Abstract. Atmospheric waves are a key driving mechanism for the circulation in the Earth's atmosphere. Such waves cover various spatial and temporal scales, e.g., planetary waves with periods of several days, atmospheric tides with periods of an integer fraction of a day and gravity waves with periods ranging from minutes to several hours. In particular, atmospheric tides gain large amplitudes at the Mesosphere/lower Thermosphere (MLT) region. Recently the day-to-day tidal variability as driver of the thermosphere-ionosphere system become an emerging topic. Here we study the intermittent behavior of atmospheric tides by using meteor radars at altitudes of 75 – 110 km accompanied with lidar measurements. The observations are compared to meteorological analyses from NAVGEM-HA to infer how well the tidal variability on a daily to a seasonal basis is captured in the model. Therefore, a new diagnostic approach, a so-called adaptive spectral filter, is used to decompose the time series into a mean wind (zonal and meridional component) and temperature containing the planetary wave activity, atmospheric tides (diurnal, semi-diurnal and terdiurnal) as well as the gravity wave activity. By combining the local data with global reanalysis fields, we extract the relative contribution of the migrating and non-migrating tides for the available data using a global version of the adaptive spectral filter. Our results indicate that the SW2 tide, which is the dominant mode at mid- and high latitudes at the MLT, shows a large seasonal variability in amplitude and phase. The comparison of NAVGEM-HA results and the meteor radar observations demonstrate that the reanalysis data reproduce rather consistent the mean seasonal behavior as well as the day-to-day variability. This is especially obvious during sudden stratospheric warmings, where the SW2 tide shows a significant phase shift and amplitude modulation. These findings show the benefit of combining global high altitude data assimilation products with ground-based observations of the MLT region to better understand the tidal variability in the atmosphere.

1 Introduction

There is a growing need to understand the global wind field from the surface up to the lower thermosphere (0-100 km) and its day-to-day variability due to meteorological processes. Planetary waves and atmospheric tides are dominant drivers at the mesosphere and lower thermosphere (MLT) that provide a highly variable dynamical lower boundary to the thermospheric/ionospheric system, e.g. at the equatorial dynamo region at altitudes from 100 to 150 km (see, e.g. Akmaev, 2011, and references therein). The upward propagation of these drivers from their source regions near the surface into the MLT region is determined in large part by the global wind field. Accurate assessments of both daily and seasonal variability in winds and tidal modes has therefore become necessary for better understanding lower atmospheric forcing of the thermosphere/ionosphere system.

10

At mid- and polar latitudes planetary waves provide a significant contribution to the variability of the winter MLT and play a major role in vertical coupling processes between the different atmospheric layers. For example, during sudden stratospheric warmings (SSWs) (Matsuno, 1971; Andrews et al., 1987) the whole middle atmosphere (stratosphere/mesosphere) responds to sudden reversals of the zonal wind from eastward to westward and back to eastward accompanied by an increase of the stratospheric temperature and a mesospheric cooling (see, e.g. Chandran et al., 2014; Zülicke et al., 2018, , and references therein). SSWs are often studied using Global Circulation Models (GCMs), which are either free-running (e.g., GAIA, WACCM, KMCM, Jin et al. (2012); Liu et al. (2010); Becker (2017); Zülicke et al. (2018)) or nudged to reanalysis fields (e.g., SD-WACCM, Marsh (2011); Stray et al. (2015); Limpasuvan et al. (2016)). Manney et al. (2008, 2009) characterized the SSW in 2006 as a vortex displacement and the SSW in 2009 as a vortex splitting event making use of global satellite observations (MLS-Microwave Limb Sounder) and data assimilated reanalysis mostly at the stratosphere and lower mesosphere. Matthias et al. (2013) investigated the role of planetary waves in the evolution of vortex splitting and displacement events combining satellite data and ground-based observations.

Atmospheric tides have been studied theoretically (e.g. Chapman and Lindzen, 1970; Forbes, 1982; Wang et al., 2016) and from observations (e.g. Portnyagin et al., 1993; Merzlyakov et al., 2009; Oberheide et al., 2009, 2011, and references therein) for decades. More recent studies analyzed the response of the semidiurnal tide during SSWs (Conte et al., 2018) using ground-based instruments and nudged GCM data (HAMMONIA) or investigated the relative importance and impact of the semidiurnal lunar tide during SSWs with TIME-GCM and WACCM (Pedatella et al., 2012; Pedatella and Maute, 2015). However, atmospheric tides propagate from their source region up to the MLT through a constantly varying altitude dependent wind field, which significantly modifies the phase of the tides, depending on their vertical wavelength, as well as the vertical wavelength itself.

30

In this study, we compare local meteor radar (MR) wind observations as well as lidar temperature measurements with meteorological analyses produced with NAVGEM-HA (Navy Global Environmental Model - High Altitude), a data assimilation

and modeling system that extends from the surface to the lower thermosphere. Recent studies (Eckermann et al., 2018; McCormack et al., 2017) have presented initial cross-validation of the mesospheric winds from NAVGEM-HA for two winter seasons using worldwide distributed MR measurements. Here, we extend these initial comparisons to include seasonal mean winds (30-day median) from NAVGEM-HA and from three MRs at mid- to high latitudes for the year 2010. Time series of
5 both NAVGEM-HA analysed winds and MR measurements are decomposed into daily mean winds, tides and GW residuals using a recently introduced analysis technique called adaptive spectral filter (ASF) (Stober et al., 2017; Baumgarten and Stober, 2019). This technique is designed to extract daily mean winds and tidal variations on a day-to-day basis. In addition to MR measurements, we also present the first comparison between midlatitude temperature observations from a resonance lidar and NAVGEM-HA analysed temperatures for the 2010 period. Finally, we present a detailed comparison of two SSWs in 2009/10
10 and 2012/13 and outline how the semidiurnal tide responds to changes in the background wind concerning the tidal phase and amplitude. Overall, the results of these comparisons show very good agreement between NAVGEM-HA analysed winds and MR observations, highlighting the utility of combining global high altitude data assimilation products with ground-based observations of the MLT to better understand tidal variability over daily to seasonal time scales.

15 Therefore, the paper is structured as follows. First, we describe the observations for winds and temperatures in the MLT region and the corresponding reanalysis data in Section 2. Section 3 provides detailed explanation of the methodology used for the data analysis. Section 4 presents the results for the climatology, comparing mean winds simultaneously seen in the meteor radar data at different locations with the NAVGEM-HA reanalysis data accompanied with available temperature measurements from a resonance lidar at one mid-latitude location. The results are also discussed for the semidiurnal tide for the whole year as
20 well as during the winter season in 2010 and 2013 in Section 5. Finally, the findings are summarized and a conclusion is given in Section 6.

2 Data description

2.1 Wind observations

In this study, we compare the 3-hourly global synoptic wind and temperature analyses from NAVGEM-HA with meteor radar
25 observations collected at three different latitudes in Andenes (69° N, 11° E) in Norway, Juliusruh (54.3° N, 13° E) in Germany and Tavistock (CMOR- Canadian Meteor Orbit Radar) (43.2° N, 80.7° W) in Canada. All three meteor radars use the same software as described in Hocking et al. (2001). All systems were almost continuously in operation for the analyzed periods. Only the Andenes system shows some data gaps, mainly due to the more extreme weather conditions in Northern Norway, which caused some damage to the antennas and from time to time a power outage. A more detailed description of the CMOR
30 radar can be found in Brown et al. (2008). A summary of the Juliusruh and Andenes MR is found in Stober et al. (2012) and Wilhelm et al. (2017).

MLT winds are obtained with a temporal resolution of 1 hour and a vertical resolution of 2 km using the wind retrieval algorithm as presented in Stober et al. (2018), which is a further development of the wind analysis presented in Hocking et al. (2001). The wind analysis contains a full error propagation of the statistical uncertainties and a physical error model based on the vertical and temporal shear as spatio-temporal Laplace filter for each wind component. Contrary to many other meteor
5 radar wind analysis, the algorithm also solves for the vertical wind velocity. The obtained mean vertical velocities show values of a few cm/s and are mainly used as quality control for successful convergence of the wind fit. In the present study, we use 4 meteors as a minimum for a successful wind fit.

2.2 Temperature observations

10 At Kühlungsborn (54° N, 12° E), around 118 km southwest of the meteor radar at Juliusruh, a resonance lidar was in operation until 2012 to derive temperatures in the MLT region. The potassium lidar measures the Doppler broadening of the 770 nm potassium D1 resonance line by scanning with a narrow band Alexandrite ring laser. The system is fully daylight capable. Further details can be found in von Zahn and Höffner (1996); Fricke-Begemann et al. (2002).

15 The temperatures are derived between approximately 80 and 105 km depending on the extension of the potassium layer. The integration time of the data used here is 1 h with a shift of 15 min. The vertical resolution is 1 km. In addition to the resonance lidar, also a Rayleigh-Mie-Raman (RMR) lidar is operated during the night at the same location until 2013. This lidar used the second harmonic output of a Nd:YAG laser at 532 nm. The Rayleigh backscatter is proportional to the atmospheric air density from which the temperatures are calculated under the assumption of hydrostatic equilibrium (Hauchecorne and Chanin, 1980).
20 The initial temperature value for integration is taken from the resonance lidar (Alpers et al., 2004). The temperatures from the RMR lidar cover an altitude range between 22 and 90 km. But as the focus of this study is on the MLT region, we use these temperatures only down to 70 km. Here, daily mean temperatures as a composite between 2003 and 2012 are used to describe the mean temperature field during the year in the MLT region.

25 2.3 NAVGEM-HA meteorological analyses

NAVGEM-HA is a high-altitude numerical weather prediction (NWP) system extending from the surface to ~116 km altitude that provides atmospheric winds, temperatures and constituent information. It is based on the operational system described in Hogan et al. (2014), which combines the NAVGEM global spectral forecast model with a hybrid four-dimensional variational (4DVAR) data assimilation algorithm ?.

30 In addition to standard operational meteorological observations in the troposphere and stratosphere, NAVGEM-HA assimilates satellite-based observations of temperature, ozone and water vapor in the stratosphere, mesosphere and lower thermosphere (McCormack et al., 2017). The NAVGEM-HA output is on a 1° latitude and longitude grid, respectively. The temporal resolution of the data output fields is 3 hours. For comparison with the ground-based instruments, vertical profiles of

NAVGEM-HA analyzed winds and temperatures are converted from the model vertical grid to a geometric altitude grid as done in Eckermann et al. (2009). The vertical resolution decreases with higher altitude and is 3-5 km between 80 and 100 km. To date, NAVGEM-HA winds and tides have been shown to be in good agreement with ground-based MR observations, as reported in McCormack et al. (2017) and Eckermann et al. (2018), and with independent satellite-based wind observations as reported in ?.

3 Local and global diagnostics

One of the challenges comparing different data sets is the use of a common diagnostic to ensure that all observations and the reanalysis data are treated in the same way. In particular, observational data can be more difficult to be analyzed due to data gaps or uneven temporal sampling. Atmospheric tidal and planetary wave amplitudes are often obtained from Fourier based techniques (e.g. Stockwell et al., 1996; Torrence and Compo, 1998) or for unevenly sampled data (Lomb, 1976). For observational data, it is also very common to derive the tidal information of amplitude and phase with a least-square fit (Lima et al., 2007) or by a multiple regression analysis assuming, for instance, a circular polarization for the semidiurnal tide (Jacobi et al., 2008).

A commonly used approach to extracted tides is a harmonic analysis:

$$u, v, T = u_0, v_0, T_0 + \sum_{n=1}^3 a_n \sin\left(\frac{2\pi}{P_n} \cdot t\right) + b_n \cos\left(\frac{2\pi}{P_n} \cdot t\right) ; \quad (1)$$

here u, v, T are the zonal, the meridional wind and the temperature, a_n and b_n are the tidal Fourier coefficients, $P_n = 24, 12, 8$ stands for the tidal periods in hours and t is the time of the observation either in UTC or local time, whatever is preferred. Harmonic tidal analysis work well for time series of several days or months, but assumes a constant mean background wind, tidal amplitude, and phase for the selected period. Recent studies of mean winds and tides using meteor radar and lidar observations indicate that tides have a fairly intermittent amplitude and phase character (Stober et al., 2017; Baumgarten et al., 2018; Conte et al., 2018; Baumgarten and Stober, 2019).

