22 **Abstract**

23 Forming a complete picture of the relationship between neural activity and body kinetics requires
24 quantification of skeletal joint biomechanics during behavior. However, without detailed
25 knowledge of the underlying skeletal motion, inferring joint kinetics from surface tracking
26 approaches is difficult, especially for animals where the relationship between surface anatomy
27 and skeleton changes during motion. Here we developed a videography-based method enabling
28 detailed three-dimensional kinetic quantification of an anatomically defined skeleton in untethered
29 freely-behaving animals. This skeleton-based model has been constrained by anatomical
30 principles and joint motion limits and provided skeletal pose estimates for a range of rodent sizes,
31 even when limbs were occluded. Model-inferred joint kinetics for both gait and gap-crossing
32 behaviors were verified by direct measurement of limb placement, showing that complex decision-
33 making behaviors can be accurately reconstructed at the level of skeletal kinetics using our
34 anatomically constrained model.

35

36 **Introduction**

37 The relationship between neural activity patterns and body motion is complex as neuronal activity
38 patterns are dependent on factors such as the intended behavioral outcome¹, task familiarity²,
39 changes in the environment but also exact limb trajectories³⁻⁵ and motion kinetics⁶. Much of the
40 motion kinematic data forming our view of the sensorimotor control of movement was collected
41 during short behavioral epochs where the animal was in various forms of restraint³⁻⁸, but how
42 these findings relate to kinematics during free behavior, where the relationship between the
43 environment and body motion is continuously changing, is largely unknown⁹⁻¹¹. While there have
44 been methodological advances recently enabling detailed neural population activity recordings¹²⁻
45 ¹⁵ and surface tracking of an animal's body¹⁶⁻²⁴, a major challenge still remains for generating
46 detailed kinetics of individual body parts, such as limbs, and how they interact with the
47 environment during free behavior^{18,25}. This poses an especially difficult problem as limb motions
48 involving muscles, bones and joints are biomechanically complex given their three-dimensional
49 (3D) translational and rotational co-dependencies^{26,27}.

