## ABSTRACT

Grafting has been proposed as an interesting strategy that improves the responses of pepper cultivars under salinity. However, very little is known about the physiological mechanisms underlying the increased tolerance provided by rootstocks on the scions. With this aim, we performed this experiment. The commercial 'Adige' pepper cultivar was grafted onto three different pepper accessions that showed differential salt tolerance (accessions 5, 12 and 14). Responses to salinity (40mM NaCl) were studied for 30 days by determining water relations, mineral content, proline accumulation, photosynthetic parameters, nitrate reductase activity and antioxidant capacity. The responses observed were depended on salinity treatment duration and the rootstock used. Higher salt tolerance was achieved when the 'Adige' cultivar was grafted onto the 12 genotype, which allowed not only lower Na<sup>+</sup> and Cl<sup>-</sup> accumulation in the scion, but also ion selectivity maintenance, particularly Na<sup>+</sup>/K<sup>+</sup> discrimination. These traits led to a minor negative impact on photosynthesis, nitrate reductase activity and lipid peroxidation in grafted scion leaves. This work suggests that using tolerant pepper rootstocks that maintain the scion's ion homeostasis is a promising strategy to provide salinity tolerance and can consequently improve crop performance when faced with farmland salinity.

*Key words:* Graft; NaCl; Ions; Pepper; Photosynthesis; Water relations

## 1. Introduction

Grafting plants onto tolerant rootstocks is one of several approaches that can reduce the impact of salinity [1], one of the most serious problems of horticultural crops in arid and semi-arid regions [2].

Pepper is one of the most important vegetable crops in these areas and is considered sensitive to salinity [3], even though salt tolerance can vary between pepper genotypes [4]. Some pepper accessions have been identified as salinity-tolerant and have been successfully used as pepper rootstocks under saline conditions [5].

Several studies have been conducted in tomato and melon to elucidate the mechanisms involved in increased salinity tolerance of grafted plants. This increased tolerance of grafted plants is generally associated with their capacity to exclude or retain and/or accumulate toxic ions,  $\text{Na}^+$  and  $\text{Cl}^-$  in rootstock roots, thus limiting their transport to leaves rather than through the synthesis of osmotically active metabolites or the induction of antioxidant systems [6–8]. Other authors have indicated that influence of rootstock on the salt tolerance of the scion is due to a more efficient control of stomatal functions (changes in stomatal regulation and water relations), which indicate that the grafting incision may alter hormonal signalling between roots and shoots [9]. In other cases, this raised tolerance has been explained by the re-establishment of ionic homeostasis [10].

Nevertheless, the mechanism of resistance against salinity in grafted plants displays great complexity in association with specific rootstock/scion interactions [11,12], and can vary among species. As far as we know, very few studies of this type have been conducted in pepper to elucidate whether or not

1 salt tolerance conferred by rootstocks is also due to exclusion and/or retention  
2 mechanisms, as in tomato or melon given their better capacity to alleviate the  
3 toxic effects of salts or other processes; e.g., maintenance of water relations or  
4 antioxidant capacity. Guifrida et al. [13] found that stunted growth due to salinity  
5 was attenuated in pepper-grafted plants when compared to non-grafted plants  
6 associated primarily with reduced uptake of salt ions and, therefore, with a  
7 lower concentration of these ions in the grafted plants instead of maintaining  
8 leaf turgor by osmotic adjustments.  
9

10 To answer this question, in previous experiments we selected three  
11 pepper accessions with different degrees of salinity tolerance [5] under mild salt  
12 stress. In this study, we aimed to identify the physiological responses to salinity  
13 stress involved in increased tolerance of pepper-grafted plants using these  
14 accessions as rootstocks and to elucidate if mechanisms to tolerance are  
15 related with the role of roots rootstocks in altering the stress perception by the  
16 scion. To fulfil these objectives, we discussed differences in pepper-grafted  
17 plants adaptation mechanisms in response to mild salt stress by comparing  
18 some physiological parameters: photosynthesis; lipid peroxidation levels;  
19 relative water content (RWC); proline concentration; osmotic potential ( $\Psi_s$ ); ions  
20 concentration; nitrate reductase activity (NR). We present evidence that grafting  
21 plants onto appropriate (tolerant) rootstocks is a good tool against salinity  
22 stress, which is mediated mainly by reducing ionic toxicity to the scion.

