This work was supported in part by the Understanding and Modeling of the Earth System with Machine Learning (USMILE) under the European Research Council (ERC) Synergy Grant 2019, in part by the Carl Zeiss Foundation within the scope of the program line "Breakthroughs: Exploring Intelligent Systems" for "Digitization—explore the basics, use applications," and in part by the German Research Foundation and the Open Access Publication Fund of the Thüringer Universitäts—und Landesbibliothek Jena Projekt 433052568.

**ABSTRACT** Describing ecosystem carbon fluxes is essential for deepening the understanding of the Earth system. However, partitioning net ecosystem exchange (NEE), i.e. the sum of ecosystem respiration (R<sub>eco</sub>) and gross primary production (GPP), into these summands is ill-posed since there can be infinitely many mathematically-valid solutions. We propose a novel data-driven approach to NEE partitioning using a deep state space model which combines the interpretability and uncertainty analysis of state space models with the ability of recurrent neural networks to learn the complex functions governing the data. We validate our proposed approach on the FLUXNET dataset. We suggest using both the past and the future of Reco's predictors for training along with the nighttime NEE (NEEnight) to learn a dynamical model of Reco. We evaluate our nighttime R<sub>eco</sub> forecasts by comparing them to the ground truth NEE<sub>night</sub> and obtain the best accuracy with respect to other partitioning methods. The learned nighttime  $R_{eco}$  model is then used to forecast the daytime R<sub>eco</sub> conditioning on the future observations of different predictors, i.e., global radiation, air temperature, precipitation, vapor pressure deficit, and daytime NEE (NEE<sub>day</sub>). Subtracted from the NEE<sub>day</sub>, these estimates yield the GPP, finalizing the partitioning. Our purely data-driven daytime R<sub>eco</sub> forecasts are in line with the recent empirical partitioning studies reporting lower daytime Reco than the Reichstein method, which can be attributed to the Kok effect, i.e., the plant respiration being higher at night. We conclude that our approach is a good alternative for data-driven NEE partitioning and complements other partitioning methods.

**INDEX TERMS** Deep state space models, net ecosystem exchange, NEE partitioning, time series forecasting.

### I. INTRODUCTION

The task of net ecosystem exchange (NEE) partitioning is highly relevant in environmental science, as it deepens the understanding of the underlying mechanisms constraining the ecosystem function, in the global warming context for instance [1]. NEE is a measure of the net exchange of carbon

The associate editor coordinating the review of this manuscript and approving it for publication was Ioannis Schizas.

between an ecosystem and the atmosphere given by:

$$NEE = R_{eco} + GPP. (1)$$

Ecological variables in Eq. (1),  $R_{eco}$  and GPP, denote the total carbon flux by respiration processes of all organisms in an ecosystem, and the gross amount of carbon uptake by photosynthesis from plants, respectively. The NEE values are measured, but the problem of obtaining either  $R_{eco}$  or GPP from those measurements is ill-posed since there can be infinitely many possible solutions contributing to the

given sum. Since no photosynthesis occurs during the night, GPP nighttime values are close to zero and hence nighttime NEE (NEE $_{night}$ ) corresponds to the nighttime  $R_{eco}$ .

Probabilistic state-space models are a rich framework for an interpretable representation of the evolution of physical processes (e.g., ecosystem respiration), and are of fundamental significance in ecological time series analysis since they can take into account latent factors and the uncertainty in the observations. Deep state space models combine the interpretability and uncertainty analysis of state space models with the ability of recurrent neural networks (RNNs) to learn the complex functions governing the data. In this paper, we propose to use a deep probabilistic state space model, namely a deep state space model DeepState [2], to partition NEE. We first learn the underlying dynamical model of R<sub>eco</sub> using measured NEE<sub>night</sub> data and both the past and the future of Reco predictors. Once the model is learned with the assistance of those predictors, we use it to predict daytime values of Reco and can then subtract the predicted values of Reco from the entire NEE time series to obtain GPP. To the best of our knowledge, our approach is the first to employ a deep probabilistic model for the task of NEE partitioning.

In addition to its ability to handle missing data, another novelty of our approach is that we use both the past and the future of  $R_{eco}$ 's predictors. The candidate predictors we use for learning the dynamical model of  $R_{eco}$  and predicting its values during the daytime are: global radiation  $(R_g)$ , air temperature  $(T_{air})$ , water vapor pressure deficit (VPD), precipitation (PPT) and daytime NEE (NEE<sub>day</sub>). We choose the predictors contributing to the best forecast of the ground truth NEE<sub>night</sub> and then use them for forecasting  $R_{eco}$  during the daytime.

#### A. RELATED WORK

#### 1) NEE PARTITIONING

The most widely used approach for partitioning NEE into Reco and GPP is the Reichstein method [3]. It uses temperature sensitivity of NEE<sub>night</sub> to predict the daytime R<sub>eco</sub>. GPP is then obtained by subtracting Reco from NEE. Similarly to other numerical NEE partitioning methods such as that by Lasslop et al. [4], although very useful and easy to implement, it does not consider multiple co-acting factors that modulate GPP and Reco. Tramontana et al. [1] develop an approach to account for the said factors modulating these two carbon fluxes by implementing a hybrid data-driven method, NN<sub>C-part</sub>, based on feedforward neural networks [5], that can use a comprehensive dataset of soil and micro-meteorological variables. The expert knowledge is incorporated in the algorithm by introducing a photosynthesis response based on the radiation-use efficiency concept. In contrast to our approach, however, this NEE partitioning approach has a limitation in the sense that it does not handle the missing data values, nor the missing predictors. This constrains its applicability to the FLUXNET sites with large quantities of missing data, which is often the case due to the sensitivity of the sensors used

for the measurements in combination with the unfavorable weather conditions at the measuring sites. Since we use a probabilistic time series forecasting method, the missing values in our  $R_{\rm eco}$  forecasts never occur. Moreover, we do not need to approximate daytime  $R_{\rm eco}$  or create proxies for GPP because we use both the past and the future of the selected  $R_{\rm eco}$  predictor variables and thereby do not incur additional approximation error.