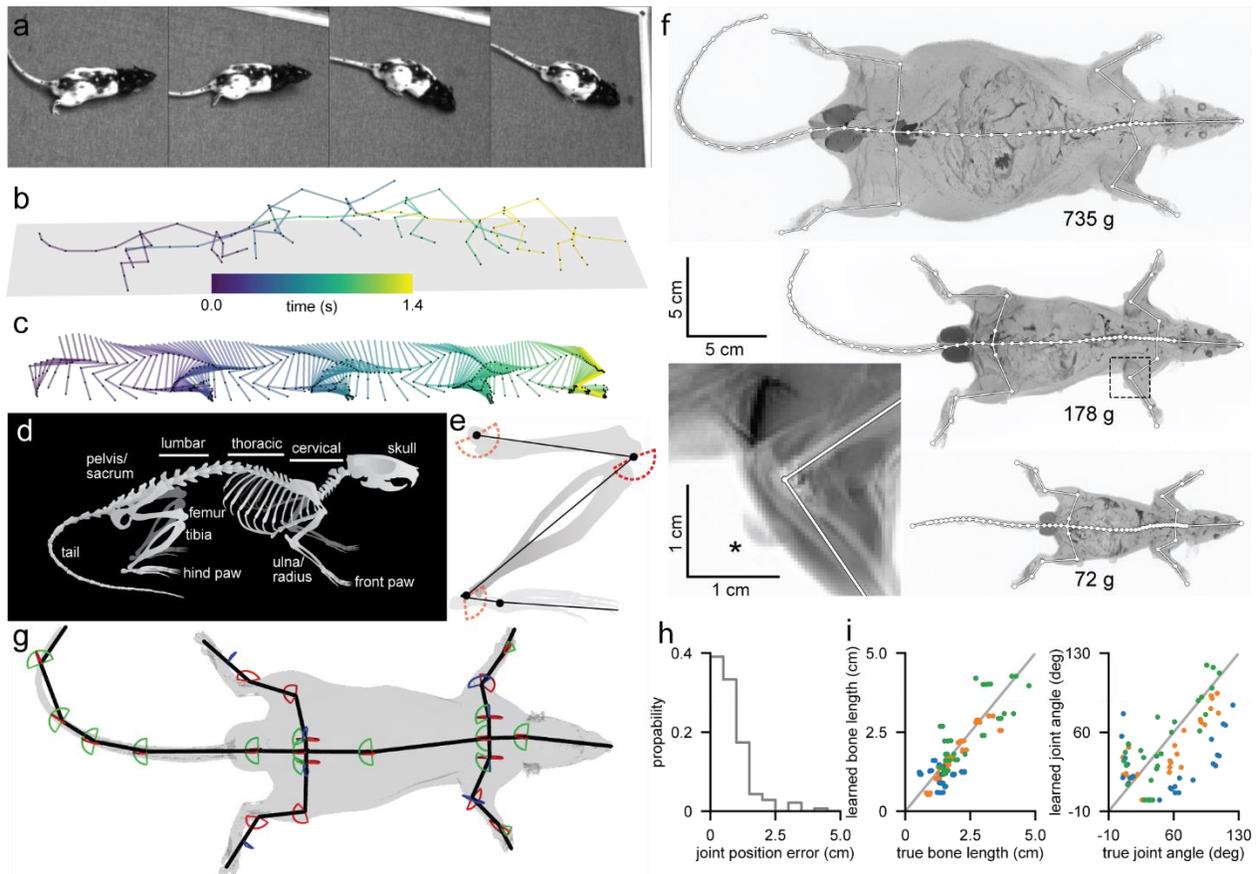

50 More recently, advances in the development of machine learning approaches have enabled limb
51 tracking in both freely-moving²³ and head-restrained insects²⁸ as the limb exoskeleton not only
52 provides joint angle limits and hard limits of limb position, but can be tracked as a surface feature
53 during behavior. When studying vertebrates, like rats, the entire skeleton is occluded by the
54 animal's fur and inferring bone positions and calculating joint kinetics becomes more complicated
55 since the spatial relationship between skeleton and overlying soft tissues are less apparent^{29,30}.
56 Despite this limitation, recent approaches have extended two-dimensional surface tracking
57 methods^{21,23,24} to include 3D pose reconstructions³¹ using a multi-camera cross-validation
58 approach and hand-marked ground-truth data sets¹⁹ allowing general kinematic representation of
59 animal behaviors and poses for multiple species³². Extending these approaches to obtain the
60 skeleton kinetics relies on knowledge of the skeleton anatomy and biomechanics as well as
61 motion restrictions of joints²⁷ because animal poses are limited by both bone lengths and joint
62 angle limits. Here, we developed an anatomically constrained skeleton model incorporating
63 mechanistic knowledge of bone locations, anatomical limits of bone rotations, and temporal
64 constraints to track 3D joint positions and their kinetics in freely moving rats. Together the fully
65 constrained skeleton enabled the reconstruction of skeleton poses and kinetic quantification
66 during gap-crossing tasks and throughout spontaneous behavioral sequences.

67

68 **Results**

69 **Constraining the model**

70 Here we tracked 3D joint positions and their kinetics in freely moving rats (Fig. 1a) over a large
71 size range (N = 6 animals, average weight: 321 g, range: 71-735 g) using videography and a
72 anatomically constrained skeleton model (ACM) incorporating mechanistic knowledge of bone
73 locations, anatomical limits of bone rotations, and temporal constraints. Together, both the
74 temporal and anatomical constraints, i.e. the fully constrained ACM, enabled the reconstruction
75 of skeleton poses of behaving animals with single joint precision (Fig. 1b) as well as smooth limb
76 and joint transitions during gait cycles (Fig. 1c) allowing the quantification joint kinetics and spatial
77 positions of the limbs throughout behavioral sequences. At the core of this approach was a
78 generalized rat skeleton based on rat bone anatomy³³ (Fig. 1d) modeled as a mathematical graph
79 with vertices representing individual joints and edges representing bones (Fig. 1c, see methods
80 for details and Supplementary Fig. 1). For example, a single edge was used to represent the
81 animal's head, the spinal column was approximated using four edges based on cervical, thoracic
82 and lumbar sections of the column as well as the sacrum³³ and the tail by five edges (Fig. 1d,
83 Supplementary Fig. 1). To constrain the model we applied angle limits for each joint based on
84 measured rotations³⁴ (Fig. 1e, see Methods "Constraining poses based on joint angle limits") as
85 well as anatomical constraints based on measured relationships between bone lengths and
86 animal weight and size³⁵ (see Methods "Constraining bone lengths based on allometry"). Finally,
87 as vertebrates are symmetrical around the mid-sagittal plane we applied a further anatomical
88 constraint to ensure symmetry for bone lengths and surface marker locations (Supplementary
89 Fig. 3). Together, this approach established a unique skeleton model for each animal. To generate
90 probabilistic estimates of 3D joint positions and provide temporal constraints, we implemented a
91 temporal unscented Rauch-Tung-Striebel (RTS) smoother^{36,37}, an extension of a Kalman filter³⁸,
92 which is suitable for nonlinear dynamics models and also incorporates information from future
93 marker locations (see Supplementary Methods "Probabilistic pose estimation" for details).
94 Parameters of the smoother were learned via the expectation-maximization (EM) algorithm³⁹, by
95 iteratively fitting poses of the entire behavioral sequence (see Methods "Performing probabilistic
96 pose reconstruction").

97

 107 (asterisk). **g**, 3D representation of a rat's MRI scan showing the animal's surface (gray) and the aligned
 108 skeleton model (black lines) and joint angle limits for flexion/extension (red lines), abduction/adduction
 109 (green lines) and internal/external rotation (blue lines). **h**, Probability histogram of the joint position error. **i**,
 110 Learned bone lengths (left) and joint angles (right) compared to MRI bone lengths and joint angles (N = 6
 111 animals). Colors represent small (blue), medium (orange) and large (green) animal sizes (blue: 71 g & 72
 112 g, orange: 174 g & 178 g, green: 699 g & 735 g).