Based on previous studies, we selected three pepper accessions (wild types) with a different salinity tolerance [5]: 'ECU-973' of *Capsicum chinense* Jacq. (code 12) as being tolerant; 'BOL-58' of *Capsicum baccatum* L. var. *pendulum* (code 14) as being moderately tolerant; and 'Serrano' of *Capsicum annuum* L. (code 5) as being less tolerant. These accessions were chosen as rootstocks and the pepper cultivar 'Adige' (Lamuyo type, Sakata Seeds, Japan) was grafted onto these three pepper accessions in this study. Pepper seeds were sown on 1 December in 100-cell polystyrene trays filled with peat-based substrate and kept in a Venlo-type glasshouse. The graft was performed on 12 February using the tube-grafting method (cutting the growing tip of the rootstock at a 45° angle below the cotyledons, attaching to the scion, previously cut at a 45° angle above the cotyledons, and fixing the rootstock and scion with a clip).

One month after grafting, the root system of the plants was washed to clean the substrate and plants were placed in 5 L polyethylene pots covered with aluminium sheets. Pots were filled with a standard nutrient solution for pepper [14]. The electrical conductivity (EC) and pH of this nutrient solution was 1.7 dS m<sup>-1</sup> and 6.5, respectively. Nutrient solution was added daily to compensate for uptake. After 7 days of leaving seedling plants to acclimatise to pots, salinity treatment was initiated by adding NaCl (40mM) to the nutrient solution to reach an EC of 5.2 dS m<sup>-1</sup> NaCl.

Treatments were defined by two salinity levels (0 and 40mM NaCl) and four plant combinations: the cultivar 'Adige' grafted onto rootstock accessions 5, 12 and 14, and ungrafted 'Adige' plants were used as the controls.

The grafted combinations (cultivar/rootstock) were labelled as A/5, A/12 and A/14. The layout was completely randomised with three replications per combination and six plants per replication.

All the physiological measurements were taken on 14 (T1) and 28 (T2) days after NaCl addition on fully expanded mature leaves (third or fourth leaf from the shoot apex).

During the culture, plants were grown in a Venlo-type greenhouse under natural light conditions ( $610\text{-}870 \mu\text{mol m}^{-2} \text{s}^{-1}$ ), temperature ranges were 21-24°C, and relative humidity was 52-72%.

## 2.2. *Water relations*

The osmotic potential of leaf sap ( $\Psi_s$  in MPa) was measured with an osmometer (Digital osmometer, Wescor, Logan, USA). Two independent determinations were made on each replicate and plant combination, obtained from six plants per treatment and combination at T1 and T2.

Leaves were tightly wrapped in aluminium foil, frozen in liquid nitrogen and stored at -80°C. After thawing, sap was collected from syringes at 25°C and placed in the osmometer. Osmolyte content ( $\text{mmol kg}^{-1}$ ) was converted into MPa using the Van't Hoff equation [15].

Six other similar leaves from two independent plants of each plant combination, salinity treatment and replicate were collected to determine the (RWC) as  $(\text{FW}-\text{DW})/(\text{TW}-\text{DW}) \times 100$ , where FW is fresh weight, DW is dry weight, and TW is turgid weight [15].

### 2.3. Ion analysis

The leaves and roots collected at T1 and T2 for  $n \geq 5$  samples of each treatment and plant combination were dried at 70°C for 4 days. Dried samples were digested in a mixture at 70% of HNO<sub>3</sub>-HClO<sub>3</sub> (2:1). Macronutrients (K<sup>+</sup>, Ca<sup>2+</sup>, Mg<sup>2+</sup> and Na<sup>+</sup>) were measured by ICP emission spectrometry (iCAP 6000, Thermo Scientific. Cambridge, United Kingdom).

The chloride concentration (Cl<sup>-</sup>) in the dry plant material was extracted with 0.1N HNO<sub>3</sub> in 10% (v/v) acetic acid and was determined by potentiometric titration with AgNO<sub>3</sub> in a chloride analyzer (Sherwood, MKII 926). The results were expressed as mg g<sup>-1</sup> DW.

### 2.4. Proline determination

Proline content (mg g<sup>-1</sup> DW) was determined as described by [16]. Leaf pepper tissue (0.05 g) was ground in 3% sulphosalicylic acid, the homogenate was filtered, and 0.75 mL of glacial acetic acid and 0.75 mL of ninhydrin reagent (1.25 g ninhydrin in 30 mL glacial acetic acid and 20 mL 6N phosphoric acid) were added to an aliquot of the filtrate. The reaction mixture was boiled for 1 h, and readings were taken at a wavelength of 520 nm in a spectrophotometer. Three independent determinations were made in three different extracts obtained from 18 plants per treatment and combination (one leaf per plant, and six plants per extract).

