2
3 34 **Extreme weather events have become a dominant feature of the narrative surrounding**
4
5 35 **changes in global climate with large impacts on ecosystem stability, functioning and**
6
7 36 **resilience, however, understanding of their risk of co-occurrence at the regional scale is**
8
9 37 **lacking. Based on the UK Met Office's long-term temperature and rainfall records, we**
10
11 38 **present the first evidence demonstrating significant increases in the magnitude, direction**
12
13 39 **of change and spatial co-localization of extreme weather events since 1961. Combining**
14
15 40 **this new understanding with land use datasets allowed us to assess the likely consequences**
16
17 41 **on future agricultural production and conservation priority areas. All land uses are**
18
19 42 **impacted by the increasing risk of at least one extreme event and conservation areas were**
20
21 43 **identified as hotspots of risk for the co-occurrence of multiple event types. Our findings**
22
23 44 **provide a basis to regionally guide land use optimisation, land management practices and**
24
25 45 **regulatory actions preserving ecosystem services against multiple climate threats.**

32

33 47 Recent large flood and drought events have received global media attention. For example,
34
35 48 unprecedented winter rainfall across the UK in 2013/14 resulted in extreme flooding and storm
36
37 49 surges with large areas of agricultural land under water for more than 80 days^[1], while over
38
39 50 60% of the state of California's land area was under varying severity of drought from 2011 to
40
41 51 2017^[2]. Flooding and drought can have large economic impacts; the World Economic Forum
42
43 52 has rated extreme weather events as the most significant risk facing humanity^[3]. Losses to the
44
45 53 UK agricultural sector of £180 million were reported as a result of the 1995 drought and
46
47 54 associated heatwave^[4], while the 2013/14 flood led to losses of over £20 million^[1]. Similarly,
48
49 55 the total economic impact of the European heatwave in 2013 was estimated at 11 billion
50
51 56 Euros^[4], while extreme snow was estimated to cost the US economy up to \$3 billion in 2016^[5].
52
53
54
55 57 Natural ecosystems are also vulnerable, for example, record heat and dry conditions in
56
57 58 2010/2011 led to a sudden collapse of large areas of Australian eucalypt forest previously
58
59
60

1
2
3 59 considered to be resilient to drought^[6]. Furthermore, the hot and dry conditions of 2018-19 in
4
5 60 the UK resulted in unprecedented wildfires in the globally rare moorland habitat with 135
6
7 61 individual fires burning 29,334 ha of land^[7]. In 2019, hot and dry conditions in Australia
8
9 62 resulted in the generation of mega-fires of unprecedented size and number covering at least 3.8
10
11 63 million ha of temperate forest^[8]

12
13
14 64 While there is a wealth of evidence that temperatures are increasing, the pattern for
15
16 65 rainfall is uncertain^[9] but predicted to become temporally uneven with the majority of annual
17
18 66 precipitation totals occurring in a small number of intense events^[10]. For many regions of the
19
20 67 UK, climate models and historical observations indicate that the frequency, intensity^[11-13] and
21
22 68 duration^[14] of winter rainfall has increased, along with the incidence and intensity of short burst
23
24 69 summer downpours^[12] and the kinetic energy of autumn rainfall^[15]. Models also predict an
25
26 70 increase in the frequency of short-term droughts of three to six months in duration^[16]. These
27
28 71 all have implications for agriculture, conservation and human health.

29
30
31 72 To date, the majority of studies investigating the risk of extreme weather events have
32
33 73 focused on the global or continental scales, and often only on a single event type^[17]. There is
34
35 74 greater uncertainty in changes at the regional scale where the immediate impacts will be felt
36
37 75 ^[18]. Spatial variation in weather patterns can be large and analysis at the national scale masks
38
39 76 regional differences in the risk of occurrence and the expected event type^[19]. Furthermore,
40
41 77 extreme events might not occur in isolation and there are an increasing number of examples of
42
43 78 direct transitions from one extreme weather regime to another (e.g. flood to drought or *vice*
44
45 79 *versa*)^[20-22]. In the UK, heavy spring rainfall in 2012 led to 78 days of flooding, while 98 days
46
47 80 of official drought were declared the following summer which the media dubbed ‘the wettest
48
49 81 drought on record’^[23]. In 2019 there were 5,600 flood warnings across England while
50
51 82 groundwater reserves were depleted in 25 areas^[24]. Such events have highlighted the need for
52
53 83 stakeholders, including farmers, water companies, forestry and environmental protection and
54
55
56
57
58
59
60

1
2
3 84 conservation bodies to prepare for the possibility of both flooding and drought within the same
4
5 85 year. The combination of more than one extreme events has been termed as ‘compound events’
6
7
8 86 in the literature and these compound events have been identified by the World Climate
9
10 87 Research Program as a research priority^[25]. Importantly, they are likely to have
11
12 88 disproportionately severe impacts on ecosystems, potentially tipping ecosystem functions into
13
14
15 89 new trajectories^[26].