The adaptive spectral filter (ASF) aims to be a simple and general diagnostic to decompose time series in 1-D (temporal filter) or 2-D (temporal-spatial filter). The technique is based on least-squares and, hence, applicable to unevenly sampled data and no additional zero-padding needs to be applied for data gaps as long as sufficient observations are available in the remaining adapted time window. Another benefit of the least-squares implementation is given in the error propagation to the derived quantities through the covariance matrix. The term adaptive in this context is similar to the wavelet technique, in that the window length scales with the number of wave cycles that are fitted. The MR and NAVGEM-HA time series are decomposed into daily mean winds, diurnal tide, semidiurnal tide, terdiurnal tide and gravity wave residuum using the ASF.

The ASF uses a sliding window and fits each tidal component applying a scaling factor of 1.3 accounting for the number of wave cycles and no de-trending is applied. At first, the daily mean wind and the diurnal tidal (amplitude and phase) components are determined considering also a potential semidiurnal and terdiurnal tide. In the next step, the semidiurnal tide is fitted using a regularization by the previously determined daily mean wind and diurnal tide and adapting the window length. The same procedure is repeated for the terdiurnal tide respectively. Due to the short window length, the bandwidth for each tidal component is rather wide and may also include some gravity wave contributions. It turns out that just applying temporal filtering leads to some contamination of the obtained tidal amplitudes and phases due to inertial gravity waves with short (less than 10 km) vertical wavelengths. However, Davis et al. (2013) has shown that the diurnal and semidiurnal tide typically has vertical wavelengths larger than 20 km. Hence, we constrain our tidal amplitudes and phases by assuming that the phase of the diurnal and semidiurnal tide only gradually change with altitude using a 16 km vertical retrieval kernel. The mean winds are constrained by a 10 km vertical retrieval kernel to avoid issues during the summer wind reversal from westward winds to eastward winds.

Since NAVGEM-HA produces global wind and temperature fields, we can extract tides as global waves and separate migrating and non-migrating tidal modes. Migrating tides are the DW1 (diurnal westward wave number 1), SW2 (semidiurnal westward wave number 2) and TW3 (terdiurnal westward wave number 3); all other tidal modes are non-migrating tidal components (e.g., Forbes et al., 2008; Miyoshi et al., 2017, and references therein). The migrating and non-migrating tidal components are obtained using the following function;

$$u, v, T = u_0, v_0, T_0 + \sum_{s=-3}^3 \sum_{i=1}^3 \left(a_{si} \cdot \sin\left(s \cdot \lambda - \frac{2\pi}{P_i} \cdot t\right) + b_{si} \cdot \cos\left(s \cdot \lambda - \frac{2\pi}{P_i} \cdot t\right) \right) + \text{further waves} \quad , \quad (2)$$

where s is the zonal wave number (negative eastward, positive westward), λ denotes the longitude at a fixed latitude circle, P_i are the periods of the diurnal, semidiurnal and terdiurnal tide and a_{si} and b_{si} are the Fourier coefficients for each wave number s and period P_i . The zonal mean zonal and meridional wind and the zonal mean temperature are given by u_0, v_0, T_0 . The function also includes longer period waves such as the quasi two day wave (QTDW) with wave number $s=1,2,3$ and stationary planetary waves with wave number $s=1,2,3$.

Daily mean tides for all the components are obtained by using a 3-day window around a central day, which is sufficient to still see some day-to-day variability and to determine potential phase drifts of each tidal component. The global tidal phase for all tidal components is referenced to the Prime meridian (Greenwich). Although NAVGEM-HA provides validated wind and temperature products up to ~ 94 km altitude, we focus our comparison to the MLT region and mostly to the available MR observations. A detailed discussion of the QTDW or planetary waves is beyond the scope of this paper and we leave these for other studies.

4 Results

In the first two parts of the results, we show the mean state of the atmosphere during the year in the MLT region using winds and temperatures from observations and NAVGEM-HA data. Next, the seasonal variation of the semidiurnal tidal component derived with the adaptive spectral filter is presented for each location. In addition to this, the analysis is also done for two examples of sudden stratospheric warming in the winter 2009/2010 and 2012/2013 to determine how well the observed variations in the MLT winds correspond to the NAVGEM-HA reanalysis data as well as to determine the day-to-day variability of the semidiurnal tide.

4.1 Mean winds

Fig. 1 shows the time variation of the zonal and meridional winds at the three locations Andenes, Juliusruh and Tavistock, from hourly meteor radar observations (left column), and the corresponding 3-hourly NAVGEM analyzed winds (center column) for the same location and each latitude as zonal mean values (right column). Daily mean winds are calculated and small scale variations such as tides and gravity waves are effectively removed using a 30-day running median. In general, there is a good agreement of the seasonal wind pattern between the meteor radar wind observations and the reanalysis data. At all three locations, the zonal wind observations show the typical eastward directed winds in winter and the prominent wind reversal in spring.

During summer, a strong transition between westward and eastward winds occurs between 80 and 90 km altitude. The transition height decreases from high to midlatitudes. Above 90 km altitude, the eastward jet reaches wind velocities of about 40 m/s for all stations. The meridional winds during winter are typically northward, while they are southward during the summer. Similar behavior is seen in the NAVGEM-HA reanalysis data, but here the magnitude of the winds is to some extent larger compared to the meteor radar observations.

Furthermore, the altitude where the zonal wind reverses during summer decreases not as much with latitude as from the meteor radar observations for the different locations. Some differences occur between the NAVGEM-HA locally analyzed winds compared to the zonal averaged NAVGEM-HA analyzed winds for each latitude of the meteor radar stations. Short-term variations during winter are much more visible in the locally analyzed winds, this is especially for the meridional wind the case.

4.2 Mean temperatures

A similar comparison to the NAVGEM-HA temperature field is done using a co-located potassium lidar at Kühlungsborn. The daily mean temperatures as composite over the years 2003-2012 from the lidar are shown in Fig. 2 together with the NAVGEM-HA analyzed temperatures between 2009 and 2010. Both data sets show the same seasonal temperature pattern with the lowest temperatures during summer. The mesopause, where the lowest temperatures occur during the year, is estimated from the lidar data at around 88 km in summer and just above 100 km in winter. For the NAVGEM-HA analyzed temperatures the altitude of

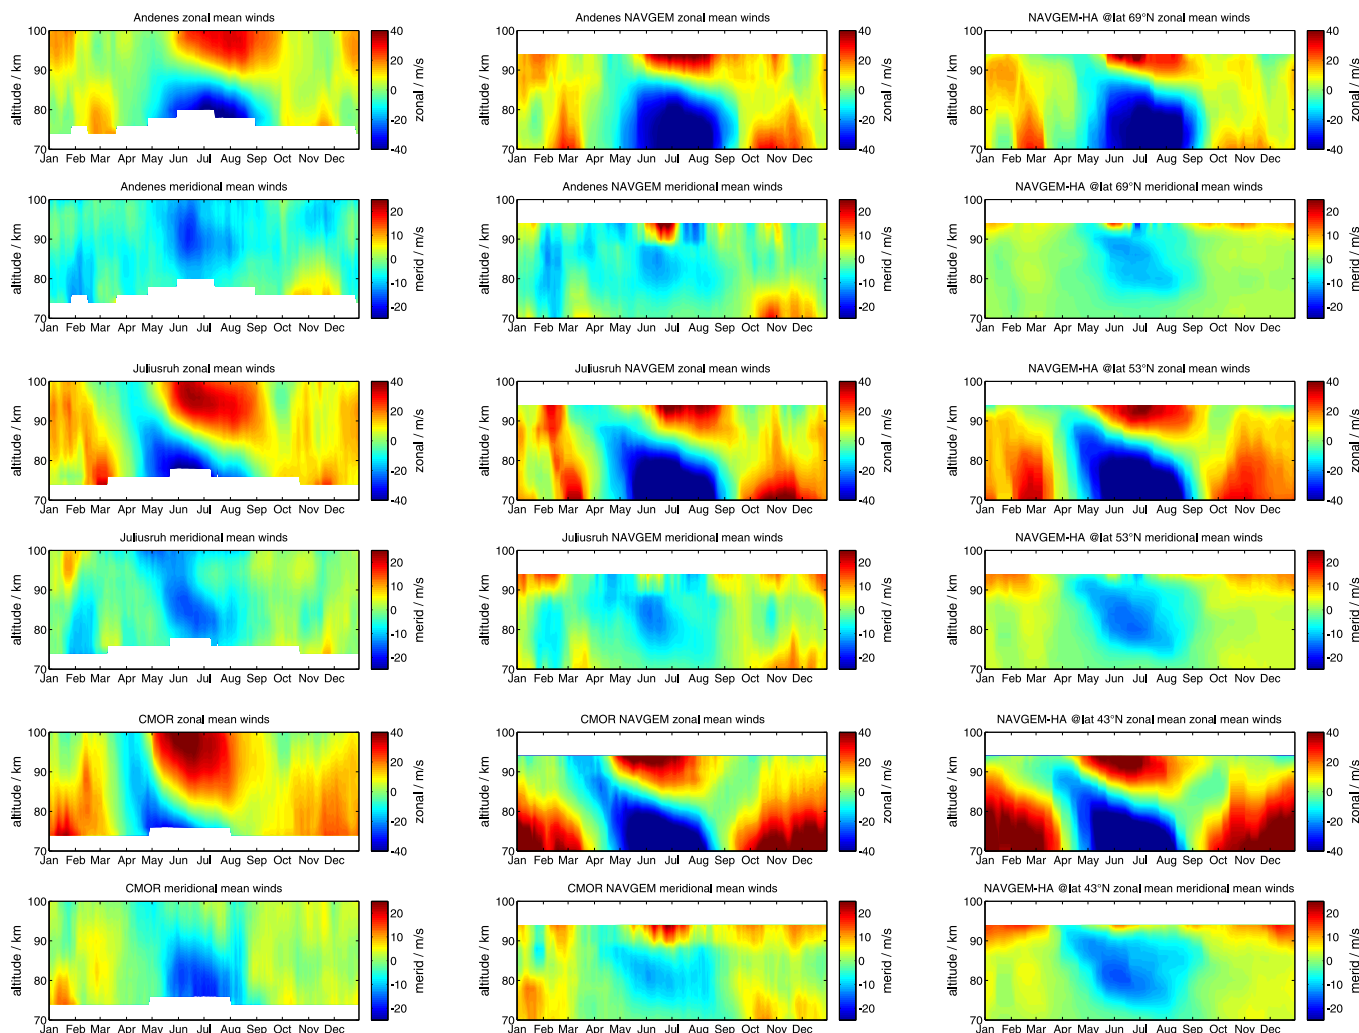

Figure 1. Comparison of mean winds above Andenes, Juliusruh and Tavistock (CMOR) using a 30-day running median with periodic boundary condition. The left panel shows the meteor radar observations. The central panel shows the NAVGEM-HA reanalysis fields for the same locations and periods. The right panel displays the zonal mean zonal and meridional winds for each latitude.

the mesopause is in nearly the same altitude range. Even the magnitude of both temperatures is in very good agreement with each other. Only the temperatures observed by lidar around 70 km are higher compared to the NAVGEM-HA data. At the upper edge of the NAVGEM-HA data, there is also a temperature enhancement during summer, which is not seen in the lidar data.

4.3 Semidiurnal tides

- In this section, we investigate the seasonal variation of the semidiurnal wind tide based on the calculation with the adaptive spectral filter. This component is the most dominant tidal component seen in the MLT region (Chapman and Lindzen, 1970).