### 2.5. Photosynthetic activity and chlorophyll fluorescence

The CO<sub>2</sub> fixation rate ( $A_N$ ,  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), stomatal conductance to water vapour ( $g_s$ ,  $\text{mol H}_2\text{O m}^{-2} \text{ s}^{-1}$ ), transpiration rate ( $E$ ,  $\text{mmol H}_2\text{O m}^{-2} \text{ s}^{-1}$ ) and

1 substomatal CO<sub>2</sub> concentration (C<sub>i</sub>, μmol CO<sub>2</sub> mol<sup>-1</sup> air) were measured in the  
2 steady state while maintaining plants at 1,000 μmol m<sup>-2</sup> s<sup>-1</sup> for 10-15 min and  
3  
4 400 ppm CO<sub>2</sub> with a LI-6400 (LI-COR, Nebraska, USA). Light curves were  
5  
6 previously performed (data not shown) and A<sub>N</sub> was saturated at 900 μmol m<sup>-2</sup> s<sup>-1</sup>

1. The gas exchange and fluorescence determinations were made from 9 am to 11 am (GMT). One measurement per plant was taken, and ten different plants were used (n=10) for each treatment (control and salinity stress) and plant combination.

## 2.6. Nitrate reductase activity

Nitrate reductase activity (EC 1.6.6.1) in leaves was determined *in vivo* following the methods described by [17,18]. Discs, 1 cm in diameter, were punched out of mature fresh leaves. Samples (200 mg) were suspended in a glass vial containing 10 mL of 100 mM potassium phosphate buffer (pH 7.5), 1% (v/v) *n*-propanol and 100 mM KNO<sub>3</sub>. The glass vial was subjected 3 times to vacuum infiltration in order to induce anaerobic conditions in the incubation medium. Plant samples were incubated in a water bath at 30°C for 60 min in the dark and were placed in a boiling water bath for 5 min to stop the enzymatic reaction. The nitrite released from the plant material was determined colorimetrically at 540 nm (spectrophotometer PerkinElmer, Lambda 25) by adding 0.02% (w/v) N-naphthylethylenediamine and 1% sulphanilamide. A standard curve with KNO<sub>2</sub> was prepared to calculate the amount of NO<sub>2</sub> that the samples contained. Sampling and replicates were used as described for proline determination.

## 2.7. Lipid peroxidation

Lipid peroxidation in leaves was estimated through malondialdehyde (MDA) determinations using the thiobarbituric acid reaction following the protocol reported by [19], and modified in [20]. The non-specific background absorbance reading at 600 nm was subtracted from the specific absorbance reading at 532 nm. The sampling and replicates used were those described for proline determination.

## 2.8. Statistical analyses

The results were subjected to a variance analysis (ANOVA; Statgraphics Centurion for Windows, Statistical Graphics Corp.). The mean comparisons were made using Fisher's least significance difference (LSD) test at  $P < 0.05$ . The data obtained in some measurement parameters were subjected to linear regression and analyses to identify the relationships between the parameters.

# 3. Results

## 3.1. Water relations

Plant water relations were assessed by the determination of RWC and  $\Psi_s$  (Figs. 1 and 2). No changes in RWC were observed in the experiment in any plant combination, except for ungrafted plants (Fig. 1A, B), where RWC diminished ( $P < 0.05$ ) after salt treatment.

The  $\Psi_s$  of all the plant combinations reduced significantly ( $P < 0.05$ ) under salinity at T1 and T2 (Fig. 2). At T1, no significant interaction was found. At T2, differences between treatments were greater in ungrafted and A/5 than in A/12 and A/14 ( $P < 0.05$ ).

### 3.2. Ion partitioning

The Na<sup>+</sup> concentration in leaves and roots increased under NaCl (Fig. 3A) in all the plant combinations. The Na<sup>+</sup> concentration in leaves was higher in ungrafted and A/5 plants (Fig. 3A) if compared with A/12 and A/14 (P<0.05) at T1 and T2 under salinity. In general terms, the Na<sup>+</sup> concentration in the roots under salinity was higher than in leaves (Fig. 3B), with a lower concentration found in A/12 and A/14.