16
17 90 To safeguard vulnerable ecosystems and the services they provide, adaption in
18
19 91 management may be required. However, the specific strategy employed will vary depending
20
21 92 on the event type. For example, the re-introduction of grazing livestock to moorland could
22
23 93 reduce fire risk during dry, hot summers but could also increase the risk of compaction during
24
25
26 94 wet periods increasing subsequent flood risk. Similarly, planting trees to sequester carbon may
27
28 95 increase fire risk under dry conditions leading to a potential reduction in air quality, water
29
30 96 quality and human health if planted in the wrong place^[27].

31
32
33 97 To advise stakeholders and guide policy we need to understand the regional risk posed
34
35 98 by different (single and multiple) extreme events and identify where they might impact delivery
36
37 99 of ecosystem services (e.g. food security, biodiversity, carbon storage) by different land-use
38
39 100 types. In this study, we utilised the historical UK weather record held by the UK Met Office
40
41
42 101 National Climate Information Centre to examine, for the first time, the change in frequency
43
44 102 and distribution of, and interaction between, indicators of four weather extremes; extreme heat,
45
46 103 extreme cold, high rainfall and low rainfall, based on thresholds indicative of heatwaves, cold
47
48 104 snaps, floods and droughts, between two time periods 1961-1988 and 1989-2016. We
49
50 105 integrated the results from this analysis with national land cover data to identify extreme
51
52 106 weather hotspots in relation to ecosystem type and their ability to deliver different ecosystem
53
54 107 services.
55
56
57
58
59
60

1
2
3 108 These datasets were statistically interrogated to answer four key questions: (1) Has the
4
5 109 frequency of extreme events in the UK increased between the two time periods? (2) Are there
6
7 110 hotspots where the annual risk of occurrence for two or more event types has increased? (3)
8
9 111 Are there areas of the UK where the probability of occurrence of two or more types of event
10
11 112 *within the same year* has increased? and (4) Are some vulnerable ecosystems more exposed to
12
13 113 changes in risk of increased numbers of events than others?
14
15
16

17 114 Through this analysis, we provide evidence for the perceived increase in the frequency
18
19 115 of extreme events across the UK. To date, most studies of this nature have focused on the
20
21 116 incidence, or impact, at the national scale. Our results show strong regional variation in the
22
23 117 direction and magnitude of change enabling the production of national risk maps which can be
24
25 118 used by stakeholders to guide land management and policy that promotes adaptation to protect
26
27 119 the delivery of ecosystem services.
28
29
30

31 120 Our analysis shows that between the two 28-year periods of high resolution
32
33 121 meteorological records there has been a notable change in the frequency of threshold
34
35 122 exceedance across the UK with strong regional response patterns (Fig. 1). Temperature metrics
36
37 123 showed the largest and most widespread response but the direction of change varied. For
38
39 124 extreme heat events, there was a significant increase in the mean number of events during the
40
41 125 last 28 years, with the south-east of England experiencing the largest change, corresponding to
42
43 126 on average 1.87 additional events each year. Significant increases (0.68–1.36) in the mean
44
45 127 number of extreme events also occurred across most of England, except the north-west and
46
47 128 across the east of Northern Ireland, and the far north of Scotland. Concurrently, the frequency
48
49 129 of extreme cold events decreased across all regions except for much of Wales and small regions
50
51 130 of south-west England and northern Scotland. The magnitude of change was greater than that
52
53 131 for heat extremes, ranging from 1–2.3 fewer events each year. Response patterns in rainfall
54
55 132 extremes were weaker than for temperature; this is consistent with the large body of research
56
57
58
59
60

1
2
3 133 showing mixed results for predicted changes in rainfall patterns across the globe^[15]. The
4
5 134 interaction and feedback cycles between the land and atmosphere lead to complex changes in
6
7
8 135 rainfall pattern^[17]. Soil moisture-temperature interactions drive rainfall patterns leading to both
9
10 136 prolonged increases and decreases in rainfall depending on the climate and environmental
11
12 137 conditions^[28]. Despite this, the results show a significant increase in wet extremes ranging
13
14 138 from 1.0 - 1.6 additional events each year in western Scotland to 0.8 - 1.0 additional events in
15
16 139 the Welsh border region, along parts of the south coast of England and East Anglia, and in
17
18 140 western Northern Ireland. The change in extreme dry events was small with no significant
19
20 141 increase overall and a decrease of 0.9 events in the far north for Scotland. However, a strong
21
22 142 spatial pattern in did emerge, reflecting the changes in heat events with an increase of up to 0.5
23
24 143 events in south-east England.