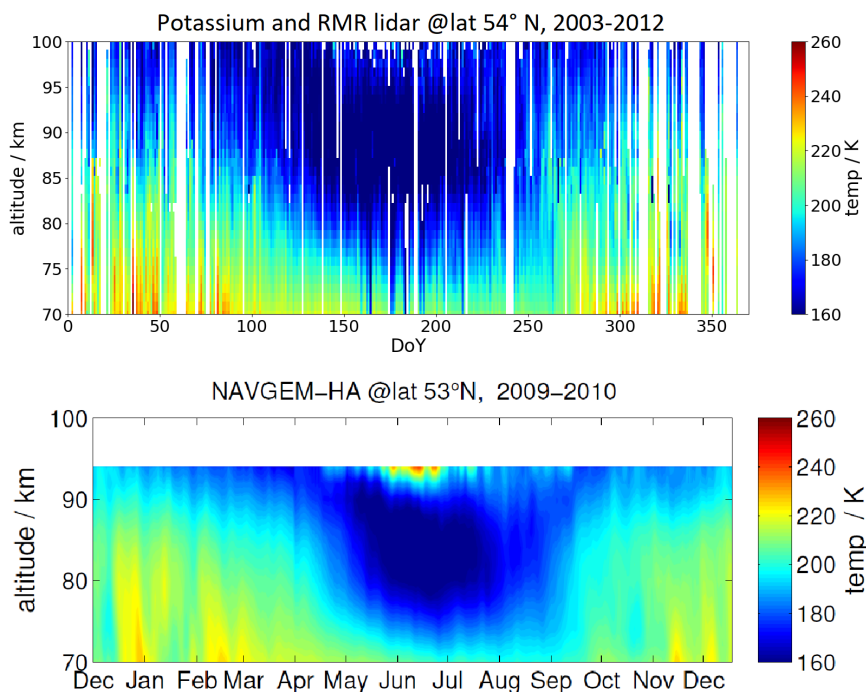

Figure 2. Comparison of mean temperatures above Kühlungsborn. The upper panel shows the temperatures derived from the potassium lidar. The lower panel shows the NAVGEM-HA reanalysis field for the same location.

The results for the semidiurnal tidal amplitude and phase for the stations at Andenes, Juliusruh and Tavistock are shown in Fig. 3, 4, and 5, respectively. Every data set is compared to the NAVGEM analyzed tidal fields from a local as well as from a global perspective as already done for the mean winds and temperatures.

The observations from all stations indicate a clear winter amplitude maximum. A further maximum is evident during September. The amplitudes are smallest during November as well as during April. The latter point is not visible above Tavistock compared to the other locations. In general, the tidal amplitudes above Tavistock are also even stronger during fall than during winter. Compared to the other locations the winter maximum above Tavistock is less pronounced. In general, the amplitudes during winter are strongest for midlatitudes (Juliusruh).

The NAVGEM-HA analyzed amplitudes reveal the same temporal variability over the year as from the observations. Above an altitude of 90 km, the amplitudes from NAVGEM-HA show a significant increase which is not seen in the observations. This was also visible in the temperature data of NAVGEM-HA compared to the lidar data.

Next to the amplitudes of the semidiurnal tide, also the phases over the year are calculated with the adaptive spectral filter. In general, for every location, the phase of the semidiurnal tide is slowly drifting over the year. During winter the phases are quite stable, at the beginning of March, the phase shows a sudden increase, which is evident in every location as well as in the observations and the reanalysis data. This behavior reverses during October/November, exactly when the atmosphere is

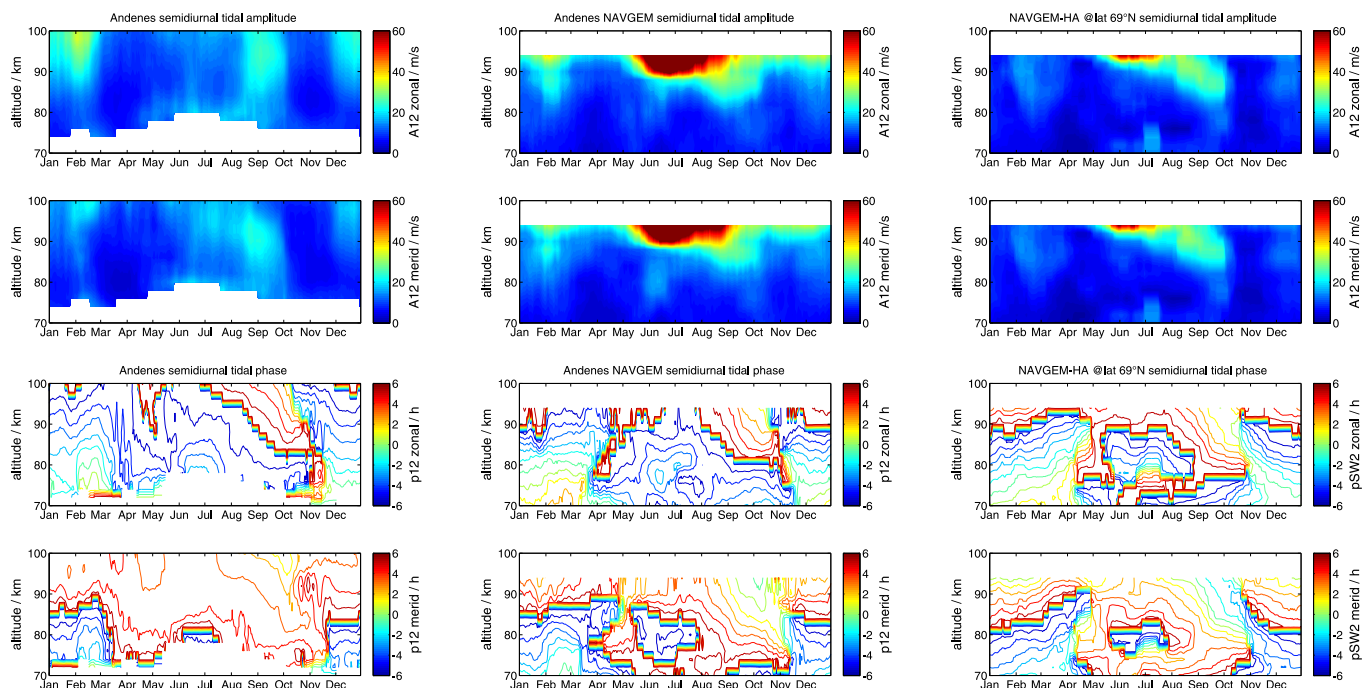

Figure 3. Comparison of semidiurnal seasonal amplitude and phase tidal climatology using a 30-day running median with periodic boundary condition. The left panels show the meteor radar observations above Andenes (69° N, 11° E). The central panels show the NAVGEM-HA reanalysis fields for the same period. The right panels visualize the zonal mean tidal amplitude and phase of the SW2.

changing from summer to winter conditions and vice versa. A similar phase progression is visible from the NAVGEM-HA locally analyzed data as well as from the global fields. There is a tendency that the global fields show larger differences to the observations during summer which is due to the coarser temporal resolution of the global data.

4.4 Day-to-day variability during a sudden stratospheric warming

- The day-to-day variability of the mean winds, the semidiurnal tidal amplitudes and phases are investigated during the sudden stratospheric warming (SSW) in 2010 and 2013 in comparison to NAVGEM-HA analyzed data from a local perspective as well as from a global view. The analysis is done for high latitudes (Andenes) and midlatitudes (Juliusruh) in the same way.

4.4.1 Winter season 2009/2010

During the winter in 2009/2010, a major sudden stratospheric warming occurred at the end of January when the polar vortex was markedly displaced from the pole (Stober et al., 2012) and afterward showed an eventual break up into two unequal strong lobes (e.g. Dörnbrack et al., 2012; Jones Jr. et al., 2018). Mean winds, the semidiurnal tidal amplitude and phase are shown in Fig. 6 from the meteor radar observations above Andenes as well as for the corresponding locally analyzed NAVGEM-HA

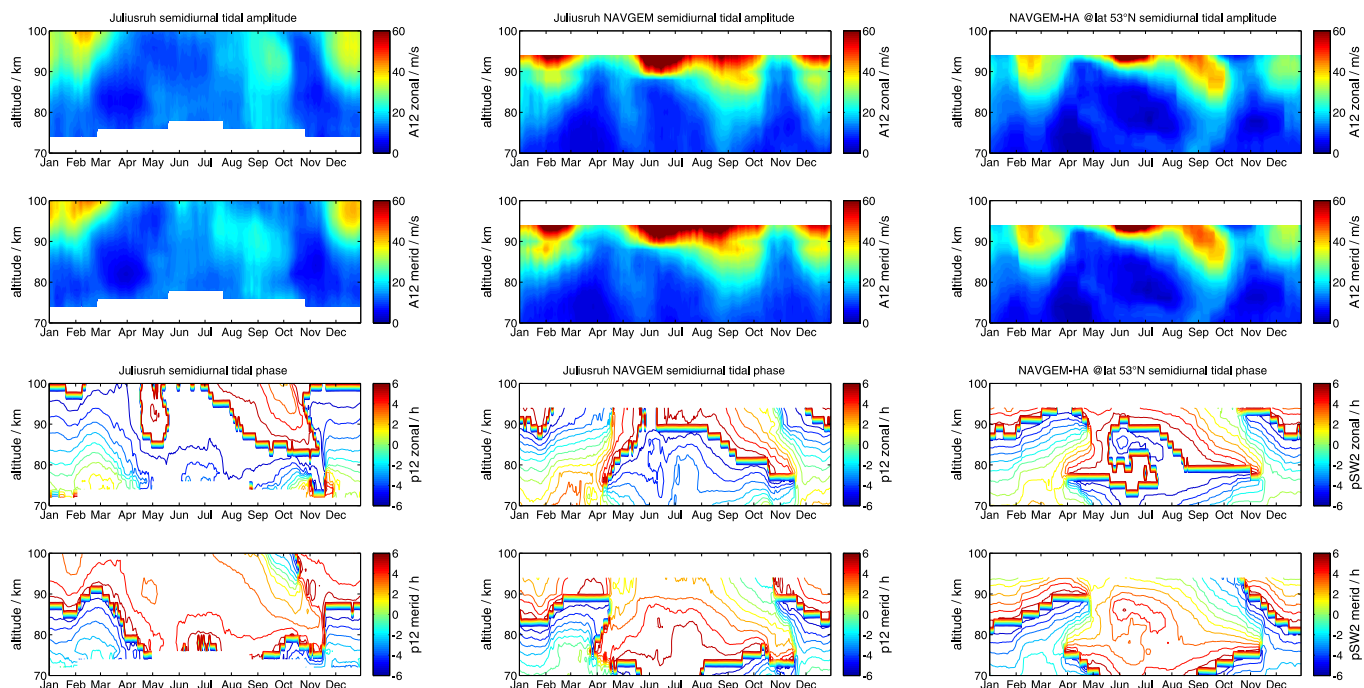

Figure 4. Comparison of semidiurnal seasonal amplitude and phase tidal climatology using a 30-day running median with periodic boundary condition. The left panels show the meteor radar observations above Juliusruh (54.3° N, 13° E). The central panels show the NAVGEM-HA reanalysis fields for the same period. The right panels visualize the zonal mean tidal amplitude and phase of the SW2.

data. In Fig. 7 the same results are shown for the station at midlatitudes above Juliusruh. Stronger changes in the winds are visible for Juliusruh than for Andenes. Even the semidiurnal amplitudes are stronger at midlatitudes. This is in agreement with the stronger seasonal variation of the semidiurnal tidal amplitude above Juliusruh. After the onset of the sudden stratospheric warming, the semidiurnal tidal amplitudes show an enhancement at the beginning of February, which is visible at both stations and in both wind components.

The semidiurnal tidal phases show a large day-to-day variability during the winter period, which is in general stronger at high latitudes than at midlatitudes. After the central date of the sudden stratospheric warming, the tidal phase shows a sudden increase which lasts only a few days. After these days, the phase shows a recovery where they become more stable again just as before the sudden stratospheric warming.