Chloride content was approximately 4 times higher than Na<sup>+</sup> in leaves. The Cl<sup>-</sup> concentration in leaves (Fig. 3C) increased with a higher NaCl concentration and time exposure, but this incident did not occur in roots (Fig. 3D) and in none of the plant combinations. Ungrafted and A/5 obtained the highest Cl<sup>-</sup> levels in leaves, whereas A/12 and A/14 plants showed a greater accumulation in roots (P<0.05) (Fig. 3D).

In general terms, a consistent K<sup>+</sup> content reduction trend was observed in leaves at T1 under saline conditions in all the plant combinations (Fig. 3E). This decrease occurred at T2 only in ungrafted and A/5 plants, but not in A/12 and A/14, where no significant differences in the K<sup>+</sup> levels were found if compared with their controls (Fig. 3E). In roots, a marked increase in K<sup>+</sup> content was observed in A/12 at T1 (Fig 3F). In contrast, the K<sup>+</sup> concentration at T2 did not change in A/5 and A/14 under salinity (Fig. 3F).

The Na<sup>+</sup>/K<sup>+</sup> ratio increased significantly depending on salt application and the exposure time in the ungrafted and A/5 leaves (Fig. 3G). The lower values (P<0.05) in leaves were observed for 12/cultivar and 14/cultivar. In the root compartment (Fig. 3H) under salt treatment at T1, the Na<sup>+</sup>/K<sup>+</sup> values increased

in ungrafted and A/5. At T2, the Na<sup>+</sup>/K<sup>+</sup> ratio in roots lowered under salt conditions if compared to the values obtained at T1 in these plant combinations due to a sharp drop in the Na<sup>+</sup> content in roots at T2.

The Ca<sup>2+</sup> (Fig. 4A) and Mg<sup>2+</sup> levels (Fig. 4C) were similar in leaves for the tandem ungrafted and A/5 plants, with reduced plant exposure to NaCl (Fig. 4). In A/12 and A/14, the Ca<sup>2+</sup> and Mg<sup>2+</sup> concentrations in leaves showed minor variations between the control and treated samples (Fig. 4 A, C). In roots, the Mg<sup>2+</sup> levels (Fig. 4D) lowered in all the plant combinations with time, while the Ca<sup>2+</sup> levels lowered in A/5 at T1 and T2, but increased in ungrafted, A/12 and A/14 at T2 (Fig. 4B).

### 3.3. *Proline content in leaves*

Under the control conditions, no significant differences were found in the proline leaf content between plant combinations with time. Salinity gave rise to increased leaf proline content (P<0.05). This increase was similar for all the plants at T1 (Fig. 5A). At T2 (Fig. 5B) under 40mM NaCl, proline content substantially increased in ungrafted and A/5 if compared with their control values, but not in 12/cultivar and 14/cultivar (P< 0.05), which showed similar values to T1.

### 3.4. *Gas exchange parameters*

As shown in Figure 6, the A<sub>N</sub> (Fig. 6A, B) and g<sub>s</sub> (Fig. 6C, D) of the grafted plants did not differ from those of the ungrafted plants under the control conditions. The photosynthesis rate significantly lowered in all the plants

65

( $P < 0.05$ ) in response to salt stress, except 12/cultivar at T2, when the  $A_N$  values did not significantly differ from those of the control (Fig. 6B).

A decrease in  $g_s$  under salt treatment was observed in all the plants (Fig. 6C, D). Significant differences were found for the ungrafted, A/5 and A/14 plants if compared to 12/A at T1 and T2. A minor decrease, but with a significant difference compared to its control, was noted for 12/cultivar.

Instantaneous carboxylation efficiency, estimated by the  $A_N/C_i$  ratio (Fig. 6E, F), reduced in ungrafted, A/5 and A/14 at T1 and T2. Interestingly at T2, minor differences were seen in the  $A_N/C_i$  values in A/12, followed by A/14, if compared to their controls, but no significant differences were observed between them.

### 3.5. Nitrate reductase activity in leaves

Salt stress resulted in diminished NR activity in leaves after 14 (Fig. 7A) and 28 (Fig 7B) days of mild NaCl treatment. Under salinity, the greatest NR activity at T1 and T2 was seen for A/12 plants, with significant differences ( $P < 0.05$ ) if compared to ungrafted and A/5. Nevertheless, the inhibition percentages due to salt application at T2 were not associated with the NR control values: 74% for ungrafted, 50% for 5/cultivar, 22% for 12/cultivar and 32% for 14/cultivar (Fig. 7B).