A study by Oikawa et al. [6] analyzed several partitioning methods, and conducted an independent empirical NEE partitioning. This approach consisted of measuring ecosystem-scale fluxes of stable C isotopes via a quantum cascade laser spectrometer, and pairing those measurements with the biophysical model CANVEG to obtain GPP and R<sub>eco</sub>. These two carbon fluxes were on average 10-13% lower than both Reichstein-partitioned GPP and Reco and GPP and Reco obtained by the gap filling [7] of NEE. The authors further state that since both of these partitioning methods use NEEnight to infer daytime Reco, they are likely overestimating GPP and Reco during the day. Moreover, they emphasize that the effect of plant respiration being higher at night, known as the Kok effect [8], possibly supports this claim. Despite our approach using NEE<sub>night</sub> to estimate daytime R<sub>eco</sub>, we also obtain lower R<sub>eco</sub> estimates than those of the Reichstein- and NN<sub>C-part</sub> partitioning methods, in accordance with Oikawa et al. [6], since we use the future of Reco predictors in addition. We are thereby able to potentially model the daytime Reco forecasts more realistically with respect to these predictors. The study performed by Lee et al. [9] uses continuous stable isotope measurements in a Pacific Northwest Douglas-fir forest ecosystem for NEE partitioning and also reports estimated daytime R<sub>eco</sub> lower than the conventional approaches. Furthermore, similar results were obtained in the most recent study on the topic by Kira et al. [10], in which the authors used a parsimonious Solar-Induced Chlorophyll Fluorescence (SIF)-based approach for NEE partitioning and examined its performance using synthetic simulations and field measurements.

#### 2) TIME SERIES FORECASTING USING DEEP LEARNING

State space models have been used for decades as one of the main methods for sequence modeling [11]. Other related algorithms from a graphical model perspective are Kalman filters [12] and conditional Markov processes [13]. With the development of deep learning and variational inference resulting in the rise of Variational Auto Encoders (VAE) [14], several methods for sequential data based on VAEs have appeared as well. Chung et al. [15] propose a recurrent latent variable model for sequential data, namely the Variational Recurrent Neural Network. It can model variability such as that observed in highly structured data like natural speech through the use of high-level latent random variables. When it comes to other deep state space models for sequential data, Doerr et al. [16] propose a probabilistic recurrent state space model with a scalable training algorithm based on a doubly stochastic variational inference and Gaussian processes.

Krishnan et al. [17] introduce the deep Kalman filter – a deep state space model, which can generate counterfactual data given an action variable, apart from its capability of time series forecasting. In 2017, Salinas et al. [18] introduced a probabilistic forecasting method based on the training of an autoregressive recurrent network model on a large number of related time series called DeepAR. A year later, two deep state space models were proposed. Namely, Zheng et al. [19] proposed the State Space LSTM models alongside a sampler based on sequential Monte Carlo method [20] that directly draws samples from the joint posterior. The other deep state space method, DeepState [2], parameterizes a per-time-series linear state space model with a jointly-learned RNN and scales from regimes with little training data to those where large amounts of time series are available to learn accurate models. It compares favorably to the state-of-the-art results on probabilistic time series forecasting tasks which is a reason why we employ it for the task of partitioning NEE.

#### B. OUTLINE OF THE PAPER

The ecological data is abundant and NEE has been measured by more than 200 FLUXNET towers all over the world for decades, yet there are very few machine learning approaches for NEE partitioning. The existing ones rely on approximations of the daytime Reco using its nighttime values and creating proxies of GPP with the use of NEEday which can incur additional approximation error. The goal of this paper is to introduce a purely data-driven approach to partition NEE based on a deep state space model DeepState [2], which we introduce in Section II. Instead of relying on other method's approximations of the daytime Reco, we use the known Reco predictors' both the past and the future to obtain daytime Reco forecasts having plausible relationships with those predictors. Our methodology is described in detail in Section III. Our method's performance compared to that of other time series forecasting methods and other NEE partitioning methods with respect to the ground truth NEE<sub>night</sub> is presented in Section III-C. Promptly thereafter, in Section III-D, we present our daytime Reco forecasts. Section IV concludes the paper.

## II. DEEPSTATE

Before introducing the DeepState model [2] in more detail, we will first discuss linear state space models, as they are an important component of DeepState's architecture. General linear Gaussian state space models can be defined as follows:

$$z_t = A_t l_t + \eta_t, \quad \eta_t \sim \mathcal{N}(0, 1) \tag{2}$$

$$l_t = F_t l_{t-1} + g_t \epsilon_t, \quad \epsilon_t \sim \mathcal{N}(0, 1). \tag{3}$$

In Eqs. (2) and (3),  $z_t$  denotes a vector of observations, aptly called the *observation vector*, whereas  $l_t$  is an unobserved vector called the *state vector* or the *latent state*, both at time t, for t = 1, ..., T, as per Durbin and Koopman [21]. Furthermore, by  $\eta_t$ ,  $\epsilon_t$  we denote the mutually-independent error terms and by  $A_t$ ,  $F_t$ ,  $g_t$  different matrices. Matrix  $A_t$  is

called the *system matrix*. Latent state  $l_t \in \mathbb{R}^L$  at time t, for  $L \in \mathbb{N}$ , changes according to the influence of the *transition matrix*  $F_t$  and a random *innovation*  $g_t \epsilon_t$ . The structure of  $F_t$  and the *innovation strength*  $g_t$  determine which type of time series patterns are encoded by the latent state  $l_t$ .