The NAVGEM-HA analyzed winds exhibit the same short-term variability during the 2009/2010 winter at both stations for the winds as well as for the semidiurnal tide. Even the phase enhancement after the central date of the SSW is remarkably well reflected by the NAVGEM-HA data. Some differences occur above an altitude of 85 km, where NAVGEM-HA data reveals larger magnitudes in the winds as well as larger amplitudes for the semidiurnal tide as previously seen. Fig. 8 shows global NAVGEM-HA results for both Andenes and Juliusruh station locations. The global analyzed NAVGEM-HA data exhibit much less variability during the winter compared to the locally analyzed data. But the central date of the SSW is better to see in

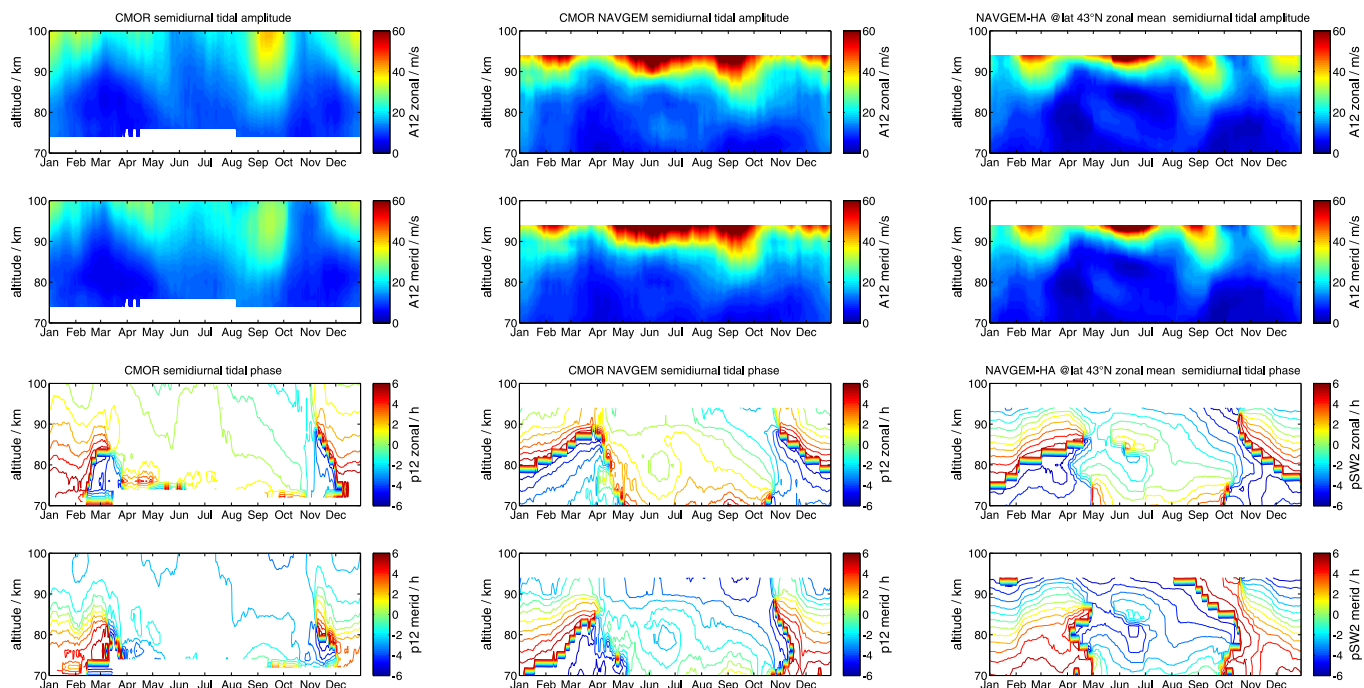

Figure 5. Comparison of semidiurnal seasonal amplitude and phase tidal climatology using a 30-day running median with periodic boundary condition. The left panels show the meteor radar observations above Tavistock (43.2° N, 80.7° W). The central panels show the NAVGEM-HA reanalysis fields for the same period. The right panels visualize the zonal mean tidal amplitude and phase of the SW2.

the winds than it was the case for the locally analyzed winds. However, the main features for the semidiurnal tide stay the same. The amplitudes show an increase after the central date of the SSW and the phases reveal a change for a few days at both locations. In contrast to the locally analyzed data, the phases from the global NAVGEM-HA fields slowly increase during the winter. But in general, the agreement with observations is still good.

5 4.4.2 Winter season 2012/2013

The winter season in 2012/2013 was also characterized by a major sudden stratospheric warming. In this case, the central date of the warming was at the beginning of January 2013 and the vortex was split into two lobes (Coy and Pawson, 2015). Again, mean winds, the semidiurnal tidal amplitudes and phases are shown in Fig. 9 and 10 for high latitudes and midlatitudes, respectively.

10

In this winter season, the mean zonal winds at high latitudes are stronger, especially after the SSW, than at midlatitudes, which is opposite to that seen in the winter season 2009/2010. The mean meridional winds are similar in strength for both stations. Nevertheless, the semidiurnal tide shows again stronger amplitudes at the midlatitude station than at high latitudes. At Andenes, we see a distinct increase of the amplitudes after the SSW, which was already seen in the winter season 2009/2010,

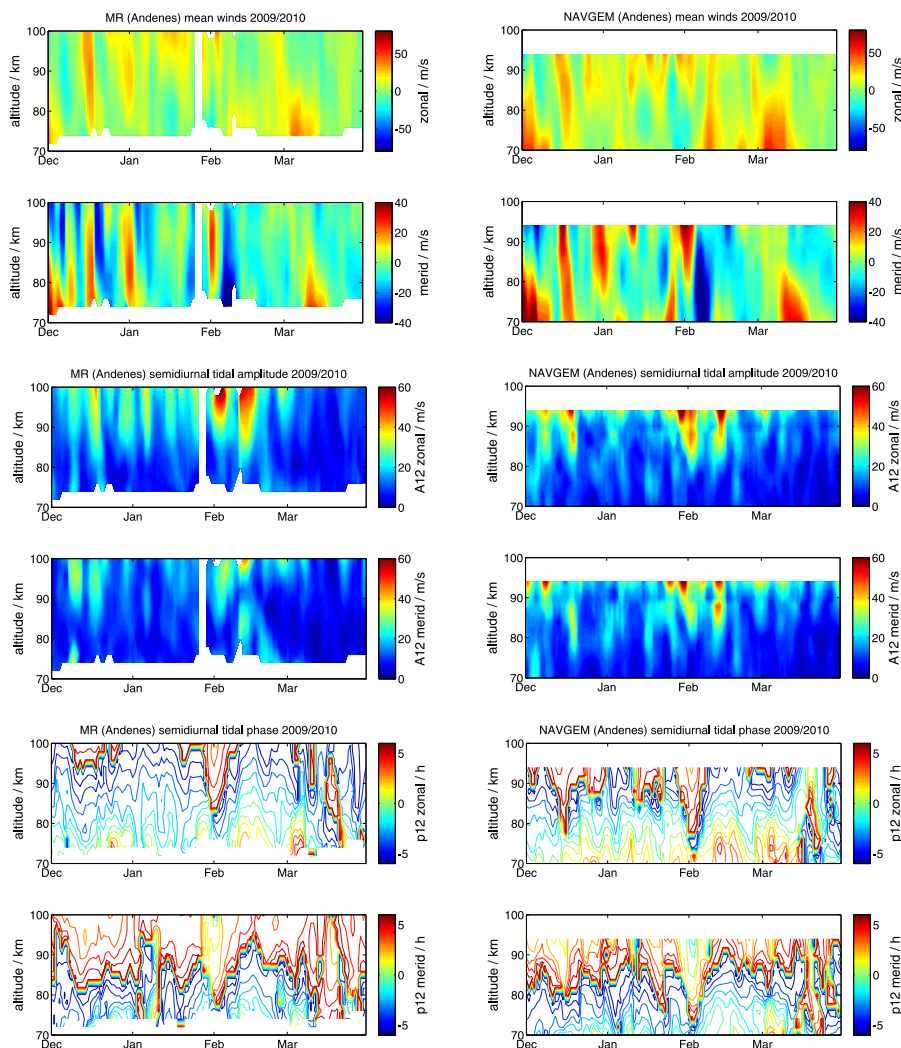

Figure 6. Comparison of meteor radar observations and NAVGEM-HA above Andenes during the winter 2009/10 for daily mean zonal and meridional winds (upper two panels), semidiurnal tidal zonal and meridional amplitude (middle panels) and semidiurnal tidal phases (lower two panels).

while in general at Juliusruh a larger tidal activity is visible. Here, before and during the central date of the SSW the tidal amplitudes decrease in the first place due to the strong changing winds. Afterward, the semidiurnal tidal amplitudes increase again stronger than during the whole winter.

- 5 The semidiurnal tidal phases show again a large variability during the whole time. A few days after the central date of the sudden stratospheric warming a sudden increase of the phase is visible in the same way as for the winter 2009/2010. The locally

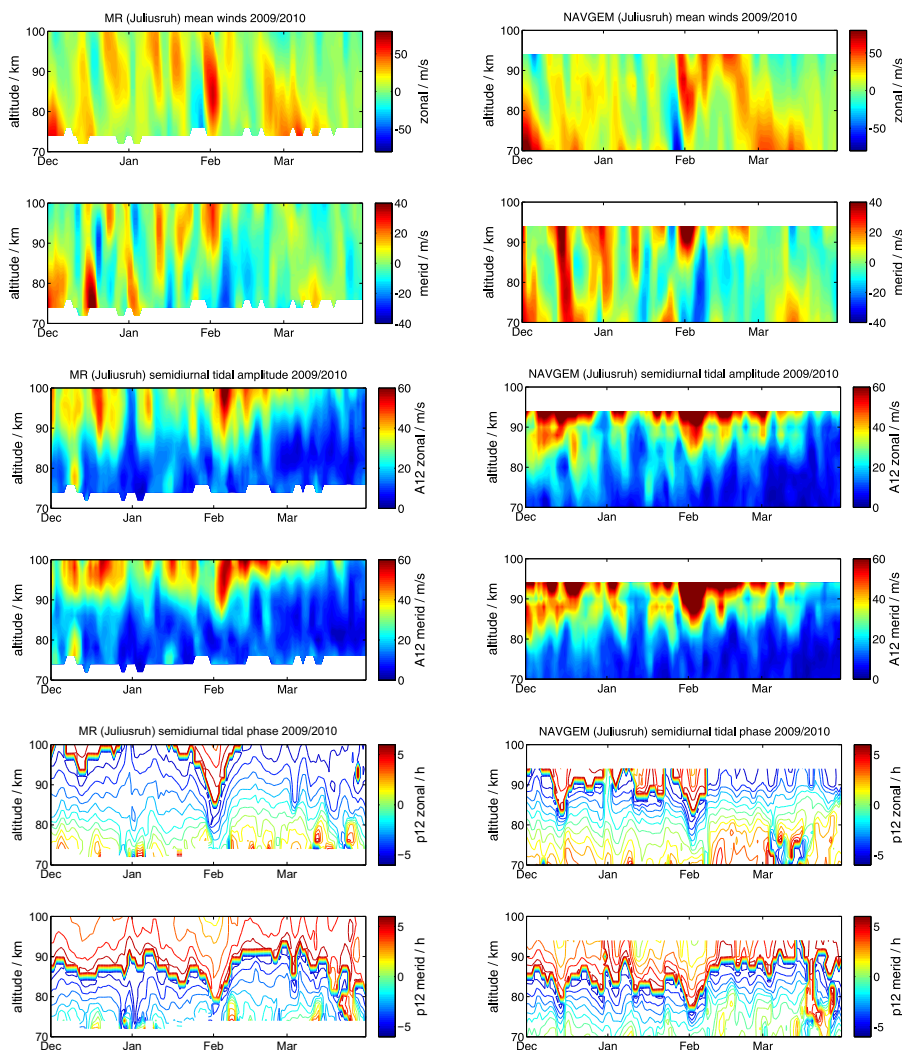

Figure 7. Comparison of meteor radar observations and NAVGEM-HA above Juliusruh during the winter 2009/10 for daily mean zonal and meridional winds (upper two panels), semidiurnal tidal zonal and meridional amplitude (middle panels) and semidiurnal tidal phases (lower two panels).

analyzed NAVGEM-HA data reveal structures during this winter period similar to those from the observations. Evident from every data set, the mean winds, as well as the amplitudes, are slightly overestimated in NAVGEM-HA. The NAVGEM-HA analyzed tidal phases exhibit also a sudden change after the SSW, but not as strong as from the observations, but this might be due to a general more disturbed winter period compared to the year 2009/2010. The globally analyzed data from NAVGEM-HA are shown in Fig. 11. As was the case for the 2009/2010 winter, in this winter season the winds from a global perspective are