### 3.6. Lipid peroxidation

At T1 (Fig. 8A), MDA content increased and significant differences were observed only in the ungrafted plants. After 28 days of salt exposure, lipid peroxidation increased significantly in the ungrafted and 5/cultivar plants

( $P < 0.05$ ). It is noteworthy that no further MDA accumulation occurred in any of the plant combinations (Fig. 8B).

### 3.7. *Relationship between osmotic potential, ions and proline concentrations and photosynthesis in leaves*

Regression analyses were performed with the physiological study parameters. Only the significant linear relations that contribute to understanding tolerance mechanisms to salinity ( $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{K}^+$  concentration and proline level vs. osmotic potential and  $A_N$ ) are shown in Table 1.

At T1 and T2, the data gave an inverse linear relationship among  $\Psi_s$  and  $\text{Na}^+$ ,  $\text{Cl}^-$  and proline, but a positive correlation with the  $\text{K}^+$  level in leaves. Proline was the parameter that obtained the steepest slope values to modify  $\Psi_s$ .

$A_N$  at T1 correlated negatively with the  $\text{Na}^+$ ,  $\text{Cl}^-$  and proline concentrations, but not significantly only for the last parameter ( $P > 0.05$ ). The regression analysis indicated inhibition of  $A_N$  with greater dependency of  $\text{Na}^+$  and  $\text{Cl}^-$ . Nevertheless at T2,  $A_N$  lowered, which was due mainly to an increased proline concentration. Although  $A_N$  showed a positive dependency with the  $\text{K}^+$  levels, no significant influence was found, not even at T1 and T2.

## 4. Discussion

NaCl addition is associated with differential responses in physiological parameters in ungrafted and grafted pepper plants. We demonstrate that tolerance to moderate salt stress can be improved by grafting. The best salt acclimation was obtained when accession 12 was used as a rootstock (A/12),

1 based on the minor negative effects caused by salt treatment on  
2 photosynthesis, NR activity and lipid peroxidation. Furthermore, some  
3 favourable physiological characteristics for salt acclimation, such as higher  $K^+$   
4  $Ca^{2+}$  and  $Mg^{2+}$  levels in leaves and a lower  $Na^+/K^+$  ratio, were seen in this plant  
5 combination. The latter parameter has been demonstrated as a good indicator  
6 of salt tolerance [21].  
7  
8  
9  
10  
11  
12  
13

14 Salt tolerance in plants is usually associated with the ability to restrict the  
15 uptake and/or transport of saline ions from roots to leaves and their  
16 compartmentalisation [22]. In this study, more  $Cl^-$  was withheld in the roots of  
17 rootstocks in A/12 and A/14, and less  $Cl^-$  was transported to their leaves if  
18 compared with the ungrafted and A/5 plants under NaCl stress ( $P<0.05$ ). This  
19 suggests either maximised  $Cl^-$  retrieval to the rootstock or a retention  
20 mechanism in the roots of these plant combinations. Unlike  $Cl^-$ , rootstocks 12  
21 and 14 showed a reduced  $Na^+$  net uptake, consequently their leaves gave a  
22 lower  $Na^+$  concentration value if compared with the others ( $P<0.05$ ). Two  
23 mechanisms can explain the lower  $Na^+$  concentration in roots: firstly, as  
24 suggested by Aktas et al. [4], in salt-tolerant pepper genotypes, a plasma  
25 membrane  $Na^+/H^+$  antiporter protein is activated in root cells upon NaCl  
26 exposure. This mechanism has been reported in different grafted plants, such  
27 as melon [23–25], tomato [22,26,27], watermelon [28] and cucumber [29].  
28 Alternatively, the root system of rootstocks 12 and 14 might be able to control  
29  $Na^+$  influx, as reported for pumpkin roots [8].

52

53 Regarding concentration; leaf  $Cl^-$  accumulation exceeded that of  $Na^+$  in  
54 all the plant combinations. This is in accordance with the results obtained by  
55 Navarro et al. [30] and Chartzoulakis and Klapaki [31] in the 'Orlando' variety  
56  
57  
58  
59

64  
65

1 and the 'Sonar' pepper variety, respectively. The higher  $\text{Cl}^-$  concentration, if  
2 compared to  $\text{Na}^+$  (mainly in roots), can be linked to a higher passive uptake root  
3 component and a very feebly active  $\text{Cl}^-$  uptake system [32]. However, it is  
4 unknown whether some rootstocks are capable of regulating the transport of  
5  $\text{Na}^+$  or/and  $\text{Cl}^-$  to leaves [33]. Based on our results, the capacity to regulate  $\text{Na}^+$   
6 and  $\text{Cl}^-$  uptake and transport was linked to the ability of rootstocks, and not to  
7 the grafting process itself (comparing A/5 vs. A/12 and A/14), indicating that the  
8 physiological and biochemical mechanisms of these salts operate at the  
9 rootstock level, as observed in grafted melon plants [7] or cucumber plants [8].

