the analyses, with their taxonomic position, trophic level and relative timing (here expressed as the mean Day of the Year when the phenological event first occurred; mean DOY).

Taxon (+ meteo events)	Trophic level	Event scored	Mean DOY
AVES			
Alaudidae			
Alauda arvensis	Secondary consumer	1st song*	93.14
Anatidae			
Anas crecca	Secondary consumer	1st occurrence	119.73
Anas platyrhyncos	Secondary consumer	1st occurrence*	101.64
Cygnus cygnus	Secondary consumer	1st occurrence	107.42
Bucephala clangula	Secondary consumer	1st occurrence	109.81
Apodidae			
Apus apus	Secondary consumer	1st occurrence*	142.78
Charadriidae			
Vanellus vanellus	Secondary consumer	1st occurrence	100.43
Corvidae			
Corvus frugilegus	Secondary consumer	1st occurrence	78.54
Cuculidae			
Cuculus canorus	Secondary consumer	1st song*	127.64
Fringillidae			
Fringilla coelebs	Secondary consumer	1st occurrence*	98.12
Gruidae			
Grus grus	Secondary consumer	1st occurrence	103.00
Hirundinidae			
Hirundo rustica	Secondary consumer	1st occurrence*	124.57
		Last occurrence	259.44
Motacillidae			
Motacilla alba	Secondary consumer	1st occurrence*	103.11
		Last occurrence	271.23

Muscicapidae			
Luscinia luscinia	Secondary consumer	1st song	125.15
Paridae			
Parus major	Secondary consumer	1st song	42.33
Picidae			
Dendrocopos major	Secondary consumer	Start of drumming	46.91
Sturnidae			
Sturnus vulgaris	Secondary consumer	1st occurrence	86.51
FUNGUS			
Boletaceae			
Leccinum aurantiacum	Saprotroph	1st occurrence	179.67
Leccinum scabrum	Saprotroph	1st occurrence	184.60
INSECTA			
Apidae			
Bombus sp	Primary consumer	1st occurrence	118.04
Culicidae			
Culicidae sp	Secondary consumer	1st occurrence	126.78
Formicidae			
Formica rufa	Secondary consumer	Livening up	103.83
Nymphalidae			
Aglais urticae	Primary consumer	1st occurrence	101.22
Pieridae			
Gonepteryx rhamni	Primary consumer	1st occurrence	102.30
MAMMALIA			
Ursidae			
Ursus arctos	Secondary consumer	Awakening	102.49
PLANTAE			
Asparagaceae			
Convallaria majalis	Producer	Onset of blooming	144.47

Caprifoliaceae			
Lonicera caerulea		Onset of blooming	150.41
Ericaceae			
Oxycoccus palustris	Producer	Onset of blooming*	163.29
Ledum palustre	Producer	Onset of blooming	156.75
Vaccinium myrtillus	Producer	Onset of blooming	145.35

		Onset of fruiting (ripe)*	195.23
		Mass fruiting	204.14
Vaccinium vitis-idaea	Producer	Onset of blooming*	162.31
		Onset of fruiting (ripe)	227.44
		Mass fruiting	239.47
Fabaceae			
Caragana arborescens	Producer	Onset of blooming	148.28
Grossulariaceae			
Ribes nigrum	Producer	Onset of blooming*	145.99
		Onset of fruiting (ripe)	205.27
Malvaceae			
Tilia cordata	Producer	Onset of leaf unfolding	129.07
		Onset of blooming*	181.85
Oleaceae			
Syringa vulgaris	Producer	Onset of blooming	150.87
Onagraceae			
Epilobium angustifolium	Producer	Onset of blooming	180.06
Pinaceae			
Pinus sylvestris	Producer	onset of blooming*	153.18
Ranunculaceae			
Caltha palustris	Producer	Onset of blooming	133.70
Trollius europaeus	Producer	Onset of blooming	150.87
Rosaceae			
Fragaria vesca	Producer	Onset of blooming*	144.48
		Onset of fruiting (ripe)	176.94
Prunus padus	Producer	Onset of budburst	114.10
		Onset of leaf unfolding	124.06
		Onset of blooming*	139.22
		Onset of mass blooming	143.10
		Onset of fruiting (ripe)	202.32
		Onset of autumn colouring	221.38
		Onset of leaf fall	232.95
		Leaf fall end	275.01
Rosa acicularis	Producer	Onset of blooming	171.34
Rubus chamaemorus	Producer	Onset of blooming*	154.64
Rubus idaeus	Producer	Onset of blooming*	166.83
		Onset of fruiting (ripe)	205.81
Sorbus aucuparia	Producer	Onset of blooming*	156.06
		Onset of fruiting (ripe)	227.55
Salicaceae			
Salix caprea	Producer	Onset of blooming*	123.08
Populus tremula	Producer	Onset of blooming	115.70
		Onset of leaf unfolding	137.18
		Onset of autumn colouring	241.60
		Onset of leaf fall	248.20
		Full autumn colouring of leaves	263.45
		Leaf fall end	280.00
REPTILIA			
Squamata			
Zootoca vivipara	Secondary consumer	1st occurrence	120.50
METEO			

Thaw		1st thawed patches to an earth surface around trunks of trees	90.00

Text S2. Description of the HMSC model

Hierarchical Modelling of Species Communities (HMSC) is a multivariate generalized linear mixed modelling framework[2,3]. HMSC was primarily developed for community ecology, so that in a typical application the response matrix (**Y**) contains species occurrences or abundances on a set of sampling units (e.g. spatial locations), the environmental predictor matrix (**X**) contains e.g. climatic conditions in those sampling units, and the species trait matrix (**T**) includes species-level traits such as body size. HMSC allows to ask how species occurrences depend on environmental conditions (how **Y** depends on **X**), and how the species responses to environmental variation depend on their traits (how **T** modulates the mapping from **X** to **Y**). Additionally, HMSC includes community-level random effects implemented through latent variables; these allow the modelling of residual (not accounted for species responses to **X**) species associations at different spatiotemporal levels.