113
 114
 115

116 **Learning the skeleton**

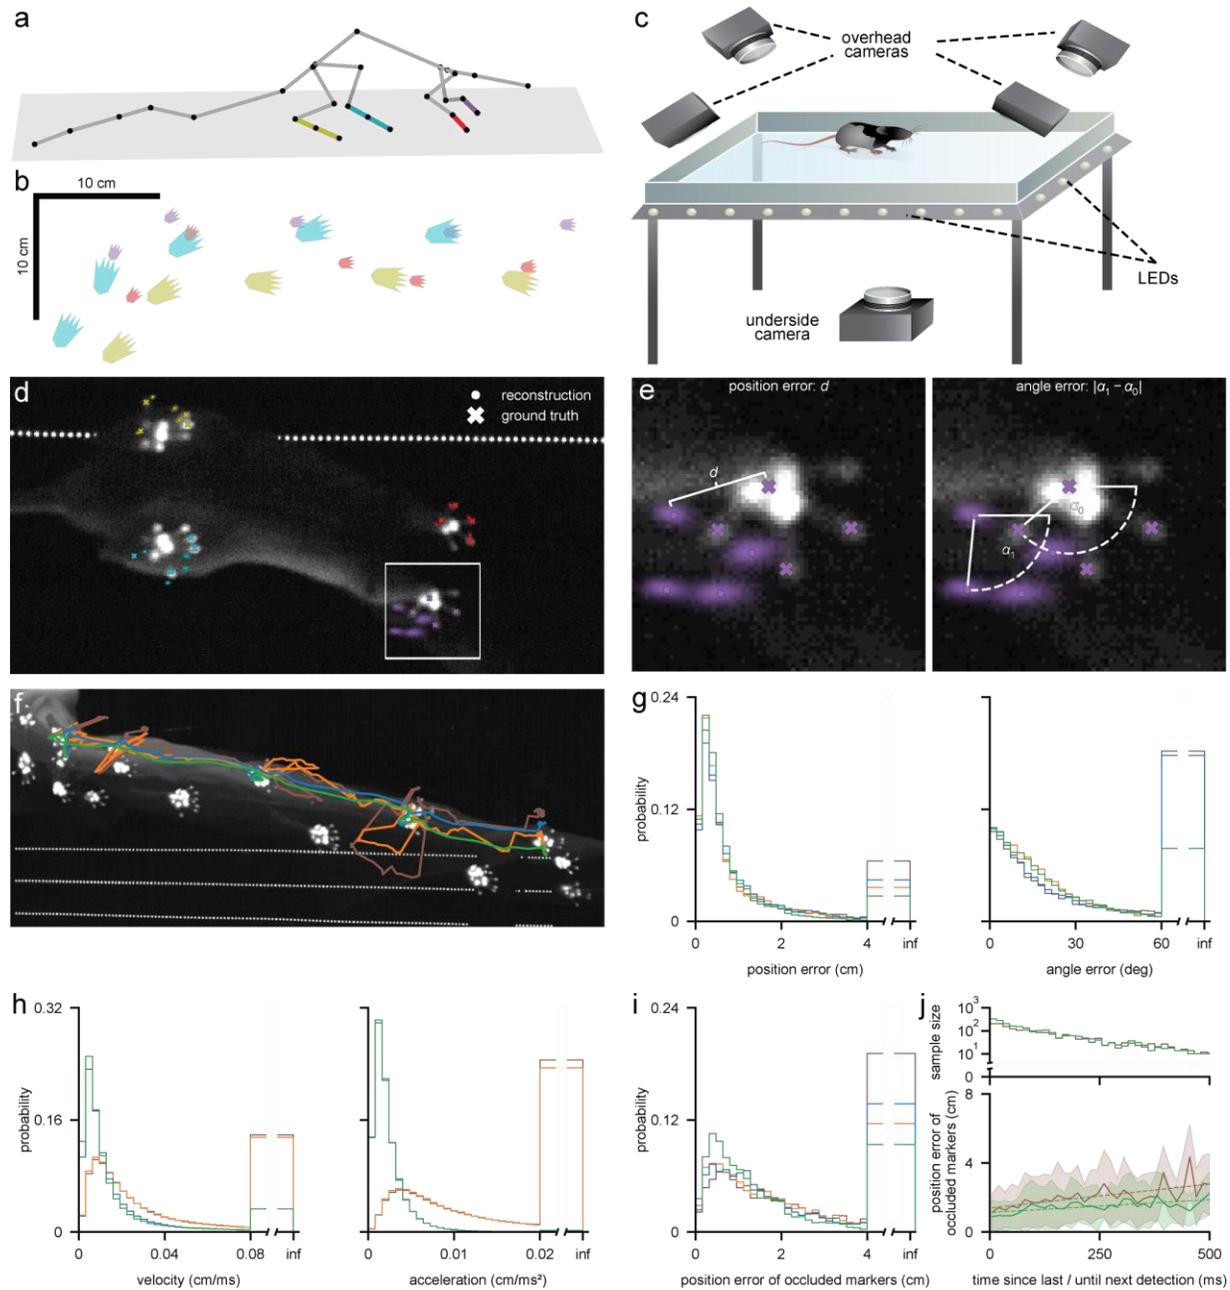

117 To relate the animal's surface to the underlying skeleton we used a grid of rationally-placed
118 surface markers, which were either distinct anatomical landmarks like the snout or were painted
119 on the animal's fur (Fig 1a, 14 landmarks and 29 spots total per animal, Supplementary Fig. 2).
120 To individually tailor the skeleton to each animal we used gradient decent optimization to learn
121 varying bone lengths and surface marker locations for each animal (see Methods "Learning bone
122 lengths and surface marker positions"). Visible surface markers were manually annotated from a
123 fraction of all recorded images to learn the skeleton that could then be used for all behavioral data
124 acquired from that animal. As the rigid spatial relationship between surface markers and the
125 underlying joints remained constant the algorithm could learn individual bone lengths as well as
126 surface marker locations by adjusting both via gradient descent optimization (Supplementary Fig.
127 3). New poses were iteratively generated for each time point by applying a global translation to
128 the generalized skeleton model and subsequently modifying positions of joints and rigidly
129 attached surface markers by rotating each bone (Supplementary Video 1). Errors were
130 established and minimized by projecting inferred 3D surface marker locations onto calibrated
131 overhead camera sensors and subsequently comparing them to manually labeled ground-truth
132 data (Supplementary Fig. 4).

133 To evaluate the accuracy of both the skeleton model and inference of joint positions over a large
134 range of animal sizes, we obtained high-resolution MRI scans for each animal (Fig. 1f, N = 6
135 animals, see methods "Comparison of skeleton parameters with MRI data") and aligned the
136 skeleton model to measured positions of 3D surface markers (Fig. 1g). Errors for inferred spine
137 and limb joint positions were low (Fig. 1h, 138 joint positions total, joint position error: 0.79 +/-
138 0.69 & 0.65 cm [mean +/- s.d. & median]) and inferred limb bone lengths and bone angles were
139 not significantly different from those measured in MRI scans (Fig. 1i, 108 bone lengths total, range
140 of measured bone lengths: 0.53 cm to 4.76 cm, bone length error: 0.46 +/- 0.34 & 0.36 cm [mean
141 +/- s.d. & median], Spearman correlation coefficient: 0.75, two-tailed p-value testing non-
142 correlation: 5.00×10^{-21} ; 84 bone angles total, range of measured bone angles: 4.13° to 123.77°,
143 bone angle error: 27.80 +/- 18.98 & 26.72° [mean +/- s.d. & median], Spearman correlation
144 coefficient: 0.47, two-tailed p-value testing non-correlation: 5.29×10^{-6}). Together this
145 demonstrated first, that the anatomically constrained skeleton model generated by our algorithm
146 was highly accurate when compared with the animal's actual skeleton across the range of animal
147 sizes, and second, that accurate joint positions could be reconstructed in a single static pose from
148 this approach.

149

150 **Accurate behavior reconstructions required both the temporal and anatomical constraints.**