25
26
27
28 144 These changes in threshold exceedances for temperature and rainfall provide statistical
29
30 145 evidence underpinning the perceived increase in UK heatwaves, floods and droughts over the
31
32 146 past decade and provide insight into which regions are most at risk. While the changes in
33
34 147 temperature drivers relate directly to heat waves or cold snaps, the use of precipitation as a
35
36 148 proxy for flood or drought events is less robust. However, an increase in extremely wet periods
37
38 149 in Scotland, parts of southern England and Wales and Northern Ireland will heighten flood risk.
39
40 150 Furthermore, runoff extremes have been shown to increase more quickly than precipitation
41
42 151 extremes in a warming climate, and increases in rainfall are likely to underestimate the risk of
43
44 152 flash flood events^[29]. These results corroborate the recent analysis of observed river discharge
45
46 153 trends between 1960 and 2010 which found the largest increase in flood discharge in these
47
48 154 areas^[26]. Similarly, drought risk is a function of both rainfall and temperature with prolonged
49
50 155 high temperatures exacerbating soil dryness and providing feedback loops further reducing
51
52 156 rainfall, increasing surface temperatures and promoting fire risk^[30]. Seasonal analysis of
53
54 157 changes in extreme dry events revealed that the greatest change occurs during spring (Fig. S1)

1
2
3 158 when new season growth begins, a vital period for sufficient soil moisture supply for
4
5 159 agricultural crops. Spring drought has been shown to be more detrimental to plant production
6
7
8 160 compared to summer drought conditions across a range of ecosystems^[31]. Increases in dry
9
10 161 spring events may be exacerbated by a spatially coupled increase in the number of periods of
11
12 162 suitable winter growing conditions utilising water reserves built up during preceding wetter
13
14 163 seasons (Fig. 2). Whilst not statistically significant (at $p < 0.05$), the indicative combination of
15
16 164 i) increased dry events with ii) an increase in heat events, and iii) increased winter growing
17
18 165 periods, points towards a heightened drought risk in the future, especially in the south-east of
19
20 166 England where these metrics showed the greatest increase. Furthermore, the probability that a
21
22 167 heat event and a dry event will occur within the same year was high and ranged from 0.80 to
23
24 168 0.98 in this area (Fig. S2). Although the evidence for increased extreme dry events, from this
25
26 169 analysis is weak, it corroborates recent modelling indicating high drought vulnerability in the
27
28 170 East of England based on reported historical agricultural impacts^[32]

33 171 The environmental impact of this increased frequency in extreme events depends on
34
35 172 the land use and the biodiversity and ecosystem services it is expected to deliver. The response
36
37 173 may vary, in magnitude and direction, based on the type of ecosystem and the dominant
38
39 174 services it provides (Table 1, Table S1). We grouped the UK land cover categories^[33] into four
40
41 175 broad classes each providing specific ecosystem services and levels of biodiversity: (1)
42
43 176 Agriculture, incorporating arable/horticultural and improved grasslands (provisioning), (2)
44
45 177 Woodlands, incorporating broadleaf and coniferous woodlands (provisioning, regulating and
46
47 178 biodiversity), (3) Conservation, incorporating National Parks and Sites of Special Scientific
48
49 179 Interest (SSSIs) (supporting regulating and biodiversity), (4) Carbon stores, incorporating
50
51 180 heathland, heath grasslands and bogs (regulating). It is important to acknowledge that exposure
52
53 181 to extreme events is occurring under an environment characterised by chronic changes in the
54
55 182 long-term climate. Well documented increases in mean annual temperatures and CO₂ levels
56
57
58
59
60

1
2
3 183 influence the resilience of the system to sudden stress events. This interaction may lead either
4
5 184 a reduction or enhancement of the impact on ecosystem service provision outlined in Table 1
6
7
8 185 and resource managers need to be prepared for unexpected response patterns^[34].
9