The desired benefits of using a state space model are estimating the underlying evolution of the unobserved signal  $l_t$  given the data  $z_i$  for  $i=1,\ldots,s,s\in\mathbb{N}$  and the corresponding system parameter updates. If s< t, the problem is called *forecasting*. When s=t, it is called *filtering*, and if s>t, *smoothing*. We will concentrate on forecasting since we would like to learn a data-driven time-dependent model of  $R_{\rm eco}$  and estimate its daytime values to partition NEE.

The deep state space method we are using is based on probabilistic forecasting. A probabilistic forecast consists of a probability density function which estimates the respective probability distributions for all possible future outcomes of a random variable. To describe the concept more formally, following Rangapuram  $et\ al.\ [2]$ , we let  $\{z_{1:T_i}^{(i)}\}_{i=1}^N$  be a set of univariate target time series, where  $z_{1:T_i}^{(i)}=(z_1^{(i)},\ldots,z_{T_i}^{(i)})$  and  $z_i^{(i)}\in\mathbb{R}$  is the value of the i-th time series at time t, for  $t=1,\ldots,T_i$  and  $i=1,\ldots,N$ , where  $T_i,N\in\mathbb{N}$ . Further, let  $\{x_{1:T_i+\tau}^{(i)}\}_{i=1}^N$  be a set of associated covariate vectors with  $x_i^{(i)}\in\mathbb{R}^D$ , for  $D,\tau\in\mathbb{N}$  and  $i=1,\ldots,N$ . The goal is to produce a set of probabilistic forecasts, i.e. for each  $i=1,\ldots,N$ , we are interested in the probability distribution of future trajectories  $z_{T_i+1:T_i+\tau}^{(i)}$  given the past ones, as well as all the past and  $\tau$  future samples of the covariate vectors:

$$p(z_{T_{i}+1:T_{i}+\tau}^{(i)} \mid z_{1:T_{i}}^{(i)}, x_{1:T_{i}+\tau}^{(i)}; \Phi).$$
 (4)

In Eq. (4),  $\Phi$  denotes the set of learnable parameters of the model, which are, in the case of DeepState, shared between and learned jointly from all N time series. For any  $i=1,\ldots,N$ , we refer to the time range  $\{1,\ldots,T_i\}$  as the training range, and to  $\{T_i+1,\ldots,T_i+\tau\}$  as prediction range. We assume that the covariate vectors  $x_t^{(i)}$  are given in both the training and the prediction range, as seen in Eq. (4).

Constructed as a fusion of deep learning and state space models, DeepState is a forecasting method that parameterizes a particular linear state space model (Eqs. (2) and (3)) using an RNN. The observations are generated from the latent state  $l_t$  according to the following model:

$$z_t = y_t + \sigma_t \epsilon_t, \quad \epsilon_t \sim \mathcal{N}(0, 1)$$
  
$$y_t = a_t^{\mathsf{T}} l_{t-1} + b_t$$
 (5)

where  $a_t \in \mathbb{R}^L$ ,  $\sigma_t \in \mathbb{R}_{>0}$  and  $b_t \in \mathbb{R}$  are additional model parameters. The initial state  $l_0$  is assumed to follow an isotropic Gaussian distribution, namely  $l_0 \sim \mathcal{N}(\mu_0, \operatorname{diag}(\sigma_0^2))$ . The state space model is entirely determined by the parameters  $\Theta_t = (\mu_0, \Sigma_0, F_t, g_t, a_t, b_t, \sigma_t)$ ,  $\forall t > 0$ . One way of estimating them is by solving the optimization problem:

$$\underset{\Theta_{1:T}}{\operatorname{argmax}} p_{SS}(z_{1:T}|\Theta_{1:T}), \tag{6}$$

where

$$p_{SS}(z_{1:T}|\Theta_{1:T}) := p(z_1|\Theta_1) \prod_{t=2}^{T} p(z_t|z_{1:t-1}, \Theta_{1:t})$$

$$= \int p(l_0) \left[ \prod_{t=1}^{T} p(z_t|l_t) p(l_t|l_{t-1}) \right] dl_{0:T}$$
 (7)

denotes the marginal probability of the observations  $z_{1:T}$ , given the parameters  $\Theta$  under the state space model.

DeepState learns a function

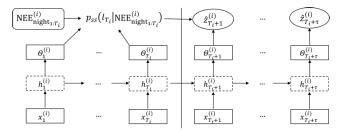

$$\Psi(x_{1:t}^{(i)}, \Phi) = \Theta_t^{(i)}, \quad i = 1, \dots, N, \ t = 1, \dots, T_i + \tau$$
 (8)

which maps the covariate vectors  $x_{1:T_i}^{(i)}$  associated with each target time series  $z_{1:T}^{(i)}$ , as well as a set of shared parameters  $\Phi$ , to the (time-dependent) parameters  $\Theta_t^{(i)}$  of a linear state space model for the i-th time series. This is done globally, over all-time series, instead of learning the state space parameters for each time series independently. This mapping is parameterized by a multi-layer RNN with LSTM cells [22] and parameters from  $\Phi$ . The parameters of the RNN are learned jointly from a dataset of raw time series and their covariates, so that the model can extract features and learn complex temporal patterns. During training, the inputs to the network are the covariate vectors  $x_t^{(i)}$ , together with the previous network output  $h_{t-1}^{(i)}$  at each time step t in the training range  $\{1, \ldots, T_i\}$ . Then, the network output, computed by a recurrent function h, namely  $h_t^{(i)} = h(h_{t-1}^{(i)}, x_t^{(i)}, \Phi)$  is used to determine the parameters  $\Theta_t^{(i)}$  of the state space model. Those parameters are then used to obtain the likelihood of the given observations  $z_{1:T_i}^{(i)}$ , as seen in Eq. (7). The shared network parameters  $\Phi$  are then learned by maximizing the likelihood  $\mathcal{L}(\Phi)$  given by Eq. (9).