151 To reconstruct behavioral sequences using the ACM, we first tracked 2D surface marker locations
152 in the recorded movies using DeepLabCut²⁴, which is specifically designed for surface landmark
153 detection of laboratory animals. As the ACM contained both joint angle limits and temporal
154 constraints, we evaluated the role of these by reconstructing poses without either the joint angle
155 limits or the temporal constraints. The resulting temporal model, only temporally constrained, and
156 the joint angle model, only constrained by joint angle limits, and the naïve skeleton model,
157 constrained by neither, were compared to the ACM. To measure animal paw positions and
158 orientations during gait we used a modified frustrated total internal reflection (FTIR) touch sensing
159 approach^{40,41} (Fig. 2a-c, Supplementary Video 2) and compared these measurements to the paw
160 positions and orientations inferred by each model (Fig. 2d,e, N = 6 animals, 29 sequences, 181.25
161 s per 145000 frames total from 4 cameras). The ACM produced significantly smaller positional
162 errors compared to all other models (Fig. 2g, left; 10410 positions total; p-values of one-sided
163 Kolmogorov-Smirnov test: ACM vs. joint angle model: 9.84×10^{-21} ; ACM vs temporal model:
164 4.38×10^{-35} ; ACM vs. naïve skeleton model: 9.03×10^{-37}), whereas orientation errors were only
165 significantly smaller when comparing the ACM to the temporal and naïve skeleton model (Fig. 2g,
166 right; 7203 and 6969 orientations total for the ACM/anatomical model and the temporal/naïve
167 skeleton model respectively; p-values of one-sided Kolmogorov-Smirnov test: ACM vs temporal
168 model: 3.20×10^{-39} ; ACM vs. naïve skeleton model: 2.51×10^{-50}). While orientation errors were
169 significantly reduced by the anatomical constraints, including temporal constraints limited abrupt
170 pose changes over time compared to either the naïve skeleton model or joint angle model (Fig.
171 2f, Supplementary Video 3-8). As a result, ACM-generated joint velocities and accelerations (Fig.
172 2h, 576288 velocities and accelerations total) were significantly smaller when compared to all
173 other models (p-values of one-sided Kolmogorov-Smirnov test: ACM vs. joint angle model
174 (velocity): numerically 0; ACM vs. temporal model (velocity): numerically 0; ACM vs. naïve
175 skeleton model (velocity): numerically 0; ACM vs. joint angle model (acceleration): numerically 0;
176 ACM vs. temporal model (acceleration): numerically 3.71×10^{-90} ; ACM vs. naïve skeleton model
177 (acceleration): numerically 0). The temporal and anatomical constraints each had an advantage
178 over the naïve skeleton model, and both constraints applied simultaneously improved positional
179 accuracy as well as motion trajectories and prevented anatomically infeasible bone orientations
180 and abrupt paw relocations. Moreover, the fraction of position errors exceeding 4 cm increased
181 when constraints were not considered (fraction of errors exceeding 4 cm: ACM: 2.72%; joint angle
182 model: 3.64%; temporal model: 4.42%; naïve skeleton model: 6.44%), and the same was
183 observed for orientation errors exceeding 60° (fraction of errors exceeding 60°: ACM: 7.78%; joint