10 186 The reduction in frequency of cold events (i.e. less frosts and snow) shows an impact
11
12 187 across all ecosystem types, ranging from 64% of all the land in SSSIs to >80% of the total area
13
14 188 under arable land use, respectively. Simplistically, if current trends continue, it might be
15
16 189 assumed that a reduction in winter cold events would be beneficial. However, many plants rely
17
18 190 on low winter temperatures for vernalisation and warmer winters can cause increased pest and
19
20 191 disease risk, loss of cold acclimation, asynchronicity of biological lifecycles and increased
21
22 192 runoff (Table 1).
23
24
25

26 193 Agricultural systems and broadleaf forests represented the largest proportion of the total
27
28 194 land area at increased risk of extreme heat events and the arable sector in particular appears to
29
30 195 be the most affected with 83% of the total area at risk (Fig. 3a). This reflects the large
31
32 196 dominance of arable land use in the East of England. Furthermore, recent research suggests
33
34 197 that heat extremes have a larger impact on grain yields than extremes in precipitation,
35
36 198 highlighting the risk to arable systems^[35] and, hot dry spells can influence agricultural water
37
38 199 use, especially under cropping. In the period between 2000 and 2017, the highest 2 years for
39
40 200 abstraction for the purpose of spray irrigation correspond with the lowest 2 years of annual
41
42 201 levels of rainfall^[36]. Temperature extremes also dominated in improved grasslands, with 56%
43
44 202 of the total area exposed to increase risk of extreme heat which directly impacts on livestock
45
46 203 production. However, the proportion of grassland exposed to increases in extreme rainfall, and
47
48 204 therefore flooding, was greater than in arable systems. Soil carbon (C) stores and coniferous
49
50 205 forests currently appear to be most at risk of extreme rain and flooding, with increased
51
52 206 frequency of events occurring across 35–55% of the total area. Forests are commonly proposed
53
54 207 as mitigation strategies to reduce flood risk through interception of rainfall and increased soil
55
56
57
58
59
60

1
2
3 208 infiltration^[37]. However, extreme rainfall events often override this increased infiltration
4
5 209 capacity and the potential to reduce the severity of major floods is limited^[38]. When flooding
6
7 210 does occur, the impact can be severe in commercial forestry operations with largescale erosion
8
9 211 and damage downstream from woody debris. For soil C stores, reduced extreme cold and
10
11 212 extreme rainfall present the largest risk. Continuation of this trend will have large implications
12
13 213 for the C cycle and is likely to increase the release of soil C and decrease sequestration through
14
15 214 increased wet-drying cycles, microbial respiration and erosion losses^[39-43] (Table 1). Our
16
17 215 analysis also indicates that large expanses of upland bog or lowland fen peat are located in
18
19 216 regions experiencing higher temperatures, droughts and therefore potential fire risk. These
20
21 217 events threaten to exacerbate greenhouse gas emissions and destabilization of terrestrial C
22
23 218 stores.

24
25
26
27
28 219 Specific regions of the UK show a significant increase in frequency of more than one
29
30 220 extreme event type (Fig. 4). Risk hotspots, with significant increased frequency of three
31
32 221 threshold exceedances are identified along the south coast of England, areas in the Welsh
33
34 222 borders and the north-east of England, highlighting areas most at risk of unexpected ecosystem
35
36 223 response and largescale impacts on function (Table 1). Land of high nature value appears to be
37
38 224 at most risk of multiple extreme event types with all three stress indicators increasing in
39
40 225 frequency in 24 and 21% of the total area covered by National Parks and SSSIs (Fig. 3b). Due
41
42 226 to the importance of these sites as niche habitats for rare or endangered species these trends
43
44 227 could lead to severe impacts on biodiversity. This was seen following the 1995 UK drought
45
46 228 which led to a shift in butterfly communities from vulnerable specialised species to widespread
47
48 229 generalist species^[44].

49
50
51
52
53 230 Exposure to an extreme event can make ecosystems more susceptible to a subsequent
54
55 231 stress, magnifying impacts^[45-47] with the potential to decrease the threshold by which climatic
56
57 232 metrics, such as precipitation amount, generate an extreme event^[48]. Our results show that the
58
59
60

1
2
3 233 overall UK mean increase in the probability of all four event types occurring with the same
4
5 234 year low at 0.275. However, the impact on ecosystem function would likely be extreme. The
6
7
8 235 increase in frequency of extreme heat events was the dominant driver of the response pattern,
9
10 236 with the highest probabilities in the south-east of the UK and the lowest probabilities in
11
12 237 Scotland, Wales, Northern Ireland and north-west England (Table S2; Fig. S2).