10  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21 Regulation of ion homeostasis and selectivity, particularly  $\text{Na}^+/\text{K}^+$   
22 discrimination, is closely linked to the lower  $\text{Na}^+$  concentration and its relation to  
23 salt tolerance [34]. Given the similar physico-chemical structure between  $\text{Na}^+$   
24 and  $\text{K}^+$ , a high  $\text{Na}^+$  concentration in the external solution can lower the  $\text{K}^+$  level  
25 in the tissues of many plants species [35]. In our study, the  $\text{Na}^+/\text{K}^+$  ratio in  
26 leaves of the ungrafted and A/5 pepper plants under salinity was significantly  
27 higher ( $P < 0.05$ ) than those of the plants grafted onto rootstocks 12 and 14, and  
28 the latter is able to select, use and transport  $\text{K}^+$  to leaves, as in many vegetable-  
29 grafted plants exhibiting salinity tolerance; e.g., tomato [6], melon [9] or  
30 cucumber [11,29]. However, the direct relation between  $\text{K}^+$  homeostasis and  
31 salinity tolerance has not been well-established [1]. In some species,  $\text{Na}^+$  can  
32 be balanced by a higher  $\text{K}^+$  concentration [36], while in other plants, tolerance is  
33 due to the capacity of roots to maintain  $\text{K}^+$  transport in the xylem, as in tomato-  
34 grafted plants [37,38].

Despite the negative effect on plant growth derived from its toxic effect,  
accumulation of ions under salinity can help maintain the turgor pressure of

1 plants [30,39]. In addition, different osmolytes can be involved in the reduction  
2 of  $\psi_s$ , including organic compounds such as sugars, free amino acids,  
3 glycinebetaine, soluble proteins, proline and organic acids [40–42], and/or  
4 macronutrients such as inorganic components [43]. According to our results, a  
5 strong negative correlation between the reduction in leaf  $\psi_s$  and salt ions  
6 content for all the plant combinations was observed in the experiment. The  
7 linear regressions equations showed that  $\text{Na}^+$  and  $\text{Cl}^-$  display a different  
8 response on  $\psi_s$ . The lower osmotic potential seems to be achieved mainly by  
9  $\text{Na}^+$  and, to a lesser extent by  $\text{Cl}^-$ . This can be explained by a more marked  
10 change in  $\text{Na}^+$  accumulation if compared to  $\text{Cl}^-$  between the ungrafted and A/5  
11 vs. A/12 and A/14 plants, rather than by the absolute concentration of both ions.  
12 The reduced osmotic potential assigned to  $\text{Na}^+$  was consistent with pepper  
13 plants [44], and salt-tolerant species such as *Centaurea ragusina* [45], *Atriplex*  
14 *nummularia* [46] or *Aster tripolium* [47]. The contribution of  $\text{K}^+$ ,  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  to  
15  $\psi_s$  under the salinity conditions in our study was more relevant in the A/12 and  
16 A/14 plants at T2, where  $\text{K}^+$ ,  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  represented 30-35% of the total  
17 ions if compared to 15% in the ungrafted and A/5 plants.

41  
42 The adjustment of the osmotic potential through inorganic ion uptake  
43 supposes a much lower energy cost than that conferred by the organic  
44 molecules synthesised in the cell [48]. However in order to reduce  $\psi_s$ , our plants  
45 required proline synthesis to produce sufficient osmotics under salt stress  
46 conditions. The synthesis and accumulation of proline depended on plant  
47 combinations and time exposure. At T1, when the ionic-osmotic phase was  
48 predominant, proline accumulation contributed less. In contrast at T2, strong  
49 proline synthesis took place in the ungrafted and A/5 plants when compared