195 models. **g**, Probability histograms for paw position (left) and angle errors (right) comparing different model
196 constraint regimes. Color-coding as in **f**. **h**, Probability histograms for paw velocities (left) and accelerations
197 (right) comparing different model constraint regimes. Color-coding as in **f**. **i**, Probability histograms for paw
198 position errors whereas only undetected surface markers are used for the calculation comparing different
199 model constraint regimes. Color-coding as in **f**. **j**, Position errors of occluded markers (bottom) and
200 corresponding binned sample sizes (top) as a function of time since last / until next marker detection
201 comparing different model constraint regimes. Color-coding as in **f**. Sample sizes differ depending on
202 whether reconstructed poses were obtained via the unscented RTS smoother (green) or not (brown).

203

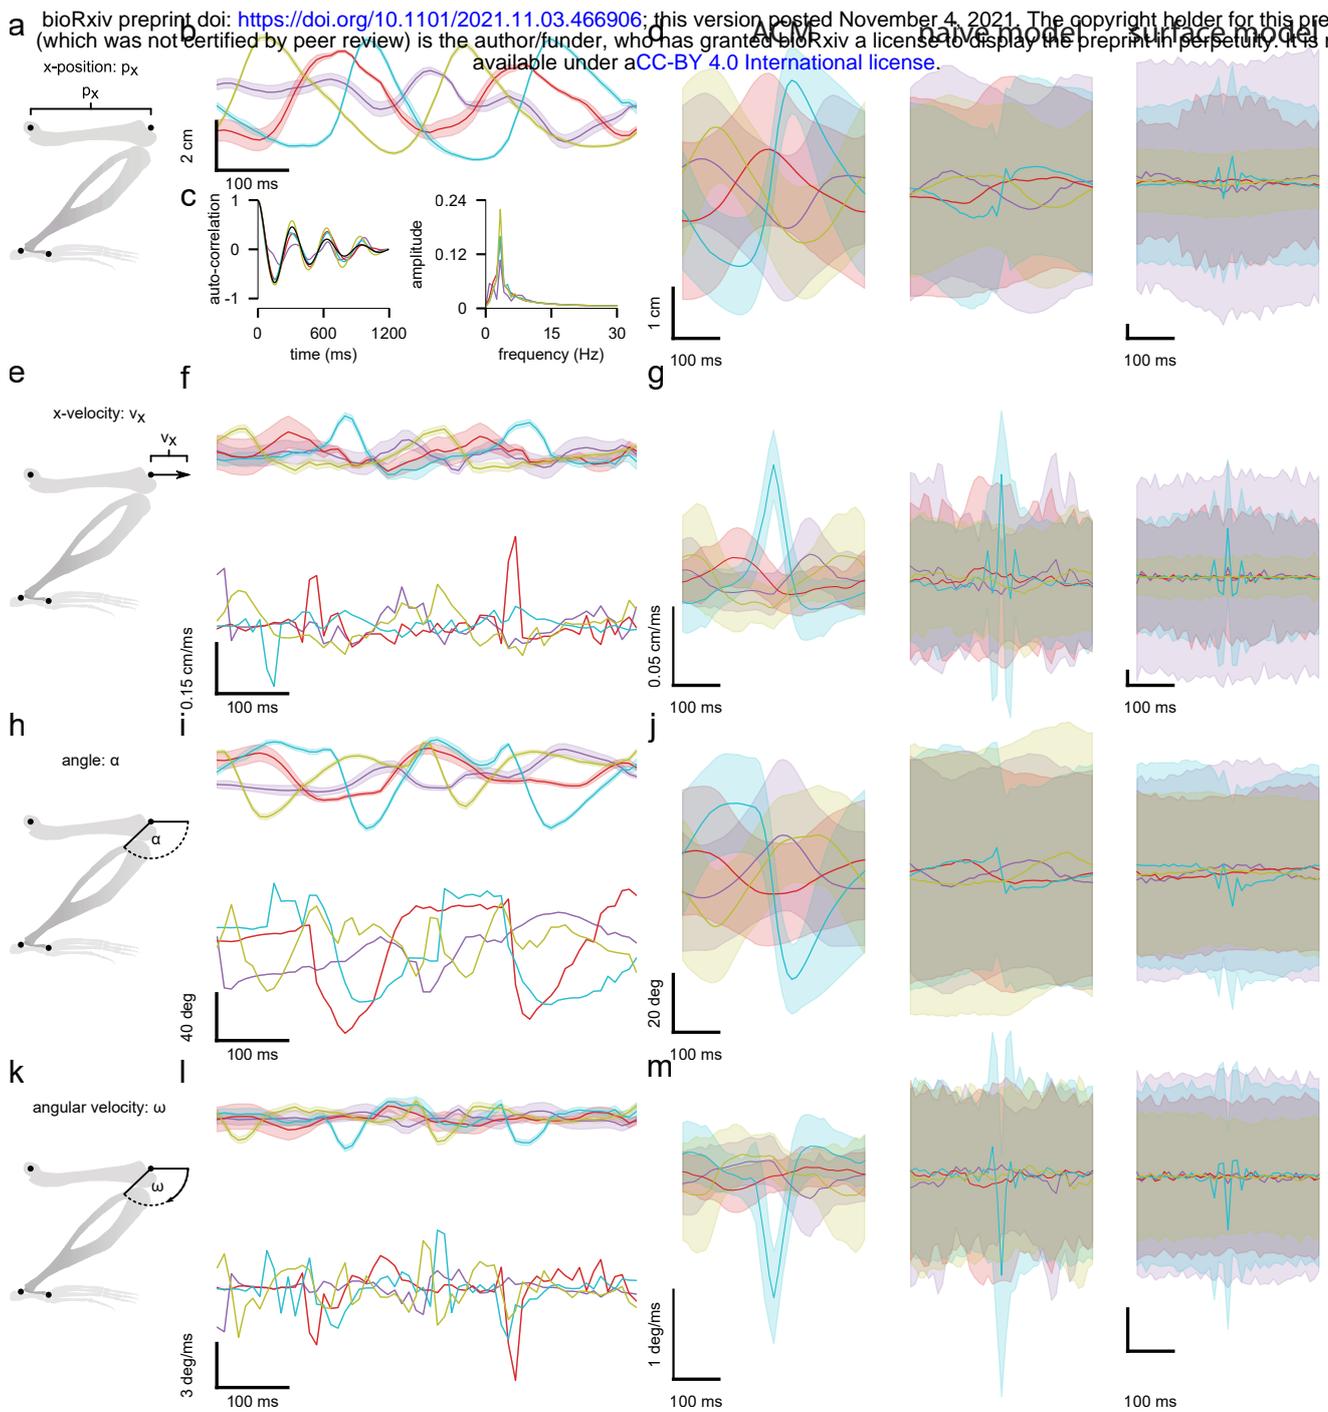

204

205 angle model: 7.81%; temporal model: 17.77%; naïve skeleton model: 18.22%). Likewise,
206 enforcing constraints also lowered the percentage of velocities exceeding 0.08 cm/ms (fraction of
207 errors exceeding 0.08 cm/ms: ACM: 3.29%; joint angle model: 13.49%; temporal model: 3.28%;
208 naïve skeleton model: 13.85%) and accelerations exceeding 0.02 cm/ms² (fraction of errors
209 exceeding 0.02 cm/ms²: ACM: 0.22%; joint angle model: 23.43%; temporal model: 0.25%; naïve
210 skeleton model: 24.55%). To test ACM robustness to missing surface markers, position errors
211 were calculated for inferred paw positions from data in which surface markers were undetected
212 (Fig. 2i, 2797 position errors total). Compared to all other models the ACM produced significantly
213 lower errors (p-values of one-sided Kolmogorov-Smirnov test: ACM vs. joint angle model:
214 9.67×10^{-23} ; ACM vs temporal model: 2.83×10^{-22} ; ACM vs. naïve skeleton model: 3.91×10^{-47}) as
215 well as the smallest number of error values above 4 cm (ACM: 9.36%; joint angle model: 11.61%;
216 temporal model: 13.72%; naïve skeleton model: 19.12%). Paw placement errors increased the
217 longer a surface marker remained undetected for the ACM and the naïve skeleton model (Fig. 2j,
218 linear regression: ACM: slope: 1.49 cm/s, intercept: 1.13 cm; naïve skeleton model: slope: 2.77
219 cm/s, intercept: 1.39 cm) and errors were significantly lower when comparing both models (p-
220 values of one-sided Mann-Whitney rank test: ACM vs. naïve skeleton model: 3.91×10^{-47}).

247

248

249 **Kinetics of cyclic gait behavior.**

250 Smooth and periodic reconstruction of an animal's average gait cycles during walking or running
251 is only possible with robust and accurate tracking of animal limb positions. To establish whether
252 the ACM could generate an average gait cycle from freely moving data, we next extracted
253 individual gait cycles from multiple behavioral sequences (Fig. 3a,b, Supplementary Fig. 5,
254 Supplementary Video 9-11) where joint velocities exceeded 25 cm/s (left; N = 2 animals, 27
255 sequences, 146.5 s per 58600 frames total from 4 cameras). The ACM extracted gait cycles were
256 stereotypical and rhythmic (Fig. 3b,c), showing clear periodicity in autocorrelations of extracted
257 limb movement (Fig 3c, left; damped sinusoid fit: frequency: 3.14 Hz, decay rate: 2.49 Hz, R²-
258 value: 0.90) and a common peak for all limbs in Fourier transformed data (Fig. 3c, right; max.
259 peak at 3.33 Hz, sampling rate: 0.83 Hz). Averaged ACM extracted gait cycles (Fig. 3d, left,
260 Supplementary Fig. 6-9) were significantly less variable than those obtained from the naïve