14 238 To illustrate the impact on agriculture, we have taken the UK arable sector as a case
15
16
17 239 study since the combination of adverse weather conditions can magnify the impacts on
18
19 240 production. In particular, the combination of extreme wet spells and extreme dry spells within
20
21 241 the same year has been shown to be particularly detrimental for crops. In 2017, there was an
22
23 242 8.3%, 17% and 19% reduction in income in England from three key crops, wheat, sugar beet
24
25 243 and potatoes, respectively. This was attributed, in part, due to reduced yields caused by wet
26
27 244 spring conditions, hot dry summer and heavy autumn rains during harvest^[49]. Reductions in
28
29 245 yields reduced the export value of wheat by 73% and 84% in 2017 and 2018 respectively, and
30
31 246 increased the import expenditure by 38% and 79%^[50]. The majority of the UK's arable and
32
33 247 horticultural land area is in the East of England, with 28% of total wheat production and 62%
34
35 248 of sugar beet production located in the South East, and East Anglia accounting for one third of
36
37 249 England's potato crop^[49]. The probability that extreme hot, dry and wet events will occur
38
39 250 within the same year is highest for this region of the country and ranges from 0.69–0.99 (Fig.
40
41 251 S2) highlighting the vulnerability of this sector to future climatic risk.

42
43
44
45 252 Globally, societies are facing unprecedented and complex threats to food and water
46
47 253 security, infrastructure and well-being due to climate change. Continuation of the increased
48
49 254 frequency of multiple extreme events across different land uses identified by our analysis is
50
51 255 having detrimental impacts on the ecosystem service provision. While some benefits to service
52
53 256 provision have been identified, these are likely to be out-weighted by the negative impacts
54
55 257 (Table 1). Furthermore, there is a large degree of uncertainty around whole system response
56
57
58
59
60

1
2
3 258 and the interplay between the delivery of different ecosystem services, especially in the context
4
5 259 of multiple extreme event exposure and gradual climate change. Natural systems are
6
7 260 consistently surprising researchers with unexpected responses to perturbation with increasing
8
9 261 documented examples of systems exhibiting regime shifts dramatically changing ecosystem
10
11 262 function^[51-54].
12
13

14 263 In May 2019, the UK government declared a state of climate emergency that was
15
16 264 swiftly followed by Ireland, France and Canada. Furthermore, large-scale land use change has
17
18 265 been identified as a strategy for the UK to meet its emission reductions in the Paris
19
20 266 Agreement^[55], and its recent target of net zero emissions by 2050. The evidence herein provides
21
22 267 vital information on the vulnerability of different areas and economic sectors to climate
23
24 268 extremes and should be used by UK policy makers, farm advisers and environmental agencies
25
26 269 to develop adaption strategies and land use change policy tailored to the specific extreme event
27
28 270 threat, based on location and ecosystem type. This research highlights the importance of
29
30 271 considering the change in exposure of land to (combinations of) extreme weather at the regional
31
32 272 scale and adoption of a similar approach in other countries could inform the safeguarding of
33
34 273 the vital ecosystem services on which society depends, or adapt to a new normal.

275 **Methods**

276 **Dataset used in this study**

277 We used the 5 km scale historical UK weather record held by the UK Met Office's National
278 Climate Information Centre^[56]. This gridded dataset covers the whole of the UK and includes
279 daily maximum and minimum temperature and rainfall data from observation stations from
280 1960 to 2016.

281 We developed indices relating to the risk of occurrence of four extreme weather
282 events;(i) heat waves, (ii) cold snaps, (iii) extreme rainfall (flood), and (iv) low rainfall
283 (drought). We employed a threshold approach and for each grid point extracted the frequency
284 each year that the five day rolling mean temperature or rainfall exceeded this threshold for a
285 set number of days. We split the resulting dataset into two 27 year time periods, 1961–1988
286 and 1989–2016, reflecting the Met Office's definition of long-term averages for weather data
287 of 30 years^[57], while keeping two discrete time periods of equal length.

289 **Setting extreme weather thresholds**

290 With the exception of the index relating to drought, thresholds were set based on deviation
291 from the mean value of the whole dataset for each grid point. Maximum daily temperature or
292 rainfall above the 95th percentile and minimum daily temperatures below the 5th percentile were
293 considered extreme^[58]. Temperature and rainfall conditions are spatially variable across the
294 UK and utilising percentiles as the threshold instead of a fixed value allows for regional
295 variation in normal conditions. What is considered an extreme temperature or rainfall amount
296 in one location may be relatively normal for another and it is likely that the largest impact on
297 ecosystem function occurs when conditions are outside the norm rather than at a fixed value^[59].