$$\mathcal{L}(\Phi) = \sum_{i=1}^{N} \log p(z_{1:T_i}^{(i)} \mid x_{i:T_i}^{(i)}, \Phi)$$

$$= \sum_{i=1}^{N} \log p_{SS}(z_{1:T_i}^{(i)} \mid \Theta_{i:T_i}^{(i)}). \tag{9}$$

The forecasts are obtained as follows, given a target time series  $z_{1:T_i}^{(i)}$  in the training range i.e. for time steps  $1,\ldots,T_i$ , and associated covariate vectors  $x_{1:T_i+\tau}^{(i)}$  in both the training and the prediction range. Namely, first the posterior of the latent state  $p(l_{T_i}|z_{1:T_i})$  is computed for the last time step  $T_i$  in the training range using the observations  $z_{1:T_i}^{(i)}$  and the state space parameters  $\Theta_{1:T_i}^{(i)}$  obtained by unrolling the RNN network in the training range. Given the posterior of the latent state  $p(l_{T_i}|z_{1:T_i})$ , prediction samples are generated by recursively applying the transition equation and the observation model where the state space parameters for the prediction range  $\Theta_{T_i+1:T_i+\tau}^{(i)}$  are obtained by unrolling the RNN in the prediction range. An illustration of the DeepState forecast with NEE<sub>night</sub> as the observation can be seen in Fig. 1. Lower and upper bounds for the diagonal of the prior covariance

**FIGURE 1.** Illustration of forecasting using DeepState. Here we substitute observations z by NEE<sub>night</sub> to portray our training data. By  $\hat{z}^{(i)}$  we denote the forecasted values of R<sub>eco</sub> for a given sample  $i \in \{1,\ldots,N\}$ , with  $T_i = 288$  and  $\tau = 48$ . In our setup, vector  $x^{(i)}$  consists of a subset of R<sub>eco</sub> predictors Rg, T<sub>air</sub>, PPT, VPD and NEE<sub>day</sub> in both training and prediction ranges separated by the vertical line.

matrix  $\Sigma$  of the latent state  $l_t$  are set to  $10^{-6}$  and 1 by default, respectively. Lower and upper bounds for the standard deviation of the innovation function  $g_t$  are by default set to  $10^{-6}$  and 0.01, respectively. Throughout this paper, we refer to covariate vectors as *predictor variables* or *predictors*.

### **III. PARTITIONING NEE USING DEEPSTATE**

Our NEE partitioning approach relies on DeepState [2] to learn the dynamical model of nighttime  $R_{eco}$  and estimate it during the day. This estimation is aided not only by the past (days and nights) of the predictor variables but also by their values during the period in which we want to estimate  $R_{eco}$ , i.e. in the prediction range. Once the daytime  $R_{eco}$  forecast is obtained, it is possible to subtract it from the observed NEE $_{day}$  values to obtain GPP and thus partition NEE.

Our source code is available at https://github.com/cvjena/nee-partitioning.

#### A. METHODOLOGY

We make use of the fact that NEEnight equals the nighttime R<sub>eco</sub>, thus putting our approach in the category of the nighttime partitioning methods [23]. However, in contrast to NN<sub>C-part</sub> method [1], for instance, we do not average the nighttime R<sub>eco</sub> values to leverage the lack of daytime R<sub>eco</sub>, since DeepState can handle missing values during training. More precisely, DeepState approximates the distribution of the target variable and samples from it during forecasting, so there can be no missing values in the forecasts. We separate the NEE observations during day and night by retrieving exact times of sunrise and sunset for each site according to its timezone. We increase these values by one hour to ensure that there is enough daylight to activate photosynthesis in the morning and that there is no daylight in the evening in order to separate nighttime observations. We train on the NEE<sub>night</sub> observations, which we do not normalize, to learn the dynamical model of Reco as a function of its previous values. To achieve this even during the daytime, we use different Reco predictors Rg, Tair, VPD and PPT, as well as NEE<sub>day</sub> as covariate feature vectors of the Deep-State model. In regard to the model parameters, we use the batch size of 32, the dropout rate of 0.1, the learning rate of  $10^{-4}$ , and the LSTM configuration of two layers and 40 cells. The training samples consist of half-hourly

TABLE 1. Vegetation type and annual mean temperature of different FLUXNET sites. Evergreen Broadleaf Forests are referred to as EBF, Deciduous Broadleaf Forests as DBF, Evergreen Needleleaf Forests as ENF, and Savannas as SAV.

NEE<sub>night</sub> observations spanning one week, originating from the four summer months, by shifting the aforementioned one-week window by two days. We train on six days and use the last day for testing. Training on longer samples, i.e. 13 or 55 days did not improve the results. We showcase the DeepState's training and test loss over 600 epochs in Fig. 5 given in the Appendix A. Adapting the hyperparameters of the DeepState such as the number of training periods when using different predictor variables did not yield a considerable difference in the forecasts. Furthermore, we tested different number of LSTM layers, dropout rates and learning rates while predicting the NEEnight as shown in Fig. 6 given in the Appendix A. This type of hyperparameter tuning also did not substantially improve the DeepState's NEE<sub>night</sub> forecasts. Moreover, the hyperparameter configuration which produces this slight improvement differs for each FLUXNET site and each subset of the predictor variables. Therefore, in order to fix a hyperparameter configuration that achieves the best NEE<sub>night</sub> forecasts on average, we chose the above-mention experimental setup to facilitate the application of our NEE partitioning method.