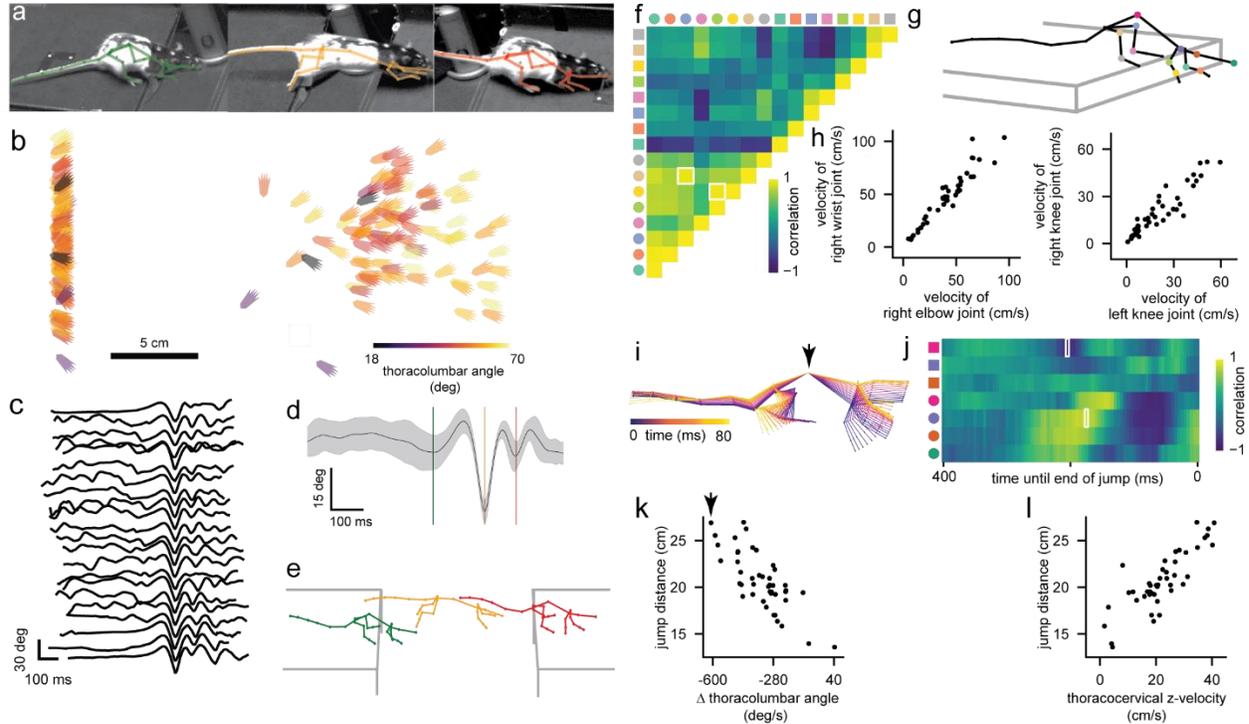

261 skeleton model (Fig. 3d, center) throughout the entire gait cycle (p-value of one-sided Mann-
262 Whitney rank test: 1.40×10^{-49}). When gait cycles were obtained from only tracking surface markers
263 alone via a deep neural network without any form of underlying skeleton (surface model), high
264 noise levels even made the periodic nature of the gait cycles vanish in its entirety (Fig. 3d, right).
265 The robustness and accuracy of limb tracking was even more apparent when analyzing joint
266 velocities (Fig. 3e-g), joint angles (Fig. 3h-j), and joint angular velocities (Fig. 3k-m), as traces
267 generated without the ACM constraints were dominated by noise in individual examples (Fig. 3f,i,l,
268 lower) and the cyclic nature of gait was less prominent when compared to traces obtained from
269 the ACM (Fig. 3f,i,l, top). Consistent with this, ACM averaged traces (Fig. 3g,j,m, left,
270 Supplementary Fig. 6-9) had significantly less variance compared to those obtained from the
271 naïve skeleton model (Fig. 3g,j,m, right, Supplementary Fig. 6-9) for all metrics (p-values of one-
272 sided Mann-Whitney rank test: velocity: 2.28×10^{-55} ; angle: 1.42×10^{-55} ; angular velocity: 1.44×10^{-5}).
273 Additionally, for all metrics the periodicity of the gait cycles in the form of equidistant peaks was
274 more variable for the naïve skeleton model (12 peaks total; sampling rate: 10 ms; time difference
275 between minimum/maximum peaks: position (min. peaks): 64.16 +/- 56.78 ms; velocity (max.
276 peaks): 80.83 +/- 54.99 ms; angle (max. peaks): 74.16 +/- 33.53 ms; angular velocity (min. peaks):
277 53.33 +/- 47.78 ms [avg. +/- s.d.]), when compared to the ACM (12 peaks total; sampling rate: 10
278 ms; time difference between minimum/maximum peaks: position (min. peaks): 75.00 +/- 29.01
279 ms; velocity (max. peaks): 78.33 +/- 10.67 ms; angle (max. peaks): 78.33 +/- 23.74 ms; angular
280 velocity (min. peaks): 75.00 +/- 10.40 ms [avg. +/- s.d.]). Together this shows that the ACM can
281 objectively extract behaviors, such as gait, from freely moving animals and quantify complex
282 relationships between limb-bones by inferring 3D joint positions over time as well as their first
283 derivatives.