Here, we apply HMSC to phenological data, so that instead of species occurrences we include in the response matrix **Y** the dates of the phenological events. In other words, phenological events (e.g. the first arrival of a given bird species) here play the role of "species". In the predictor matrix **X**, we include the climatic conditions of the study locations, as well as the year of the observation, with the latter capturing the trends over time that are the main focus of this paper. In the species trait matrix **T**, we include key characteristics of the phenological events: the mean timing of the event (e.g. to distinguish spring events from autumn events), and the type of event (e.g. to distinguish abiotic from biotic events).

We call a given site-year pair as "sampling unit", and denote by y_{ij} the date at which the phenological event j took place in sampling unit i. Each data point is then the vector $y_{i\cdot}$, where the dot notation stands for the vector of y_{ij} values for all indices j, thus $y_{i\cdot}$ consisting of the dates at which all phenological events took place for the site-year pair i. We modelled the data with the multivariate hierarchical linear mixed model defined as:

$$y_{ij} = \sum_k x_{ik}\beta_{kj} + a_{s(i)j} + b_{t(i)j} + c_{ij} + \varepsilon_{ij}.$$

- Concerning the fixed effects, β_{kj} is the effect of the covariate k on the phenological event j. The covariates included for each sampling unit i were the year, the climatic descriptor of the site, and the interaction between these two. Additionally the model includes the intercept, so $x_{1i} = 1$ for all i.
- Concerning the community-level random effects, $s(i)$ denotes the site and $t(i)$ denotes the year of the sampling unit i. Thus $a_{s(i)j}$ is the random effect of the site, $b_{t(i)j}$ is the random effect of the year, and c_{ij} is the random effect of the sampling unit. Each of these is modelled through the latent variable model described in detail in [2], so that e.g. $a_{sj} = \sum_{h=1}^{n_f^s} \lambda_{hj}^s \eta_{hs}^s$, where n_f^s is the number of factors included at the site level (as indicated by the superscript s), η_{sk}^s is the latent variable k for site s, and λ_{kj}^s is the loading of phenological event j for factor k. We note that the association matrix among the phenological events can be constructed from the loadings λ_{kj}^s as $\Omega_{j_1 j_2}^s = \sum_{h=1}^{n_f^s} \lambda_{hj_1}^s \lambda_{hj_2}^s$; see [2].
- Concerning the residual, we assume a linear model, so $\varepsilon_{ij} \sim N(0, \sigma_j^2)$, where σ_j^2 is the residual variance of phenological event j.

The responses of the phenological events to the covariates were further modelled with a linear regression, using the traits of the events as predictors. The expected response $\mu_{kj} = E[\beta_{kj}]$ was modelled as $\mu_{kj} = \sum_l t_{jl}\gamma_{kl}$ and the realized response with the multivariate normal model as

$\beta._j \sim N(\mu_k., \mathbf{V})$. As the trait predictors t_{jh}, we included the intercept, the mean day of the phenological event, the type of the phenological event, and the interaction between them. To account for the periodic nature of the day of the year, the mean day of the phenological event d was modelled with the predictors $\cos(2\pi d/356)$ and $\sin(2\pi d/356)$. The type of event was implemented as a factor, with the levels of abiotic events, producers, primary consumers, secondary consumers, and saprotophs.

We fitted the models with R-package Hmsc[4] assuming the default prior distribution. For a technical description of the default prior distribution we refer to [4], whereas for an ecological motivation of the default prior distribution we refer to [2]. We performed posterior sampling for four Markov Chain Monte Carlo (MCMC) chains, each of which we sampled for 375,000 iterations, out of which we discarded the first 125,000 as a transient and thinned the remaining by 1000, thus yielding 250 samples per chain and 1000 samples in total. To evaluate MCMC convergence, we examined the distributions of the potential scale reduction factor over the parameters related to the fixed effects (β –parameters) and the random effects (Ω-parameters), equivalent to the Gelman-Rubin statistic[5].

Text S3. Convergence of the Markov chain Monte Carlo (MCMC) scheme used for posterior sampling

For each model we obtained 250 samples for each of the four MCMC chains, and thus in total 1000 samples. The 250 samples for each chain were obtained by running the MCMC for 375*thin iterations, out of which 125*thin were discarded as transient, and the remaining 250*thin iterations were then evenly thinned to yield 250 samples. We applied thin=1, 10, 100, 1000 to check which level of thinning was sufficient to ensure satisfactory convergence. We assessed MCMC convergence by computing the effective number of samples and the potential scale reduction factor. These are shown in Fig. S3 for the beta-parameters of the HMSC model[4], which parameters measure the responses of the species to the included covariates. As the majority of the potential scale reduction factors are close to one and the effective sample size is close to the actual sample size of 1000, we conclude the MCMC convergence was satisfactory.

Figure S1. MCMC convergence statistics, measured as potential scale reduction factors and effective sample sizes.

Each boxplot shows the distribution of values over the species-specific beta-parameters for models that include the mean annual temperature (T), latitude (L), photoperiod (P) or chilling sum (C) as the climatic predictor.