298 Using this approach, the following thresholds were proposed as an event metric for
299 extreme heat, cold and rainfall based on recommendations provided in the draft guidelines on
300

1
2
3 300 the definition and monitoring of extreme weather and climate events produced by the World
4
5 301 Meteorological Organization (WMO)^[58].

6
7
8 302 *Heat*: The number of times each year where the 5-day rolling mean of the maximum
9
10 303 temperature exceeds the 95th percentile of the whole dataset for 3 or more days.

11
12 304 *Cold*: The number of times each year where the 5-day rolling mean of the minimum
13
14 305 temperature is below the 5th percentile of the whole dataset for 3 or more days.

15
16
17 306 *Extreme rainfall*: The number of times each year where the 5-day rolling mean of the daily
18
19 307 rainfall total is above the 95th percentile for 3 or more days.

20
21 308 *Low rainfall*: The number of times each year where the 5-day rolling mean of total daily
22
23 309 precipitation was below 1 mm for 14 days or more, based on a historical definition of
24
25 310 agricultural drought used in Britain of rainfall below 1 mm for more than 15 days^[60].

26
27
28 311 For this study, extreme rainfall was used as a proxy for flood risk. While it is recognised
29
30 312 that flood generation encompasses many complex variables, including the hydrology and
31
32 313 topography of the landscape, we focus on rainfall totals as an indicator of the change in risk
33
34 314 potential. Daily rainfall totals in the preceding 0 to 3 days was shown to be the best predictor
35
36 315 of river flood events across the Swiss Alps^[61]. In the UK the total rainfall over 3 days was
37
38 316 linked to 40 year maximum peak river discharge and recorded flood events in 3 out of 4 studied
39
40 317 river catchments^[62]. In China, persistent extreme precipitation events, considered to indicate
41
42 318 high damage potential were defined as daily precipitation total above 50 mm for 3 or more
43
44 319 days^[63]. Similarly to the flood index, we used rainfall as a proxy indicator for drought risk. Soil
45
46 320 moisture deficit is the main parameter controlling the ecosystem response to drought.
47
48 321 Unfortunately, this has not routinely recorded at the same temporal or spatial scale as
49
50 322 temperature and rainfall. However, prolonged dry spells, rather than a deviation from the
51
52 323 minimum rainfall long-term average are likely to be more significant in reducing soil moisture
53
54 324 content and increasing risk of drought. Future research looking at predicting future extreme
55
56
57
58
59
60

1
2
3 325 events may be able to take advantage of new remote sensing methods and planned satellite
4
5 326 programs to measure soil moisture more accurately.
6
7

8 327

9
10 328 **Data analysis**

11
12 329 To investigate how the risk of each event type occurring within a year has changed between
13
14 330 the two time periods, we plotted the change in the number of events between 1961–1988 and
15
16 331 1989–2016 on a gridded map of the UK, using output from the following model:

17
18
19 332 *Single extreme weather event models:* Generalized Additive Models or GAMs^[64] were
20
21 333 adopted as the modelling framework to characterise the trends in extreme event frequency. This
22
23 334 well-established class of models allows for flexible characterisation of the spatio-temporal
24
25 335 variability of a modelled environmental variable and has been used extensively to characterise
26
27 336 natural hazards^[65] and in modelling environmental variables more generally^[64]. The data
28
29 337 extracted relates to counts of events $y_{s,t}$ in grid cell s and year t . To capture the variability of
30
31 338 these counts in space and time, we assume a Poisson distribution with mean $\mu_{s,t}$: the mean
32
33 339 count in cell s and year t . This mean is then characterised as a function of s and t in the
34
35 340 following way:

36
37
38 341
$$\log(\mu_{s,t}) = \mu_0 + f_T(t) + f_S(s) + f_{S,T}(s,t)$$

39
40
41 342 The three unknown functions $f(\cdot)$ were all assumed smooth in the sense of capturing spatial
42
43 343 and temporal variation that does not change too extremely in neighbouring locations or points
44
45 344 in time. Much more extreme variation was captured by the random element of the model (i.e.
46
47 345 the Poisson variability). The one dimensional function $f_T(t)$ of time (in years) was used to
48
49 346 capture the overall temporal trend in the counts across space, whereas $f_S(s)$, a two-dimensional
50
51 347 function of longitude and latitude was used to capture overall spatial variability (across time).
52
53 348 Lastly, the three dimensional $f_{S,T}(s,t)$ captured spatio-temporal variability, in the sense of
54
55 349 allowing for different spatial patterns for each time point (year). This captured inter-annual
56
57
58
59
60

1
2
3 350 variability in the spatial patterns exhibited by $y_{s,t}$. Such models were estimated using the
4
5 351 statistical language R^[66] and the package mgcv^[66].