1 with A/12 and A/14 ( $P < 0.05$ ), and as result, the reduction in  $\psi_s$  strongly related  
2 with proline accumulation in these plant combinations ( $r^2 = 0.95$ ), but more  
3 weakly in the latter ones ( $r^2 = 0.36$ ). An larger amount of proline or other  
4 compatible solutes may protect plants by scavenging the oxygen-free radicals  
5 caused by salt stress [1,29], which has been observed in different grafted plants  
6 like tomato [49], cucumber [29] or tobacco [50]. Conversely, the concomitant  
7 increase in proline with a prolonged exposure time in the ungrafted and A/5  
8 plants was consistent with the higher leaf proline concentrations in salt-sensitive  
9 genotypes reported for other species such as wheat [51], barley [52], *Centaurea*  
10 *ragusina* [45] or rice [53]. This indicates that significant proline accumulation  
11 generally occurs only beyond the salt stress threshold [54]. The energy cost  
12 imposed by ion exclusion and/or compartmentalisation mechanisms are  
13 relatively low when compared with the synthesis of organic molecules [52,55]  
14 but, conversely, accumulation of saline ions may interfere with the normal  
15 biochemical activities taking place within the cell [56].

Plants respond to lower water availability under salinity by reducing their  
leaf transpiration, stomatal conductance, and by adjusting their root water  
uptake [57]. Under prolonged periods of exposure to salt, root conductivity can  
be partially recovered, mainly through the accumulation of compatible solutes  
and/or ions in roots. These responses should be involved in the maintenance of  
the relative water content in the leaves of grafted pepper genotypes in the  
experiment. Despite the reduction of the leaf osmotic potential and stomatal  
conductance described in the ungrafted plants, no root conductivity recovery  
should occur in the experiment since RWC was significantly lower under  
salinity. According to this relation, a reduction in either the functionality or the

1 amount of aquaporins has been reported to occur in pepper plants under  
2 salinity [30,58].  
3

4 In this experiment, the Na<sup>+</sup> and Cl<sup>-</sup> concentrations did not provoke salt  
5 toxicity symptoms in our pepper plants, and only minor leaf chlorosis and small  
6 necrotic areas was/were observed in ungrafted plants. These results agree with  
7 the lipid peroxidation levels reported in ungrafted plants when compared with  
8 grafted plants. Lower MDA concentrations were found in A/12 plants, followed  
9 by A/14. Nevertheless, gas exchange parameters were affected after a 2-week  
10 salt exposure and extended to T2. Excessive Na<sup>+</sup> and Cl<sup>-</sup> accumulation is  
11 harmful and may disrupt the integrity of the photosynthetic apparatus [24].  
12 Reduced photosynthetic capacity can be related to higher leaf Na<sup>+</sup> or Cl<sup>-</sup>  
13 concentrations [22,28,59,60]. In our experiments, the highly significant  
14 correlation found between A<sub>N</sub> and Na<sup>+</sup> and Cl<sup>-</sup> foliar concentrations suggested  
15 that both ions can be involved in reduced photosynthesis, although the  
16 regression analyses indicated a predominant inhibition effect by Na<sup>+</sup>. This  
17 effect can be linked to the concentration level in leaves and/or a major toxic  
18 power to promote inhibition. In contrast to the reductions observed in the other  
19 plant combinations, maintenance of A<sub>N</sub> in the A/12 plants can be attributed, at  
20 least in part, to increased K<sup>+</sup> levels or to other beneficial macronutrients, such  
21 as Ca<sup>2+</sup> and Mg<sup>2+</sup>, which contribute to better regulate stomata regulation under  
22 salinity [35]. Notwithstanding, g<sub>s</sub> significantly lowered under mild salt stress in all  
23 the plant combinations and for the time exposures, which corroborates a  
24 previous finding that g<sub>s</sub> are very sensitive to salt [49,61]. In addition, the  
25 diminished instantaneous carboxylation efficiency (A<sub>N</sub>/C<sub>i</sub>) noted at T1 and T2 in  
26 the ungrafted, A/5 and A/14 plants suggests that salt stress affects

photosynthesis by metabolic limitations, probably in association with reduced Rubisco carboxylase activity [62]. In contrast, stomatal limitations to photosynthesis should occur in A/12 at T1 and T2 since no changes in  $A_N/C_i$  were observed under salinity [63].

There is evidence that photosynthesis regulates nitrate reduction by modulating NR activity [64,65], which agrees with the results presented herein, which indicate that salt application diminishes  $A_N$  and NR activity. The most tolerant rootstock (A/12) in  $A_N$  terms exhibited lower NR inhibition if compared with the others. A drop in NR by salt can be due to: reduced nitrate transport to leaves, mainly because of nitrate/chloride competition [66]; inactivation of  $\text{NO}_3^-$  transporters by toxic effects of salt ions [67]; the disruption of root membrane integrity [58]; diminished  $\text{NO}_3^-$  transport from roots to leaves due to a lower transpiration flow [15] and, consequently, low  $\text{NO}_3^-$  loading into the root xylem, which affects NR activity [68]. Accordingly, and in accordance with the results obtained, the more marked decrease noted in NR activity (ungrafted and A/5 plants) in leaves can be associated with higher  $\text{Cl}^-$  and  $\text{Na}^+$  accumulations and/or lower carbon fixation rates.