We forecast one full day of  $R_{eco}$  which can then be subtracted from NEE for obtaining GPP. The quantitative evaluation is performed for the nighttime samples to assess the prediction accuracy of the learned night  $R_{eco}$  model with respect to the ground truth NEE<sub>night</sub>. Due to the non-stationarity of the training data, our method sometimes yields suboptimal nighttime  $R_{eco}$  forecasts, however this occurs in less than 3% of the forecasts and are shown in Fig. 7 given in the Appendix B. The interpretation of the daytime  $R_{eco}$  forecast obtained by using its learned model while conditioning on different daytime values of the predictors will be discussed in Section III-D with respect to the multiple empirical studies as there is no ground truth daytime  $R_{eco}$ .

We apply our NEE partitioning approach to data from the FLUXNET sites of different climate regions. European sites in France (FR-Pue), Germany (DE-Hai), the Netherlands (NL-Loo), and Italy (IT-Ro1), as well as equatorial sites in Brazil (BR-Sa3) and Congo (CG-Tch) were analyzed. Table 1 shows an overview of vegetation types and the average annual temperature at each site. The sites are chosen to enable a fair overview in context of other NEE partitioning methods and provide a broader analysis of our NEE partitioning methods aross different vegetation and climate conditions. We selected the FLUXNET sites IT-Ro1 and NL-Loo specifically so that the correlation of  $T_{\rm air}$  and  $R_{\rm eco}$  is the lowest compared to all the sites we use. We did this to prevent the DeepState from simply learning the  $T_{\rm air}$  dynamics and

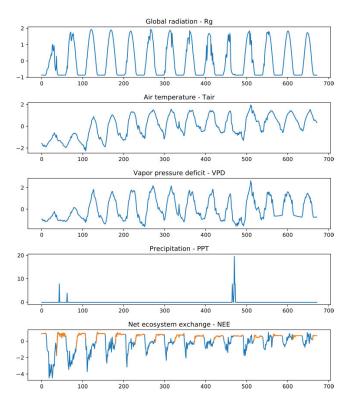

FIGURE 2. Two-week data sample - FR-Pue. Two weeks of half-hourly Rg, T<sub>air</sub>, VPD, PPT and NEE, measured at the French site Puechabon.

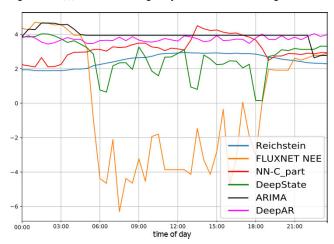

FIGURE 3. Nighttime R<sub>eco</sub> qualitative evaluation. One day R<sub>eco</sub> forecast of different time series forecasting methods and NEE partitioning methods on the site IT-Ro1.

producing good  $R_{eco}$  forecasts due to the high correlation between these two variables. The data is selected from June to September of each year in the case of sites FR-Pue, DE-Hai, IT-Ro1, and NL-Loo. For BR-Sa3 and CG-Tch, we selected data from January to April of each year. These equatorial sites are chosen to analyze how different climate regions and different  $T_{air}$  and PPT variation during the day vs during the night influence the learned  $R_{eco}$  model. As  $R_{eco}$  predictors, we use SW\_IN\_F\_MDS, TA\_F\_MDS, P\_F, VPD\_F\_MDS and NEE\_VUT\_USTAR50 during the daytime, corresponding to  $R_g$ ,  $T_{air}$ , PPT, VPD, and NEE<sub>day</sub>, respectively.

TABLE 2. NEEnight estimation accuracy. Quantitative results of forecasting one day of nighttime Reco, using different predictor variables for training DeepState on sites FR-Pue, DE-Hai, BR-Sa3 and CG-Tch. The best results are shown in bold.

#### **B. EVALUATION METRICS**

The error metrics we use for evaluating our method in comparison with the other partitioning methods with respect to the ground truth NEEnight are the Root Mean Square Error (RMSE) and the Mean Absolute Percentage Error (MAPE), defined as:

$$RMSE(P,R) = \sqrt{\frac{1}{T} \sum_{t=1}^{T} (R_t - P_t)^2}$$

$$MAPE(P,R) = \frac{1}{T} \sum_{t=1}^{T} \frac{|R_t - P_t|}{|R_t|}$$
(11)

MAPE
$$(P, R) = \frac{1}{T} \sum_{t=1}^{T} \frac{|R_t - P_t|}{|R_t|}$$
 (11)

In Eq. (10) and Eq. (11), by  $R = [R_1, ..., R_T]$  we denote the vector of real target values and by  $P = [P_1, \dots, P_T]$  the vector of prediction values, while  $T \in \mathbb{N}$  denotes the number of time steps.

## C. LEARNING A DATA-DRIVEN TIME-DEPENDENT MODEL OF NIGHTTIME Reco

For training DeepState, we used the past values of NEE<sub>night</sub>, i.e. the nighttime R<sub>eco</sub>, together with the past and the future of Rg,, Tair, VPD, PPT and NEEday in all possible combinations as predictors. This allowed the model to learn the underlying dynamics of Reco at night on multiple FLUXNET sites. We evaluate how well this nighttime dynamical model is learned by comparing our nighttime R<sub>eco</sub> forecasts with the ground truth NEEnight on multiple sites, as shown in Table 2. We find that using R<sub>g</sub>, T<sub>air</sub>, VPD and NEE<sub>day</sub> as predictors provides the best ground-truth NEE<sub>night</sub> estimates on the European sites FR-Pue and DE-Hai. For the equatorial site BR-Sa3, the best predictors are PPT and  $NEE_{day}$ , whereas the combination of predictors  $R_g$ ,  $T_{air}$  and PPT, and the combination of Rg, PPT, VPD and NEEday yield the best NEE<sub>night</sub> estimates on the Congolese site CG-Tch.