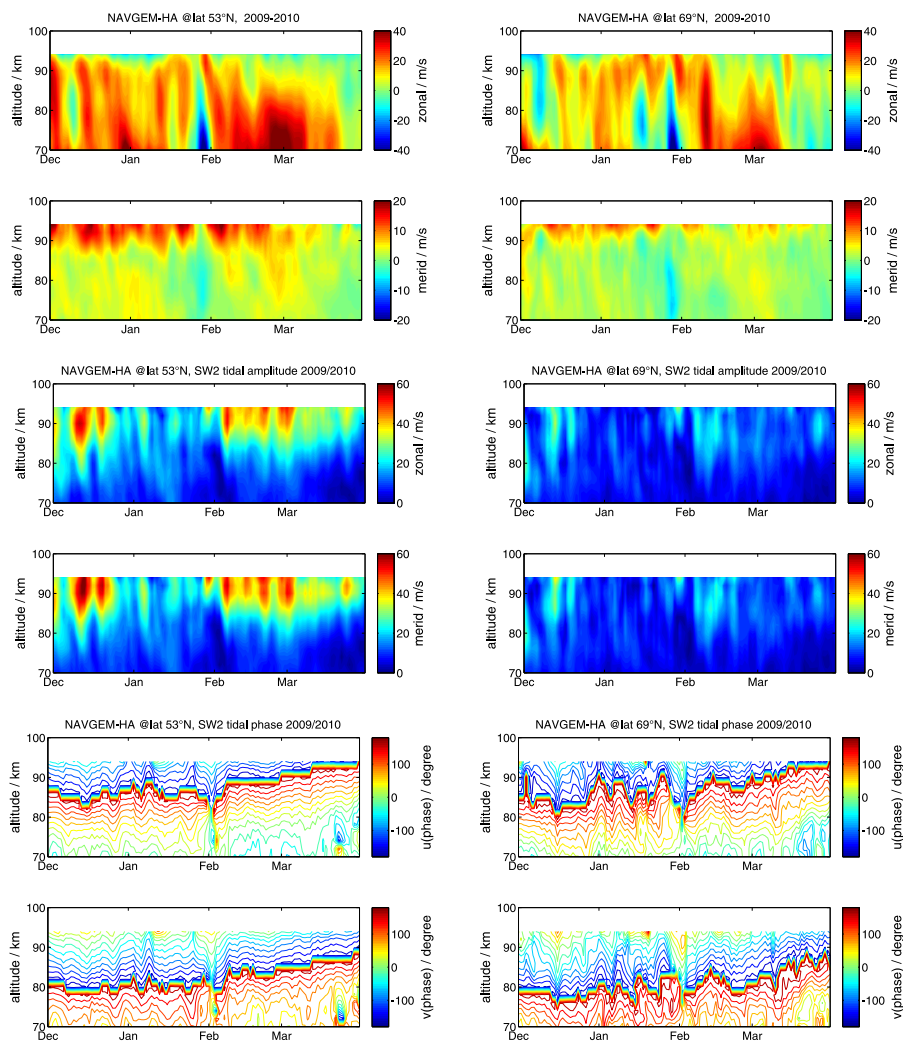

Figure 8. Comparison of global NAVGEM-HA above Andenes and Juliusruh during the winter 2009/10 for daily zonal mean zonal and meridional winds (upper two panels), zonal mean semidiurnal tidal zonal and meridional amplitude (middle panels) and zonal mean semidiurnal tidal phases (lower two panels).

much stronger and uniformly distributed over the winter months, except for the wind reversal during the SSW, which is visible at the beginning of January.

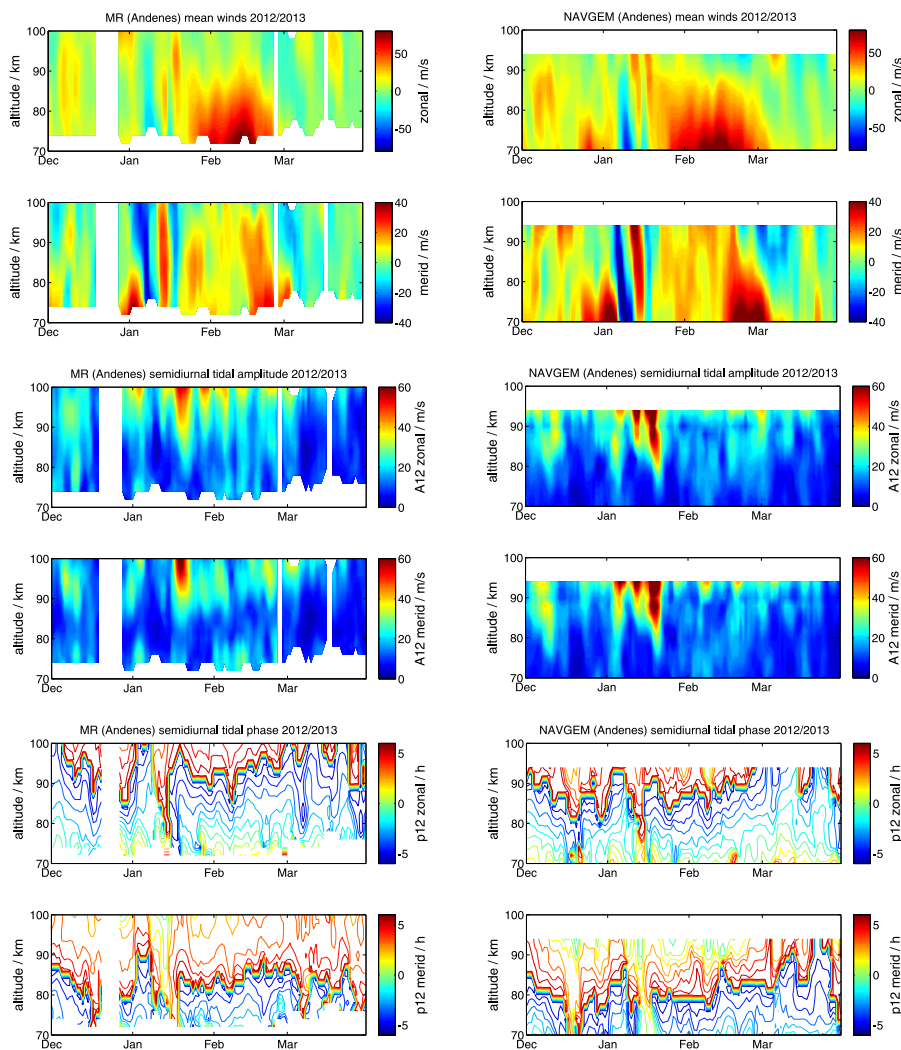

Figure 9. Comparison of meteor radar observations and NAVGEM-HA above Andenes during the winter 2012/13 for daily mean zonal and meridional winds (upper two panels), semidiurnal tidal zonal and meridional amplitude (middle panels) and semidiurnal tidal phases (lower two panels).

5 Discussion

5.1 Implications of the ASF constraint by the vertical wavelength

Atmospheric tides are a major driver of the short term variability of the lower thermosphere/ionosphere. The developed ASF technique provides a new tool to decompose time series to assess this short term variability from local and global data sets and

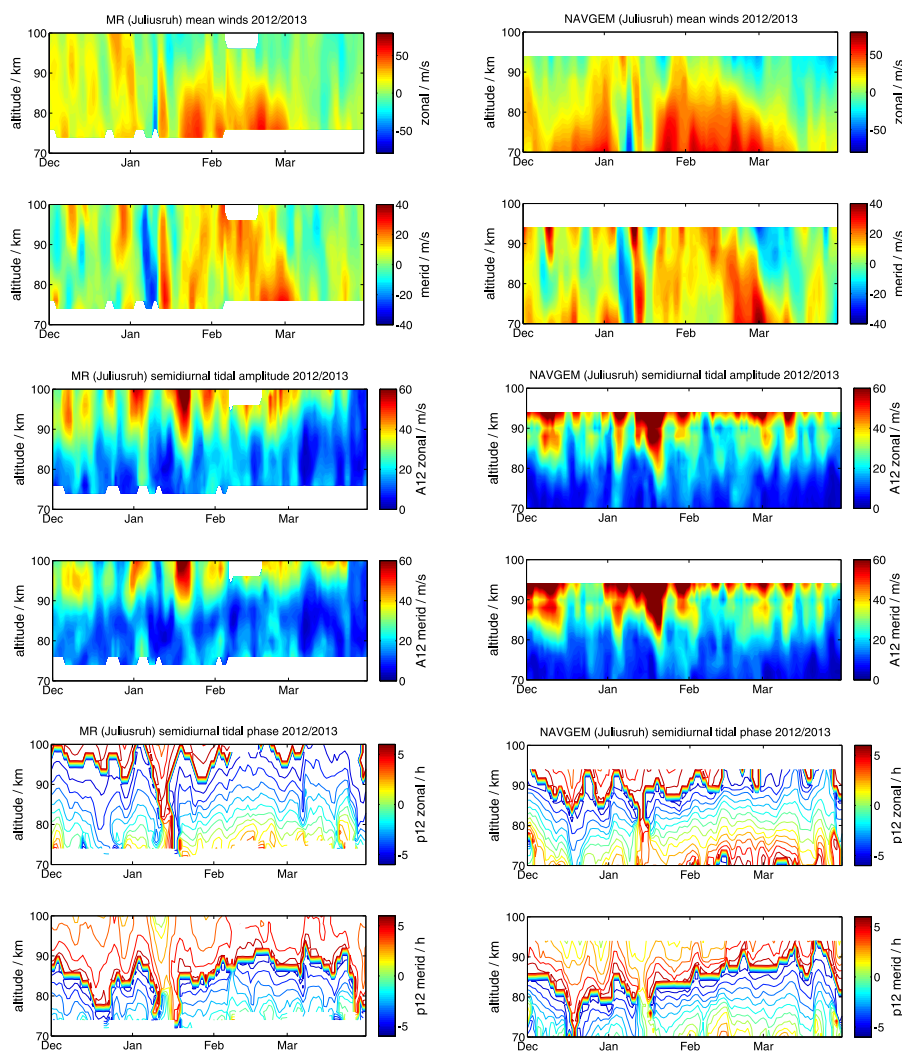

Figure 10. Comparison of meteor radar observations and NAVGEM-HA above Juliusruh during the winter 2012/13 for daily mean zonal and meridional winds (upper two panels), semidiurnal tidal zonal and meridional amplitude (middle panels) and semidiurnal tidal phases (lower two panels).

allows a unified data analysis from observations and models or reanalysis such as NAVGEM-HA. The benefits of the method are:

- data can contain data gaps (gaps have to be shorter than adapted window length)
- applicable to unevenly sampled time series

5 – full error propagation through covariance matrices

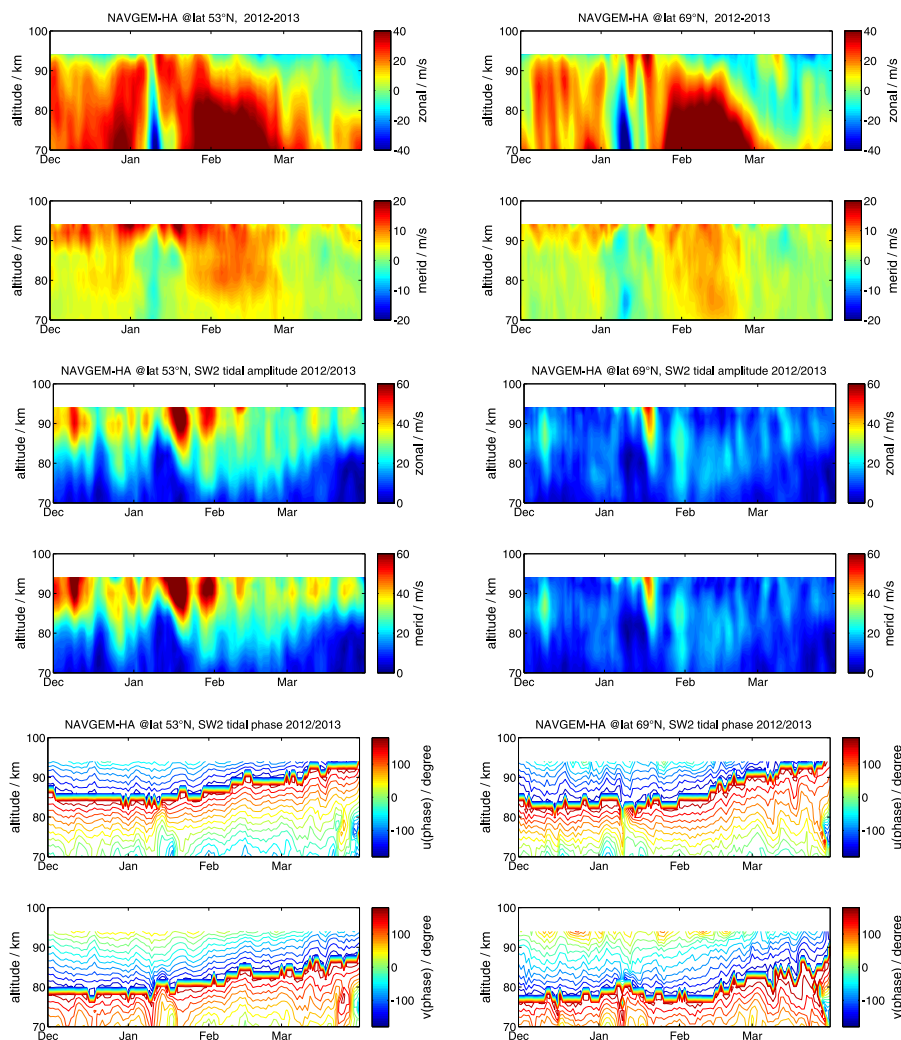

Figure 11. Comparison of global NAVGEM-HA above Juliusruh (left column) and Andenes (right column) during the winter 2012/13 for daily zonal mean zonal and meridional winds (upper two panels), zonal mean semidiurnal tidal zonal and meridional amplitude (middle panels) and zonal mean semidiurnal tidal phases (lower two panels).