In conclusion, the greater salt tolerance of grafted plants, mainly the A/12 (and A/14) combinations, can be attributed to their ability to restrict  $\text{Cl}^-$  transport to leaves and to diminished  $\text{Na}^+$  loading in roots, thus favouring  $\text{K}^+$  ( $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ ) uptake and allowing a smaller osmotic potential with a lower energy cost. These traits led to a minor inhibitory effect on photosynthesis and NR activity, which favourably affected yield [5] when compared with the A/5 and ungrafted plants. Knowledge of the physiological and biochemical processes that promote salt stress tolerance can improve our understanding of not only the mechanisms

involved in the scion and rootstock interaction, but also of the selection of robust rootstocks to be used under field salinity conditions.

**Fig. 7.** Nitrate reductase activity ( $\mu\text{mol NO}_2 \text{ g}^{-1} \text{ FW h}$ ) in the leaves of ungrafted pepper plants (cultivar 'Adige') and the cultivar grafted onto accessions 5, 12 and 14 after addition of NaCl at 0mM (□) and 40mM (■) for exposures of 14 days (A) and 28 days (B). Dates are mean values $\pm$ SE for n=6. In each plant combination, different letters indicate significant differences at  $P < 0.05$  (LSD test).

**Fig. 8.** Leaf malondialdehyde (MDA) content ( $\text{nmol MDA g}^{-1} \text{ FW}$ ) in the leaves of ungrafted pepper plants (cultivar 'Adige') and the cultivar grafted onto accessions 5, 12 and 14 after addition of NaCl at 0mM (□) and 40mM (■) for exposures of 14 days (A) and 28 days (B). Dates are mean values $\pm$ SE for n=6. In each plant combination, different letters indicate significant differences at  $P < 0.05$  (LSD test).

**Table 1.**

Linear regression and statistical analysis between mineral ions concentration (mg g<sup>-1</sup> DW) in the leaves of the cultivar “Adige” ungrafted and grafted onto different pepper genotypes (5, 12 and 14), and proline (mg g<sup>-1</sup> DW), as related to the osmotic potential ( $\Psi_s$  s in MPa) and CO<sub>2</sub> fixation rate ( $A_N$ ,  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ).

Salt treatment time	Regression equations	<i>P</i> *	<i>R</i> <sup>2</sup>
T1	$\Psi_s = -0.021[\text{Na}^+] - 1.05$	0.0035	0.782
	$\Psi_s = -0.006 [\text{Cl}^-] - 0.99$	0.0003	0.898
	$\Psi_s = 0.02 [\text{K}^+] - 1.61$	0.008	0.716
	$\Psi_s = -0.22 [\text{Proline}] - 0.64$	0.0229	0.616
	$A_N = -0.641 [\text{Na}^+] + 21.35$	0.0002	0.919
	$A_N = -0.1616 [\text{Cl}^-] + 22.47$	0.0017	0.828
	$A_N = 0.642 [\text{K}^+] + 2.48$	0.1333 ns	0.701
	$A_N = -7.856 [\text{Proline}] + 37.28$	0.0548 ns	0.593
T2	$\Psi_s = -0.029 [\text{Na}^+] - 1.13$	0.0001	0.923
	$\Psi_s = -0.0065 [\text{Cl}^-] - 1.105$	0.0031	0.792
	$\Psi_s = 0.021 [\text{K}^+] - 1.87$	0.0514 ns	0.495
	$\Psi_s = -0.143 [\text{Proline}] - 1.02$	0.0332	0.986
	$A_N = -0.647 [\text{Na}^+] + 21.81$	0.0004	0.897
	$A_N = -0.144 [\text{Cl}^-] + 22.46$	0.0032	0.788
	$A_N = 0.537 [\text{K}^+] + 4.88$	0.0794 ns	0.635
	$A_N = -2.943[\text{Proline}] + 24.38$	0.0018	0.910

Determinations were made after 14 (T1) and 28 (T2) days. Fisher's least significance difference (LSD) test at  $P < 0.05$  was used.

\*For all the linear regressions, the degrees of freedom are  $n = 4$ .