We compared the DeepState's nighttime R<sub>eco</sub> forecasts to the corresponding Reco estimates of other partitioning methods and to two other time series forecasting methods in order to justify our choice of this deep state space model. Namely, we compared to the Reichstein method, the NN<sub>C-part</sub>, as well as to a more traditional time series forecasting method ARIMA [24] and to the RNN-based deep learning method for time series forecasting, namely, DeepAR [18]. In the case of ARIMA however, since our training data contains only the nighttime R<sub>eco</sub> values, the missing daytime values are imputed by a Kalman filter [12]. In Table 3 we present the quantitative comparison of the nighttime Reco to the ground truth NEE<sub>night</sub> for all the sites we apply our method to when using different partitioning and time series forecasting methods. We conclude that DeepState provides the best nighttime

107878 **VOLUME 9. 2021** 

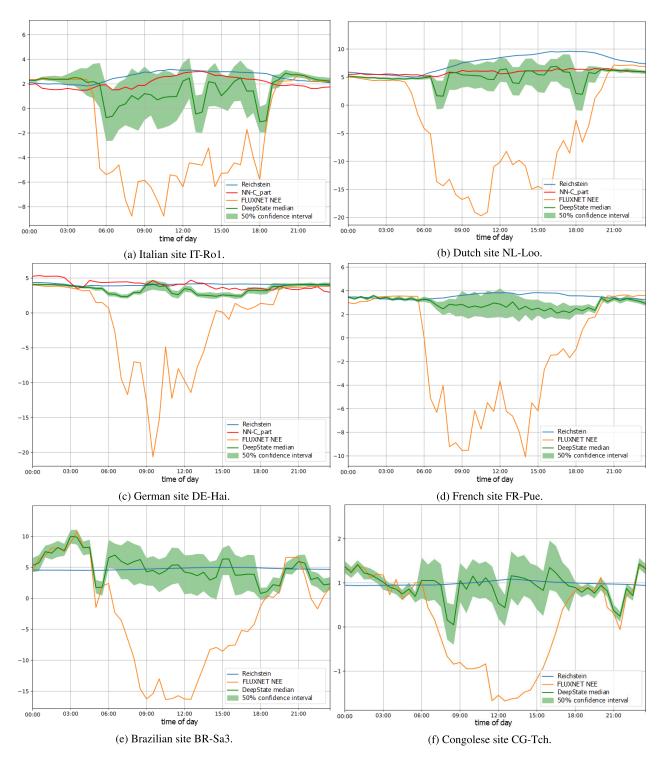

FIGURE 4. One-day Reco forecast (green) using DeepState with T<sub>air</sub> as a predictor. Observed NEE is shown in orange, the Reco obtained by the Reichstein method in blue and Reco estimated by the NN<sub>C-part</sub> method is shown in red.

 $R_{eco}$  forecasts with respect to the ground truth NEE<sub>night</sub> in comparison to other partitioning methods, i.e. Reichstein and NN<sub>C-part</sub>, and attains very similar MAPE values to those of ARIMA on the two European sites FR-Pue and DE-Hai. Even though ARIMA sometimes performs slightly better, it is not suitable for the daytime  $R_{eco}$  forecasts, as depicted in Fig. 3 for the site IT-Ro1. Moreover, the ARIMA model

tends to be difficult to fit due to the non-stationarity of the data.

We consider the  $R_{eco}$  forecasts from midnight to 5 a.m. and from the 7 p.m. until 11:59 p.m. to denote the nighttime. We note that in the period from midnight to 5 a.m. our method produces considerably better nighttime  $R_{eco}$  forecasts than the other NEE partitioning approaches. Furthermore, our

TABLE 3. Comparison of different methods' nighttime  $R_{eco}$  forecasts to the ground truth  $NEE_{night}$ . For the sites where  $NN_{C-part}$  can be applied, we show the  $NEE_{night}$  estimation MAPE error metric of other methods both on the same (reduced) amount of data samples as provided by the  $NN_{C-part}$  method, and on the entire data in brackets when these two values differ. The best results on each site are shown in bold.

Method	FR-Pue	DE-Hai	NL-Loo	IT-Ro1	CG-Tch	BR-Sa3
DeepState	0.17	0.16	0.51 (0.69)	0.11 (0.3)	0.18	0.69
NN <sub>C-part</sub>	/	0.24	0.54	0.18	/	/
Reichstein	0.26	0.24 (0.25)	0.56 (0.9)	0.14 (0.58)	0.54	1.4
ARIMA	0.16	0.15	0.52	0.31	0.4	1.38
DeepAR	0.24	0.2	0.73 (0.75)	0.45 (0.42)	0.4	1.41

 $R_{\rm eco}$  forecasts using  $T_{\rm air}$  as a predictor are depicted in Fig. 4 for each of the six above-mentioned sites. The DeepState's ability to model the ground truth NEEnight better than the Reichstein's method is particularly visible in Fig. 4e and Fig. 4f on the sites BR-Sa3 and CG-Tch, respectively. This is expected since we use the past NEEnight values during the training phase, but the results on other sites in Fig. 4 show that DeepState fits the nighttime NEEnight better than NNC-part as well. Additionally, the identification of the best predictors gives us a valuable insight into which variables to use when partitioning NEE. In addition, the results from Table 2 confirm that  $T_{\rm air}$  is a good  $R_{\rm eco}$  predictor, as suggested by Platenius in 1942 [25]. Namely, when considering a single  $R_{\rm eco}$  predictor, the NEEnight estimation error metrics when using  $T_{\rm air}$  tend to be among the two best ones across all sites.