7
8 352 Note that the Poisson distribution is a well-established choice for characterising count data^[67].
9
10 353 Moreover, it is loosely motivated by extreme value theory, as the distribution that describes the
11
12 354 rate of occurrence of exceedances above a high threshold^[68].

14
15 355

16
17 356 The model was used to estimate event counts $y_{s,t}$ using the simulation from the
18
19 357 predictive distribution $p(y_{s,t})$. This distribution captures both the Poisson variability in the
20
21 358 counts as well as the uncertainty in estimating the three unknown functions. From this, we
22
23 359 computed the distribution of the difference in mean counts between the two time periods, i.e.
24
25 360 mean count in 1989-2016 less the mean count in 1961-1988. This difference was plotted as a
26
27 361 Z score in figure 1 and figure 2 and figure S1. Probabilities where this difference is not zero at
28
29 362 the 5% significance level are termed significant (analogous to a p value < 0.05).

30
31
32
33 363 The impact of rainfall on soil moisture is controlled to some extent by seasonality of
34
35 364 resource use. Additionally, the impact of soil moisture deficit on plant response is related to
36
37 365 growth stage. Therefore, we also investigated the change in dry spells at the seasonal time
38
39 366 scale. To do this, we split each year into four, three-month time periods; Spring (March, April,
40
41 367 May), Summer (June, July, August), Autumn (September, October, November) and Winter
42
43 368 (December, January, February), and carried out the above data analysis on the defined
44
45 369 threshold for low rainfall in each season.

46
47
48
49 370

51 371 **Multiple event interactions**

52
53 372 To investigate how the potential for the interaction of different extreme events types has
54
55 373 changed, we employed two methods to answer two slightly different questions.

- 1
2
3 374 1. Are there areas of the UK where the annual risk of occurrence at an individual grid
4
5 375 point has increased between the two time periods (1961–1988 and 1989–2016) for two
6
7
8 376 or more of the classes of extreme event?
9

10 377 To investigate this question we overlaid the grid points from the single event analysis to
11
12 378 determine those points where there was a significant increase in two or more event metrics.
13

- 14 379 2. Are there areas of the UK where the risk of two or more different types of extreme
15
16
17 380 event occurring at an individual grid point within a single year has increased between
18
19 381 the two time periods?
20

21 382 To investigate this question we extended the methodology used for the single events to allow
22
23 383 for dependence between them, and investigated how the probability of events of two or more
24
25 384 types occurring within a single year has changed over the two time periods.
26
27
28 385

30 386 **Multiple extreme weather event models**

31
32
33 387 To quantify the correlation between the counts of the various stress events we used the single
34
35 388 event models to detrend the data for each event metric and create a transformed data set which
36
37 389 does not exhibit spatio-temporal variability. Using the transformed data, the dependency across
38
39 390 the various event metrics was quantified using correlation. The single event Poisson models
40
41 391 were used to transform the original data $y_{s,t}$ (for each stress) to the scale of a Gaussian random
42
43 392 variable with mean zero and variance one. At that scale, all spatial and temporal variability has
44
45 393 been factored out and the sample correlations between the transformed counts for each event
46
47 394 are estimates of the dependency between each event. The Appendix provides a more detailed
48
49 395 description of this approach.
50
51
52
53

54 396 A modified simulation technique was employed to sample from the predictive
55
56 397 distribution of the counts for each event, allowing for the correlation between them. Firstly, we
57
58 398 generated random samples of the data at the detrended scale, respecting the correlation between
59
60

1
2
3 399 the event metrics at this scale. Then, we transformed these samples back to original scale of
4
5 400 the data to obtain a set of simulated counts in each grid cell and year, thus maintaining both the
6
7 401 spatio-temporal variability in each event but also the correlation between event metrics.
8
9

10 402 The thresholds were set as the sample mean of each event metric across all grid cells
11
12 403 and years. The joint probability that the annual mean count of two or more event categories
13
14 404 exceeds a particular threshold was then determined. Comparison of differences in these
15
16 405 probabilities between 1961–1988 and 1989–2016 lie in the region between -1 and 1, and
17
18 406 conveys information about whether the risk of two or more stress events occurring within one
19
20 407 year has increased. Significant changes are ones that are above 0.05 or below -0.05.
21
22
23
24 408