- vertical regularization for each atmospheric parameter

However, there are also some drawbacks due to the short window length required to assess the short term tidal variability. The frequency bandwidth around each tidal frequencies is rather wide. The contamination due to other waves falling into these windows, (for instance gravity waves), is minimized by the vertical regularization of the tidal vertical wavelength, which turns out to be a key element of the ASF.

5

The vertical regularization was implemented by allowing gradual changes with altitude for each of the derived wind compo-

nents. The mean winds are regularized using a 10 km vertical retrieval kernel, the diurnal and semidiurnal tides are retrieved applying a 16 km vertical retrieval kernel. We optimized these vertical wavelength values considering the results of previous studies using meteor radars investigating the vertical wavelengths of tides (Yu et al., 2013; Davis et al., 2013; Fritts et al., 2019). These earlier studies showed that the vertical wavelengths for most of the tidal modes are much larger than >25 km. Only Yu et al. (2013) found for some Hough modes vertical wavelengths shorter than <25 km. To avoid potential contamination of shorter tidal wavelengths in our vertical retrieval kernel, we did not implement a hard cut off vertical wavelength. Instead, we just constrain the smoothness of the vertical tidal phase within the averaging kernel and even allow a gradual change. The vertical regularization constraint is an essential feature of the ASF compared to many other diagnostic techniques based on wavelet or Fourier methods. Previous studies based on lidar observations (e.g., Ehard et al., 2015; Baumgarten et al., 2017, and reference therein) already investigated how the potential gravity wave energy changes with the applied filtering. Temporal filters tend to underestimate inertia gravity waves due to their long periods combined with short vertical wavelengths, whereas vertical filters are designed to eliminate the tidal contribution due to their large vertical wavelengths. As a consequence, this filter underestimates gravity waves with comparatively large vertical wavelengths. The ASF is much less prone to such biases due to the combination of spatio-temporal information for the specific waves.

5.2 NAVGEM-HA and MR mean wind climatology

The comparison of the NAVGEM-HA mean winds and the meteor radar climatologies at Andenes, Juliusruh and CMOR is remarkable up to an altitude of 94 km. Due to the data assimilation, NAVGEM-HA captures the main features of the seasonal wind climatologies such as the weak eastward winds during the winter, the asymmetry of the seasonal pattern between the spring and autumn wind reversals as well as the gradual descent of the summer wind reversal between the mesospheric westward winds and the higher altitude thermospheric eastward jet. The good agreement during the winter months was already outlined in McCormack et al. (2017) presenting initial cross-validation of the NAVGEM-HA winds with globally distributed and available meteor radar wind observations.

Comparing the seasonal morphology of the zonal and meridional winds between NAVGEM-HA and other comprehensive GCMs, such as WACCM or SD-WACCM Smith (2012); Chandran and Collins (2014), and the meteor radar and lidar data indicate a slightly better agreement for the meteorological reanalysis for altitudes beyond 80 km. Similar results have been found by comparing meteor radar winds to free running mechanistic GCMs Pokhotelov et al. (2018). Smith (2012) performed a detailed assessment of the WACCM model using various ground-based and satellite measurements in the MLT and also noted some discrepancies between the observations and the model fields.

The general thermal structure and seasonal climatology are also well-reproduced in NAVGEM-HA for the lidar observations presented in Fig. 2 at the mid-latitude station of Kuehllungsborn. The reanalysis captures the seasonal course of the altitude variation of the mesopause. Further, we identified a small offset between the lidar and the NAVGEM-HA temperatures. The reanalysis data has a tendency toward slightly warmer temperatures compared to the resonance lidar. These slightly higher temperatures may also explain the magnitude of the mean winds from the MR observations.

At mesospheric altitudes, NAVGEM-HA assimilates satellite measurements from TIMED and AURA satellites and radiances

from the Defense Meteorological Satellite program (DMSP) (Eckermann et al., 2018). Systematic differences between the meteorological reanalysis and the data herein may have different origins. There could be intrinsic differences due to the model physics leading to such deviations or the assimilated data itself may show some systematic differences in relation to the observations used for the comparison. Further, considering that the *true* state of the atmosphere temperature and winds remains
5 elusive, it is hard to determine which of the observational techniques provides a better representation of this *true* state. Thus, it is essential to assess some of the systematic differences, which can arise due to the methodology employed for the comparison e.g., does applying different diagnostics or different spatio-temporal sampling of the instruments make a large difference. Validation and assessment of potential biases between the SABER temperatures and ground-based lidar measurements can be found in Xu et al. (2006); Dawkins et al. (2018). A cross comparison of the MLS and SABER temperatures is presented
10 in Schwartz et al. (2008). A detailed description of how the data assimilation in NAVGEM-HA treats the temperature biases between both satellites is given in Eckermann et al. (2018).

Another important point that requires a thorough discussion is the vertical regridding of the NAVGEM-HA data to a geometric altitude grid. NAVGEM-HA uses a fixed top level pressure of $6 \cdot 10^{-5}$ hPa (e.g., McCormack et al., 2017; Eckermann et al., 2018, and references therein), which corresponds to an approximate altitude of 116 km. However, at the upper three model
15 levels, an enhanced diffusion is applied to reduce the effects of wave reflection. These layers effectively act as a "sponge layer" and should not be included in the data analysis. McCormack et al. (2017) used for the initial validation geometric altitudes up to 95 km for the mean winds and a maximum altitude of 90 km for the wave analysis. In particular, during the cold summer months (hemispheric summer) the geometric altitude of a specific pressure level is much lower compared to the winter months. This squeezing of the pressure levels due to the much colder mesosphere explains why the agreement between the meteor radar
20 winds and the NAVGEM-HA wind components is significantly degraded beyond 90 km altitude during summer. A similar effect can be found in the temperature comparison.

5.3 NAVGEM-HA and MR mean wind semidiurnal tidal comparison

Atmospheric tides are global-scale waves having periods which are an integer fraction of a day. At the MLT height, tides gain huge amplitudes and contribute significantly to the daily variability of the zonal and meridional winds. At mid- and polar
25 latitudes, the semidiurnal tide is the most prominent tidal wave in the MLT that can be observed throughout the course of the year (Portnyagin et al., 2004; Pokhotelov et al., 2018; Wilhelm et al., 2019).

In principle, local observations (single measurements) can not distinguish between migrating and non-migrating tidal components and only observe a total tide. Earlier studies (e.g., Portnyagin et al., 2004) have investigated the global nature of the diurnal and semidiurnal tide at polar latitudes using a chain of radars at approximately 70° N. They found very good agree-
30 ment between monthly tidal amplitudes and phases for all stations along the latitudinal circle. Recently, there have been some attempts to separate migrating and non-migrating tides using globally distributed chains of meteor radars (He et al., 2018) assuming theoretical tidal wave fields consisting of migrating and non-migrating components. However, due to the small number of meteor radars at the latitudinal circles, the analysis still contains a high degree of ambiguity.

Combining the benefits of high resolution local measurements with global meteorological reanalysis data solves this problem.

The comparison of the semidiurnal tidal climatology reveals that NAVGEM-HA reproduces the seasonal morphology of the tidal magnitudes for both wind components up to an altitude of 90 km applying the ASF tidal diagnostic. The local ASF diagnostic shows remarkable agreement between the global tidal analysis of the migrating SW2 tide in magnitude and phase. The non-migrating semidiurnal components show only very small and often negligible amplitudes.

5

5.4 NAVGEM-HA and MR winds and tidal day-to-day variability and lunar tides during SSW events

In this study, we present a cross-comparison of mean winds and semidiurnal tidal day-to-day variability during two SSW events. Such short time variations are essential for the understanding of the forcing from below of the thermosphere and ionosphere (Liu, 2016). Meteorological reanalysis data, such as NAVGEM-HA, provide a much more realistic forcing of the upper atmosphere due to tides and mean winds compared to current versions of other comprehensive models. Chandran and Collins (2014) investigated SSW events using WACCM-SD nudged with reanalysis fields from the GEOS-5.2 reanalysis system up to an altitude of about 40 km. However, at altitudes above 70-80 km the nudged model started to substantially deviate from the observed wind climatologies (Wilhelm et al., 2019). In particular, the nudged model showed a wind reversal from eastward to westwards winds between 70-80 km, which is not confirmed from the wind climatologies. Such reversal of the zonal wind can be also found in other comprehensive models or mechanistic models (Smith, 2012; Becker, 2012). Liu (2016) shows a comparison among several GCMs indicating that there are substantial deviations at the mesosphere and upper atmosphere, although each of the GCMs was nudged up to the lower stratosphere (see also Pedatella et al. (2014) for more details). Only the GAIA model (Jin et al., 2012; Liu et al., 2014) showed during winter eastward winds at the MLT.

Besides comparing mean winds, we also investigated the day-to-day variability of the semidiurnal tide during two winter seasons with a major SSW event at the mid-latitude location Juliusruh and polar latitudes above Andenes. Atmospheric tides are generated in the troposphere and stratosphere mostly through the absorption of sunlight by water vapor and ozone (e.g., Lindzen, 1979). In 2010 there was a vortex displacement event (e.g., Stober et al., 2012; Matthias et al., 2013), which was already validated by a cross comparison of the mean winds and waves in McCormack et al. (2017) using several worldwide-distributed meteor radars. The second SSW event occurred during winter 2012/13 and evolved as a vortex splitting event (e.g., Xu and San Liang, 2017).

Daily mean winds and tidal amplitudes were diagnosed by the ASF. The meteorological reanalysis of NAVGEM-HA reproduces the general day-to-day variability of winds and even shows a high level of agreement for individual planetary waves passing over the stations. In particular, the timing of the SSW event itself with the zonal wind reversal and the formation of an elevated stratopause is well-captured. Similar to the zonal and meridional wind climatologies, the reanalysis tends to show higher magnitudes of the winds. Previous comparison of wind observations to reanalysis model data, such as ECMWF or MERRA2, were limited to a maximum altitude of approximately 70-75 km and below (Rüfenacht et al., 2018) and, thus, we omit here any further detailed discussion.

Another very important aspect of this study is the phase variability on a day-to-day basis. The ASF provides information on the phase stability of tides with basically the same resolution as the original measurement time series. Very often tidal phases

are assumed to be stable over long periods of up to several months in the analysis. However, for instance, the TIMED satellite requires 60-days to cover all local times due to its orbit geometry (Zhang et al., 2006; Oberheide et al., 2011). Our results indicate that during an SSW the phase of the SW2 tide is significantly altered on a global scale as well as on a regional or local scale as the dynamics of the middle atmosphere change (e.g., Manney et al., 2009; Matthias et al., 2012). Fuller-Rowell et al. (2016) discussed three possible mechanisms to understand these changes of the tide; Fuller-Rowell et al. (2010); Jin et al. (2012) attributed the change of the migrating tidal phase to changes of the mean winds in the middle atmosphere, whereas Pedatella and Forbes (2010) suggested non-migrating tides as a source of the SW2 phase variability. Other studies favor an amplification of the lunar tide during an SSW (Fejer et al., 2010; Forbes and Zhang, 2012).