#### D. DAYTIME Reco FORECAST EVALUATION

In the previous section we have seen how well DeepState learns the dynamical model of Reco at night, as well as how it is trained. Now we can interpret our daytime Reco forecasts having in mind that there is no ground truth with which to compare these forecasts directly. We compare our findings to those of the recent empirical NEE partitioning methods [6], [9], [10] which suggest that R<sub>eco</sub> is lower during the day than during the night, and can be attributed to the Kok effect [8]. In Fig. 4, we observe that this is also the case with our daytime R<sub>eco</sub> forecasts on most of the inspected sites. Oikawa et al. [6] report on average 10-13% lower daytime R<sub>eco</sub> than that of the Reichstein method, whereas our forecasts are on average 16-17% lower than the Reichstein method's R<sub>eco</sub>. The lower R<sub>eco</sub> forecasts during the day might also be attributed to the findings of Wehr et al. [26], i.e. that the nighttime Reco is twice as large as daytime Reco during the first half of the growing season in a temperate forest. The NN<sub>C-part</sub> method's R<sub>eco</sub> estimates also tend to be slightly lower than the Reichstein method's, but are very sparse due to many missing values in the training data. The influence of the missing data on the NN<sub>C-part</sub> model's performance is reflected in the fact that there are much less output Reco estimation values and that some FLUXNET sites are not considered for partitioning using NN<sub>C-part</sub> due to many missing values in any given year for which a threshold can be set. In contrast, since DeepState's predictions are sampled from the estimated probability distribution, the missing values do not occur in our

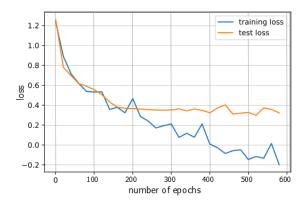

FIGURE 5. DeepState's training and test loss.

forecasts. Moreover, deep state space models are more robust to the missing values during training which makes our method applicable to any FLUXNET site without further restrictions.

On certain sites, such as CG-Tch, depicted in Fig. 4f, our daytime  $R_{\rm eco}$  forecasting is fluctuating more than expected in comparison to the other two partitioning methods, but as shown empirically by Oikawa *et al.* [6], this behaviour can sometimes indeed occur.

#### IV. CONCLUSION

In this paper we have proposed an NEE partitioning approach based on the deep probabilistic state space model DeepState, thus leveraging the interpretability and uncertainty analysis of state space models with the advantages of deep networks in learning complex dynamical models. The quantitative analysis of our method for estimating Reco during the nighttime justified our choice of DeepState for learning the dynamical model of Reco. Furthermore, our daytime Reco forecasts, aided by both the past and the future of the Reco predictors, are in line with the empirical studies which suggest that R<sub>eco</sub> during the day is usually lower than that of the Reichstein method. This discrepancy can also be attributed to the observation that nighttime Reco is twice as high as the daytime Reco in temperate forests during the first half of the growing season [26] and to the Kok effect [8]. Therefore, we conclude that our approach offers a good alternative to data-driven NEE partitioning across a diverse set of vegetation types when the right Reco predictors are selected and complements other NEE partitioning methods.

## APPENDIX A DEEPSTATE TRAINING PROCESS

In Fig. 5 we depict the DeepState's training and test loss after each 20th epoch. The training is done for 600 epochs without validation, but we note that the forecasts are no longer improving after about 300 epochs when the plateau occurs. We can therefore stop after 600 epochs despite the difference between the training and the test loss becoming larger if trained further. The training data is from the Congolese site CG-Tch when using  $T_{air}$  as a predictor. We note that the loss can be negative as DeepState optimizes the negative likelihood of the Student-t distribution.

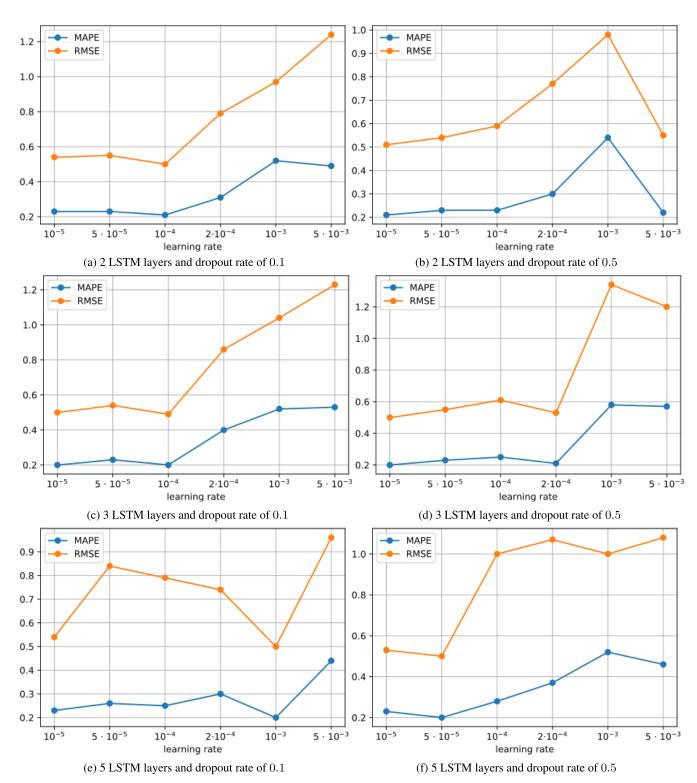

FIGURE 6. Hyperparameter optimization. Nighttime NEE forecast accuracy on the site CG-Tch using T<sub>air</sub> as a predictor, for a different number of the LSTM layers and dropout rates, while varying the learning rate.