25 26 409 **Spatial mapping of the extreme weather event datasets**

27
28
29 410 Data were exported from R as ascii text files with grid cell centroid locations provided as
30
31 411 absolute integer coordinates in British National Grid projection to facilitate import into ArcGIS
32
33 412 10.5 for visualisation and further analyses. Null values (NA) representing offshore locations
34
35 413 were recoded to (-9999), ensuring compliance with numeric format prior to import. The point
36
37 414 locations were plotted and then spatially joined to a pre-calculated vector 5 km grid, whereupon
38
39 415 joined null values and their corresponding grid squares were identified and removed. The
40
41 416 resulting datasets were then used to create thematic maps.
42
43
44

45 417 Geoprocessing (clipping) was used to extract underlying published land cover data^[33].
46
47 418 The resulting land cover data required planimetric areas to be re-calculated, and these were
48
49 419 subsequently summarized by ecosystem type and aggregate area.
50
51

52 420 Where the analyses had revealed significant change, a field attribute selection was used
53
54 421 to identify the corresponding grid squares, extracted, and then exported as separate geospatial
55
56 422 datasets. To facilitate further quantification of land cover types affected, the boundaries
57
58 423 between resulting significant grid squares were dissolved, so that only the perimeters of
59
60

424 aggregated squares remained. These two datasets were combined to produce a map for each of
 425 the four land cover categories overlain with areas of significant increase in frequency of each
 426 extreme event metric.

3 626 **Appendix: Mathematical description of transforming the data to a Gaussian scale using**
4 627 **the fitted Poisson models.**
5
6 628

7 629 The idea behind this approach was to first model the marginal spatio-temporal behaviour of
8 630 our count random variables, say $y_{s,t}$ and $z_{s,t}$ (using only two for brevity without loss of
9 631 generality). We then transformed the data so that this spatio-temporal behaviour was no longer
10 632 present, and quantified any dependence between $y_{s,t}$ and $x_{s,t}$ that is not due to spatial proximity
11 633 or temporal similarity (such as effects from climate indices such as the NAO).
12
13 634

14 635 Here, the marginal models are all Poisson GAMs with probability mass function $p(y_{s,t};\mu_{s,t}) =$
15 636 $e^{-\mu_{s,t}}\mu_{s,t}^{y_{s,t}}/(y_{s,t}!).$ The cumulative distribution function (cdf) is given by $F(y_{s,t};\mu_{s,t}) = \Pr ($
16 637 $Y_{s,t} \leq y_{s,t};\mu_{s,t}),$ which is the left tail area probability. After fitting the models, we generated
17 638 estimates of $\mu_{s,t}$ for any s and t and transformed the observed data to a probability scale $[0,1]$
18 639 using $u_{s,t} = F(y_{s,t};\mu_{s,t}).$ This technique is known as the probability integral transform or PIT⁶⁹.
19 640 If the model is a good description of the data, then $u_{s,t}$ will have a Uniform distribution in $[0,1],$
20 641 meaning that all the spatial and temporal structure that was captured by $\mu_{s,t}$ is no longer present.
21
22 642

23 643 Using the same rationale, we converted $u_{s,t}$ to the scale of a random variable following any
24 644 known distribution. In particular, we transformed them to a $N(0,1)$ distribution (Normal
25 645 distribution with mean 0 and variance 1) via $z_{s,t} = \Phi^{-1}(u_{s,t})$ where $\Phi()$ is the cdf of the $N(0,1)$
26 646 distribution.
27
28 647

29 648 Given the original variables $y_{s,t}$ and $x_{s,t}$ we obtained corresponding $z_{s,t}^{(1)}$ and $z_{s,t}^{(2)}$. Since they
30 649 are both on the scale of a $N(0,1)$, the sample correlation, $cor(z_{s,t}^{(1)}, z_{s,t}^{(2)})$, is an estimate of their
31 650 dependence as would be explained by a bivariate Normal distribution. With more than 2
32 651 variables, we replaced correlation with the correlation matrix, which describes the dependence
33 652 across all the variables as would be explained by a multivariate Normal distribution (mean
34 653 vector zero, variance vector 1).
35
36 654

37 655 To obtain correlated realisations of the original variables, we proceed backwards. First
38 656 simulating values from the multivariate Normal distribution using the estimated correlation
39 657 matrix. Then converting the samples to the probability scale of $[0,1]$ using the cdf $\Phi()$. We
40 658 then converted those to the original scale (counts) using the inverse cdf $F^{-1}()$. This is the
41 659 procedure followed in the paper to obtain correlated simulations with the right spatio-temporal
42 660 (marginal structure).