We want to disentangle these three aspects using the results obtained from the ASF decomposition of the local and global measurements and meteorological reanalysis data. Fejer et al. (2010) investigated vertical plasma drifts above Jicamarca and found a drift in local time of the semidiurnal oscillation, which was attributed to the lunar tide assuming that all other tidal waves remained stationary and monochromatic. Later Forbes and Zhang (2012) proposed that the lunar tide enhancement is a result of a shifting of the Perkeris resonance to the lunar tide M2 (12.42 h) due to changes in the mean zonal winds caused by the SSW. They tested the proposed physical mechanism on satellite observations from SABER, CHAMP and GRACE and the steady state Global-Scale-Wave-Model (GSWM). To separate the lunar tide from the semidiurnal SW2 tide, they used a window of 24 days to ensure sufficient frequency resolution and assumed monochromatic and stationary tidal waves within the window.

However, our analysis of the day-to-day variability indicates that the tidal phase are not stable with time and show significant variability, which appears to be related to changes in the zonal wind in the middle atmosphere driven by the polar vortex and planetary waves. In Fig. 12 we show a holographic reconstruction based on the ASF decomposition of the semidiurnal tide. This technique only assumes monochromaticity within the adopted window length (less than a day for the semidiurnal tide) and, thus, captures non-stationary processes on an interday basis. The hologram shows that during the SSW event in 2012/13 the phase behavior of the semidiurnal tide itself is shifted to the period range that is expected for the lunar tide M2 (solid white line) and N2 (dashed white line). Moreover, Forbes and Zhang (2012) reported a delay of 5 days between the occurrence of the lunar tide amplification and the central day of the SSW event. This delay of approx. 5 days is consistent with the holographic analysis, which also shows that the frequency/period shift towards the lunar tide frequency/period (M2 and N2) occurs after the SSW event, at the beginning of the formation of an elevated stratopause or when the polar vortex begins to restore.

Many publications investigating lunar tides use window lengths that are long enough to ensure an unambiguous frequency resolution to separate the lunar tide from the semidiurnal tide, which requires at least 21-days or more (e.g., Forbes and Zhang, 2012; Conte et al., 2017; He et al., 2018; Siddiqui et al., 2018, and reference therein). The ASF analysis indicates that there is a considerable interday tidal variability in amplitude and phase, which poses a challenge to the signal processing. Such intermittent behavior suggests that long windows (longer than even a day) might lead to spurious results, and do not allow separation of the different waves from each other. SSWs last only for a few days (much shorter than the typical window length used for the lunar tides) and cause significant changes in zonal mean wind at mid- and polar latitudes altering the propagation conditions for the tides. As a consequence, such a long window would not allow one to capture SSW effects, which themselves

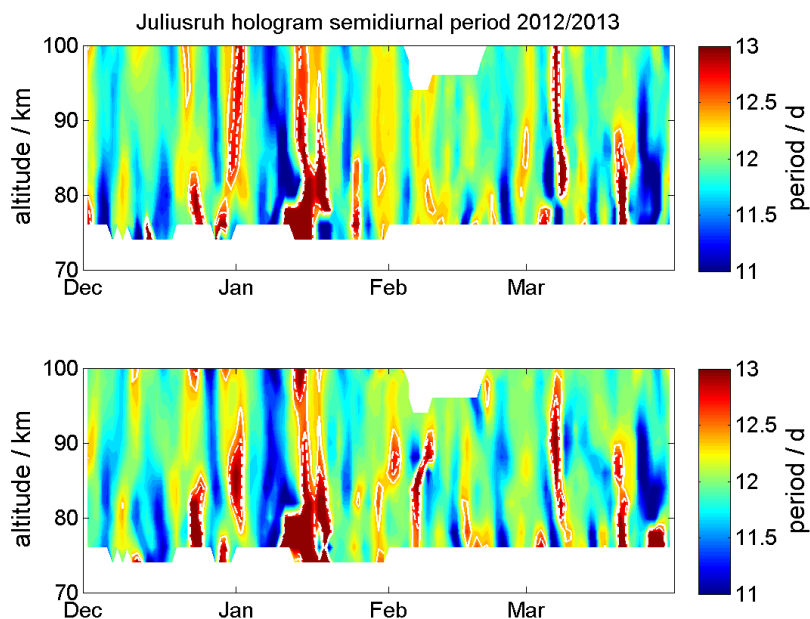

Figure 12. Holographic reconstruction of the semidiurnal tidal phase variability. The hologram shows the periods using a time variable phase, which is equivalent to a frequency shift or change in period. The white contour lines indicate the lunar tide M2 (12.42 h) (solid line) and N2 (12.66 h) (dashed line).

cause changes in the semidiurnal tide. Thus, if one does not notice that an SSW occurred, one cannot know whether the 12.4 hour tide is lunar or a semidiurnal tide that was altered by the SSW.

We also investigated the non-migrating tidal components (see appendix) from the NAVGEM-HA. It appears that only the SW1 and SW3 tides show a response to the SSW event depending on the latitude and how the SSW evolved. This is consistent with previous studies (Liu et al., 2010). The SW3, SE1, SE2, SE3 and S0 semidiurnal tides show much smaller amplitudes and are negligible compared to the SW2 tide, in particular, at polar latitudes. Another interesting aspect when comparing the migrating and non-migrating tides from NAVGEM-HA is the winter seasonal phase behavior of the SW2 tide. The phase of the tide drifts by several hours between December to March, which correlates to the mean wind morphology. Apparently, the change of the phase of the semidiurnal tide is not explainable by a superposition of migrating and non-migrating tides. However, this needs to be examined in more detail and is beyond the scope of this paper.

Based on the present analysis, there was no amplification of the lunar tide at mid- and high-latitudes during the two examined SSW events. Previous analysis of the lunar tide facilitating multi-year observations from meteor radars by Sandford et al. (2006) showed that the signal is much weaker compared to the total S2 tide. Their spectral analysis also confirms that tides show some spectral broadening. Such a line broadening is also found in our holographic analysis. In principle, it is possible to separate the lunar tide from the semidiurnal tide by modeling the line shape of the S2 tide.

Similar to previous studies (Fuller-Rowell et al., 2010, 2016) we attribute the day-to-day variability of the semidiurnal tidal amplitudes and phases to changes of the zonal winds in the middle atmosphere altering the vertical propagation conditions. Although atmospheric tides are global scale waves, their vertical propagation depends on the regional meteorological situation. As a consequence, the observed period or phase at the MLT can be altered. Due to the long horizontal wavelength of the semidiurnal tide, a change in the wind pattern in the middle atmosphere manifests as changes in phase for a single station measurement accompanied by a change of the vertical wavelength of the tide. The holographic reconstruction shows that the day-to-day variability of phase is equivalent to a Doppler shifting of the intrinsic tidal frequency, which causes the line broadening at the MLT.

6 Conclusions

In this study, we cross-validate the meteorological reanalysis model NAVGEM-HA with ground-based meteor radar and lidar observations at mid- and high latitudes. For the validation, we performed a detailed analysis of mean winds and temperatures and atmospheric tides using a recently developed tool called adaptive spectral filter (ASF). We present a climatological comparison of mean winds, temperatures and the semidiurnal wind tide and its phase behavior. We also presented a detailed discussion of the day-to-day variability of the semidiurnal tide during two SSW events in 2009/10 and 2012/13 combining global and local diagnostics. We discussed our results in the context of previous studies, in particular, on the lunar tide amplification during SSWs and have outlined potential issues due to the day-to-day semidiurnal tidal variability. Our main conclusions are:

- The agreement between MR/lidar climatologies and NAVGEM-HA reanalysis data is remarkably good compared to the seasonal wind and temperature pattern of comprehensive models. NAVGEM-HA tends to show slightly higher winds and temperatures compared to the ground-based instruments.
- NAVGEM-HA reflects the day-to-day variability of the wind and semidiurnal tide amplitude and phase behavior during SSW events.
- The temperature and wind fields in NAVGEM-HA are realistic compared to ground-based sensors up to an altitude of 90 km (geometric altitude).
- The combination of NAVGEM-HA meteorological reanalysis data and ground-based observations allowed us to develop new diagnostics to retrieve atmospheric information and to investigate physical processes. The cross-validation suggests that the global fields of NAVGEM-HA can be used to provide a realistic nudging for other GCMs coupling the middle atmosphere to the upper atmosphere. In particular, the good agreement of the tidal phases provides an essential quality benchmark for the lower forcing of the thermosphere and ionosphere through atmospheric tides.
- The ASF diagnostic allows us to capture the intermittent tidal behavior on a day-to-day basis and is applicable to different data sets.

- The semidiurnal tidal phase shows a significant variation over the year. This is highly relevant for the extraction of tides from satellite measurements or for the determination of the lunar M2 tide.
 - The ASF and holographic analysis provides no signature of a lunar tide amplification during SSW events at mid- and high latitudes as reported by Forbes and Zhang (2012); Conte et al. (2017); He et al. (2018). However, we confirmed that the SSW event causes a shift of the semidiurnal tide towards the Perkeris resonance, which occurs 3-5 days after the SSW.
 - The day-to-day tidal variability (amplitude and phase) of the semidiurnal tide is attributed to changes in the wind pattern in the middle atmosphere altering the vertical propagation conditions of the tide. This is in agreement with previous studies by Fuller-Rowell et al. (2010); Jin et al. (2012); Fuller-Rowell et al. (2016).
- 10 In this work we demonstrate the value of meteorological reanalysis data from NAVGEM-HA to investigate the day-to-day variability of tides in a global context and for local meteor radar observations. Such data sets are essential for nudging thermospheric and ionospheric models for space weather applications. Further, we emphasized that new analysis techniques are required to infer the tidal variability or to separate lunar tides from the semidiurnal tide. Holographic reconstructions and spectral line models for atmospheric tides might be part of such a solution.

15

Data availability. The meteor radar can be obtained from Gunter Stober upon request by from the Leibniz-Institute for Atmospheric Physics. The NAVGEM-HA data used in this study can be obtained from (<https://map.nrl.navy.mil/map/pub/nrl/navgem/iap>). The lidar observations are available upon request from Kathrin Baumgarten.

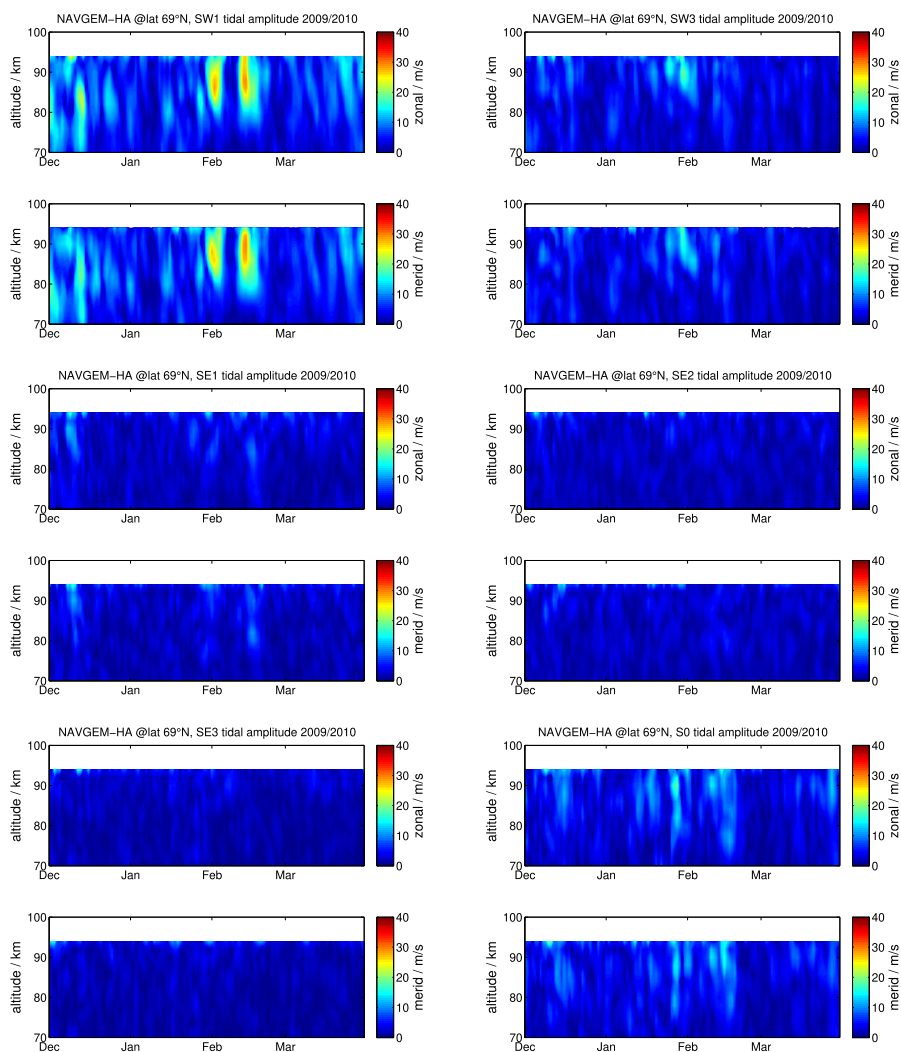

Figure A1. Non-migrating tides derived from global NAVGEM-HA winds above Andenes during the winter 2009/10 for SW1 and SW3 (upper two panels), SE1 and SE2 (middle panels), and SE3 and S0 (lower two panels) tidal components.