In Fig. 6, we show the MAPE and the RMSE metrics of the DeepState's nighttime  $R_{\rm eco}$  forecast with respect to the ground truth NEE<sub>night</sub>. The forecasts are performed on the data from the site CG-Tch with  $T_{\rm air}$  as a predictor, as was previously the case for calculating the training and

the test losses above. We varied the number of the LSTM layers between 2, 3 and 5, the dropout rate between 0.1 and 0.5, whereas the learning rates we tested are  $10^{-5}$ ,  $5 \cdot 10^{-5}$ ,  $10^{-4}$ ,  $2 \cdot 10^{-4}$ ,  $10^{-3}$  and  $5 \cdot 10^{-3}$ . The configuration that we used throughout all our experiments,

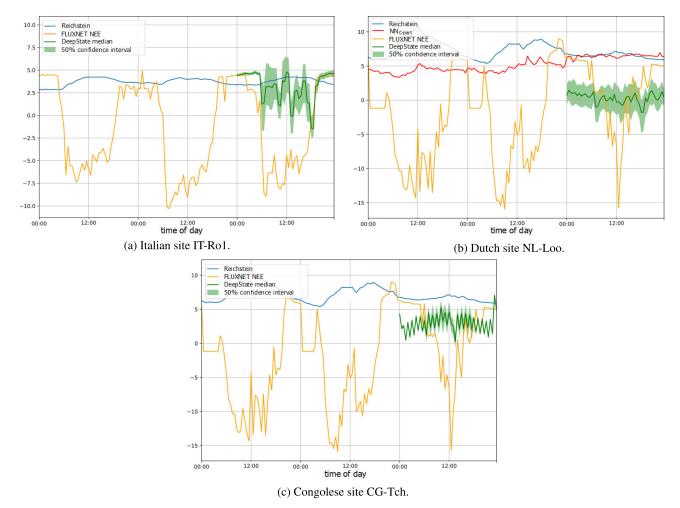

FIGURE 7. Sub-optimal forecasts. In green we show the one-day Reco forecast from NEE<sub>night</sub> on different FLUXNET sites with T<sub>air</sub> as a predictor. Observed NEE is shown in orange, the FLUXNET Reco in blue and Reco estimated by the NNC-part method is shown in red.

i.e., 2 LSTM layers, the dropout rate of 0.1 and the learning rate of  $10^{-4}$  provides the MAPE of 0.21 and the RMSE metric of 0.5, whereas tuning the above-mentioned hyperparameters lowered these error metrics by 0.01 when using 3 LSTM layers. Using 2 layers, however, provided the best NEE<sub>night</sub> forecasts on average, which is why we fixed this hyperparameter configuration for all our experiments and thus facilitated the use of our NEE partitioning approach.

## APPENDIX B SUBOPTIMAL Reco FORECASTS

We here present our method's suboptimal forecasts. Namely, in Fig. 7, we illustrate samples where our method does worse at reproducing NEE<sub>night</sub>, as well as in comparison to the FLUXNET R<sub>eco</sub> baseline. This is mostly due to more drastic changes of the NEE levels of the prediction range compared with those during training. These forecasts, however, occur in less than 3% of all forecasts over all tested sites.

MAHA SHADAYDEH received the Ph.D. degree in electrical communications engineering from Tohoku University, Sendai, Japan, in 1999. She was an Associate Professor of signal processing with the Electronic Engineering Department, Damascus University, Syria, from 2000 to 2011, and a Researcher with the Machine Perception Research Laboratory, Institute for Computer Science and Control, Hungarian Academy of Sciences, from 2012 to 2016. Since 2017, she

has been working as a Researcher and a Team Leader with the Computer Vision Group, Department of Mathematics and Computer Science, Friedrich Schiller University Jena, Germany. Her research interests include dynamical system analysis, remote sensing and biomedical signal processing, event detection, and causal reasoning.

JAKOB RUNGE received the Ph.D. degree in physics from Humboldt University Berlin, in 2014, as a Researcher at the Potsdam Institute for Climate Impact Research. From 2016 to 2017, he was a fellow at Imperial College London, U.K. In 2020, he won an ERC Starting Grant with his interdisciplinary project CausalEarth. Since 2017, he heads the Climate Informatics Group at German Aerospace Center, Institute of Data Science, Jena, Germany, and has been a Guest Professor of com-

puter science at TU Berlin, since 2021. He was a recipient of Carl-Ramsauer Doctoral Prize and the Fellowship Award in Studying Complex Systems by James S. McDonnell Foundation.

**MARKUS REICHSTEIN** received the Ph.D. degree from the Department of Plant Ecology, University of Bayreuth, in 2001.

He is currently the Director of the Biogeochemical Integration Department, Max Planck Institute for Biogeochemistry, Jena, Germany. Since 2013, he has been a Professor of global geoecology at Friedrich Schiller University Jena, and the Founding Director of Michael Stifel Center Jena for Data-Driven and Simulation Science. His

research interests include around the response and feedback of ecosystems (vegetation and soils) to climatic variability with an Earth system perspective, considering coupled carbon, water, and nutrient cycles, as well as specific interest in the interplay of climate extremes with ecosystem and societal resilience. He has been serving as a lead author of the IPCC special report on Climate Extremes (SREX), as a member of German Committee Future Earth on Sustainability Research, and Thuringian Panel on Climate.

VIOLETA TEODORA TRIFUNOV received the B.Sc. degree in theoretical mathematics from the University of Novi Sad, Serbia, and the M.Sc. degree in mathematics from the University of Bonn, Germany, in 2015 and 2017, respectively. She is currently pursuing the Ph.D. degree in computer science with a focus on deep probabilistic graphical models and causal inference as a member of the Computer Vision Group, Faculty of Mathematics and Informatics, Friedrich Schiller

University Jena, and the Climate Informatics Group, German Aerospace Center, Institute for Data Science, Jena.

JOACHIM DENZLER (Member, IEEE) received the Diplom-Informatiker, Dr.-Ing., and Habilitation degrees from the University of Erlangen, Germany, in 1992, 1997, and 2003, respectively. He currently holds a position as a Full Professor of computer science and the Head of the Computer Vision Group, Friedrich Schiller University Jena, Germany. He is also the Director of the DLR Institute of Data Science, Jena. He is the author and coauthor of over 300 journal articles and con-

ference papers as well as technical articles. His research interests include automatic analysis, fusion, and understanding of sensor data, especially the development of methods for visual recognition tasks and dynamic scene analysis. He contributed in the area of active vision, 3D reconstruction, and object recognition and tracking. He is also a member of IEEE Computer Society, DAGM, and GI.