Appendix A: Tidal components from global NAVGEM-HA analyzed winds

In addition to the semidiurnal tide locally observed from the meteor radar as well as from NAVGEM analyzed winds here we provide the results for the westward- and eastward-propagating non-migrating semidiurnal tidal components (SW1, SW3, SE1, SE2, SE3) as well as for the stationary semidiurnal tide (S0) during the winter 2009/2010 and 2012/2013 for the stations at

5 Andenes and Juliusruh from the global fields of NAVGEM-HA.

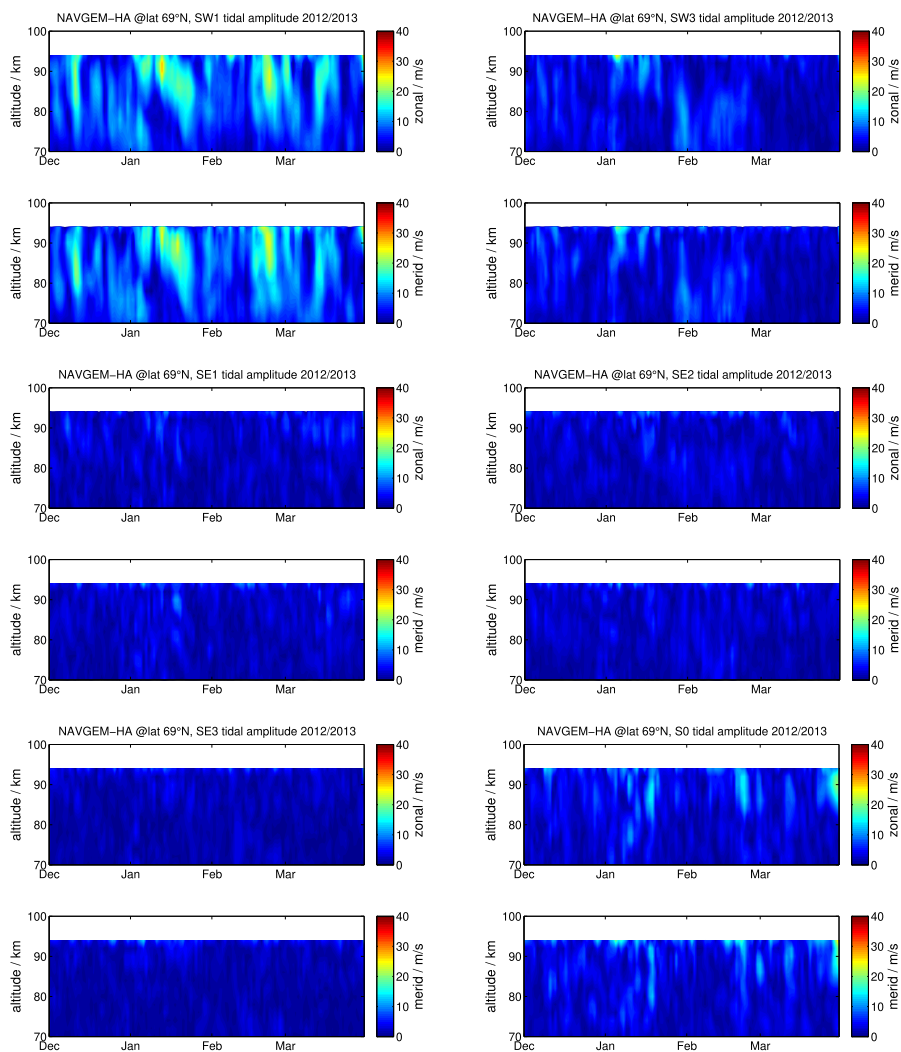

Figure A2. The same as Fig. A1 but for the winter 2012/2013.

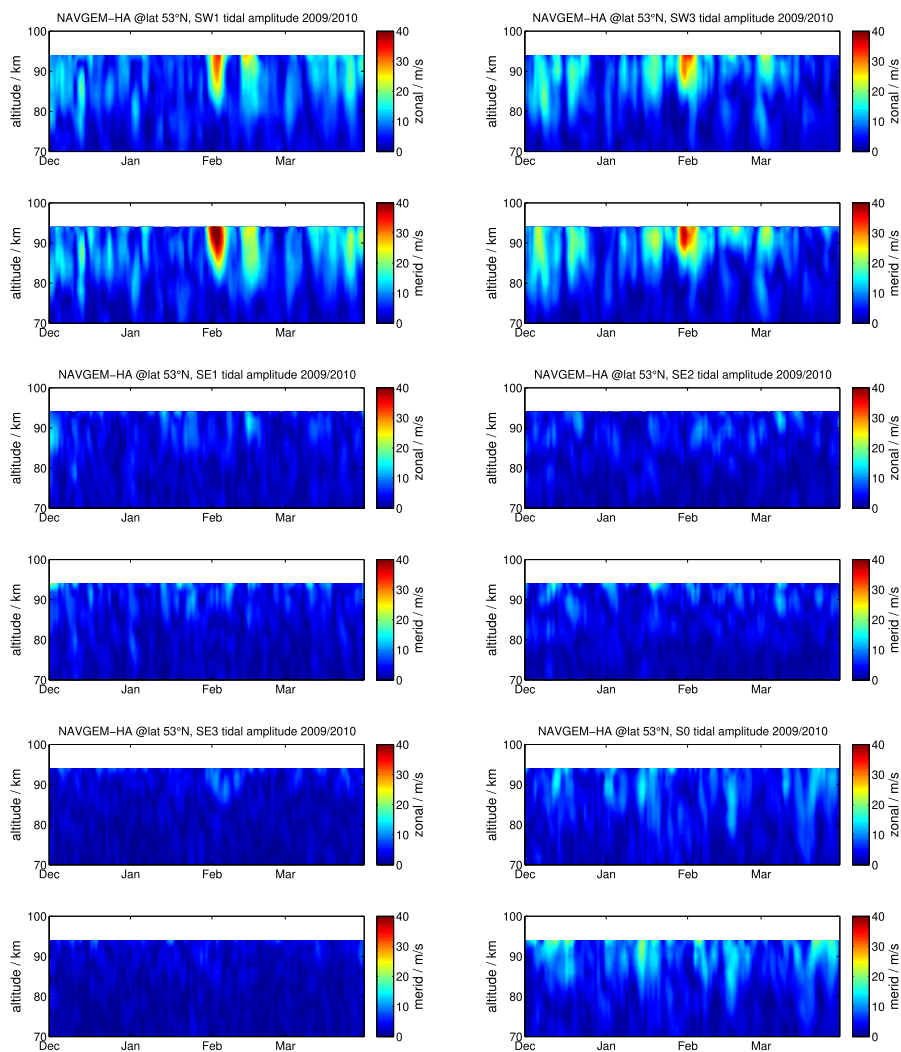

Figure A3. The same as Fig. A1 but above Juliusruh and for the winter 2009/2010.

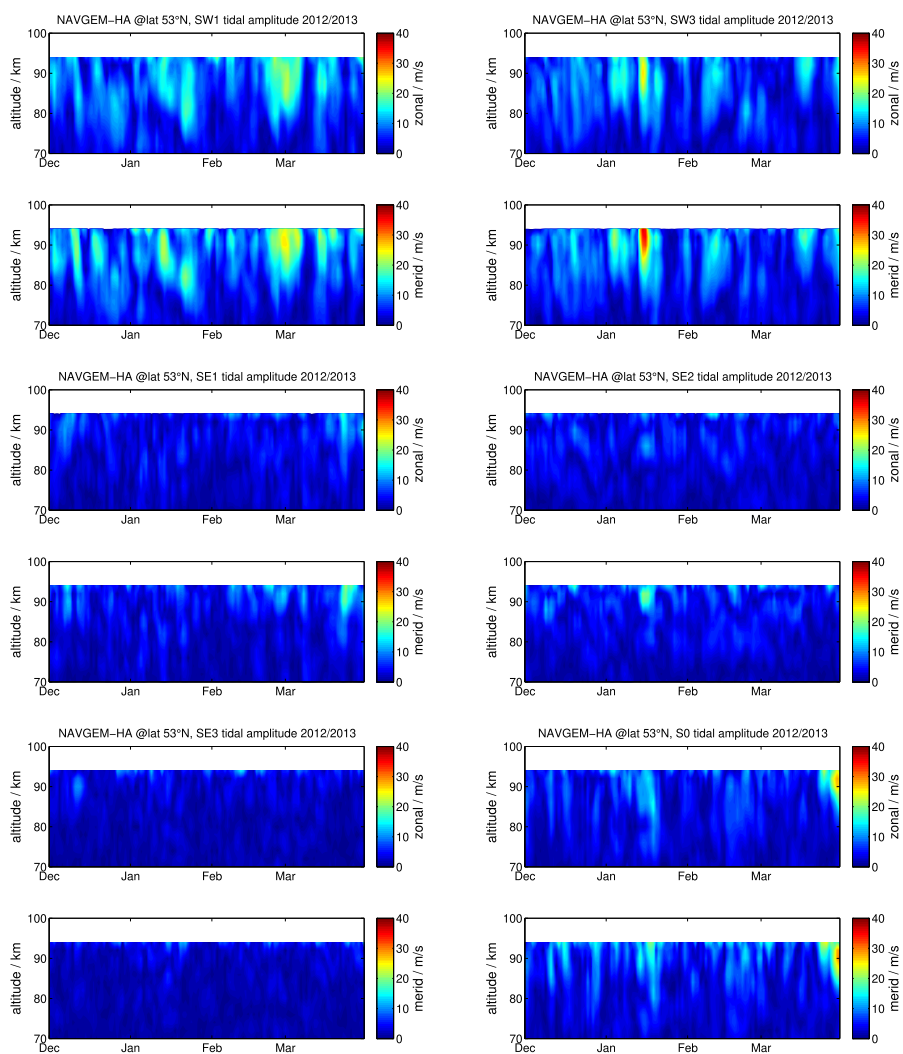

Figure A4. The same as Fig. A1 but above Juliusruh and for the winter 2012/2013.

Author contributions. The manuscript is edited and discussed with all authors. The conceptual idea of the manuscript was developed by Gunter Stober, Kathrin Baumgarten and John McCormack. The meteor radar data analysis is performed by Gunter Stober. Kathrin Baumgarten computed partly the lidar temperatures and analyzed both lidar data sets. Josef Höffner computed the resonance lidar temperatures. Peter Brown contributed with the CMOR radar data, read and edited the manuscript and helped with the discussions. Jerry Czarnecki provided support in the data analysis and helped discussing the results.

Acknowledgements. This work is supported by the University of Bern Institute of Applied Physics and the Oeschger Center for Climate Change Research. Kathrin Baumgarten is supported by the Deutsche Forschungsgemeinschaft (DFG; German Research Foundation) under project LU1174/8-1 (PACOG) of the research unit FOR1898 within the Research Unit MS-GWaves. The work at the Naval Research Laboratory was supported by the Chief of Naval research and by a grant of computer time from the High Performance Computing Modernization Program. We gratefully acknowledge Michael Gerding, Michael Priester and Torsten Köpnick for the maintenance and operation of the lidar systems at IAP as well as all students for helping in lidar operation. We appreciate the support from Josef Hoeffner in computing the resonance lidar temperatures. We acknowledge the technical support of the IAP technicians in the operation of the meteor radars.