284

285 **Kinetics of complex behavior**

286 We next used the ACM to analyze motion kinetics and segment a more complex decision-making
287 behavior, the gap crossing task, in which the distances between two separate platforms are
288 changed forcing the animal to re-estimate the distance to jump for each trial (Fig. 4a).
289 Reconstructed poses during gap-estimation and jump-behaviors consisted of sequences where
290 animals either approached or waited at the edge of the track and jumped (N = 42, Supplementary
291 Fig. 10, Supplementary Video 12,13) or reached with a front paw to the other side of the track
292 before jumping (N = 2, Supplementary Video 14,15). As with the inference of paw placement
293 during gait (Fig. 2b,f), hind-paw spatial position could be inferred throughout the jump and
294 compared to skeletal parameters during the behavior, such as the angle of the thoracolumbar

295 joint at jump onset compared to the paw positions upon landing (Fig. 4b; 44 trials, N = 2 animals).
296 As rats jumped stereotypically, we next tested whether the jump-related pattern of movements
297 could be analyzed using the ACM to objectively define decision points in the behavior, such as
298 time of jump, from each individual trial. The changes in joint angles in the spine segments and
299 hind limbs around the time of the jump were highly consistent. Averaging these joint angles to
300 give an averaged joint-angle trace provided a metric with a global minimum (Fig. 4c) during the
301 jump that was independent of whether the animal crossed the gap immediately, paused and
302 waited at the track edge or reached across the gap (Supplementary Fig. 11). This approach
303 enabled objective identification of jump start-, mid- and end-points, from each individual jump.
304 Traces of joint angles averaged across joints and trials (Fig. 4d) and average ACM poses (Fig.
305 4e) illustrate the consistency of the pose changes through the jump. We next used this to quantify
306 relationships between joints and changes in joint kinetics throughout a jump sequence. Auto-
307 correlations for spatial and angular limb velocities allowed quantification of the interdependency
308 of joint movements at any point within the jumping behavior, for example at the start-point of a
309 jump (Fig. 4f,g). This displayed relationships like a significant correlation between the spatial
310 velocity of the right elbow and wrist joints (Fig. 4h left, Spearman correlation coefficient: 0.95, two-
311 tailed p-value testing non-correlation: 5.40×10^{-24}), as well as joint interactions across the midline,
312 such as a significant correlation between spatial velocity of the right and left knee joints (Fig 4h,
313 right, Spearman correlation coefficient: 0.93, two-tailed p-value testing non-correlation: 6.79×10^{-20}).
314 As the animal jumped across the gap, changes in the bone angles and their derivatives (Fig.
315 4i) were correlated with distance that the animal jumped (Fig. 4j). For example, angular velocity
316 of the thoracolumbar joint and vertical velocity (z-velocity) of the thoracocervical joint were
317 significantly correlated with jump distance 205 ms and 175 ms respectively, before the animal
318 landed (Fig. 4k,l, Spearman correlation coefficient: -0.73, two-tailed p-value testing non-
319 correlation: 1.13×10^{-8} , and 0.81, two-tailed p-value testing non-correlation: 1.12×10^{-11}).

323 paws at the start and end of the jump color-coded by the joint angle of the thoracolumbar joint for each gap

324 crossing event of the population. **c**, Averaged joint-angle traces (spine and hind limb joint angles) from 22

325 out of 44 jump trials. **d**, Joint-angle trace averaged across joints and all jump trials. **e**, Average poses at the

326 start- (green), mid- (orange) and end-point (red) of the jump from all jump trials. The three different time

327 points are indicated by colored lines in **d**. **f**, Cross-correlation of the spatial and angular velocities of the

328 limb joints at the start-point of a jump. Different marker shapes indicate whether rows/columns represent

329 spatial or angular velocities (circles and squares respectively). Marker color corresponds to joint markers

330 in **g**. **g**, Average pose at the start of a jump calculated from all jump trials. Joint colors are consistent with

331 the marker colors in **f** and **j**. **h**, High correlation examples for spatial velocities of different limb joints as a

332 function of each other for both animals. The data shown represents the correlation values highlighted in

333 white in **f**. **i**, Overlaid poses of a single animal 240 ms to 160 ms before the end of a jump. Arrow indicates

334 the thoracolumbar joint. **j**, Correlations of the z- and angular velocities of the head and spine joints for time

335 points up to 400 ms before the end-point of a jump. Marker conventions as in **f**. **k**, Jump distance as a

336 function of angular velocity of the thoracolumbar joint for both animals 205 ms before the end of the jump.

337 Poses corresponding to the single data point highlighted with the arrow are shown in **i**. Displayed data

338 represents the correlation value highlighted with a white rectangle in **j**. **l**, Jump distance as a function of z-

339 velocity of the thoracocervical joint for both animals 175 ms before the end of the jump. Displayed data

340 represents the correlation value highlighted with a white rectangle in **j**.

341

342 **Discussion**

343 We developed an anatomically constrained model (ACM) for tracking skeletal poses of untethered
344 freely-moving animals, at the resolution of single joints, that enabled the quantification of joint
345 kinetics during gait and gap-crossing behaviors. From these kinetic measurements the ACM was
346 able to build a comparative map of the kinetic-sequences throughout decision-making behaviors
347 that could be compared to the behavioral outcome. Accurate generation of skeleton kinetics relied
348 on incorporating skeleton anatomy, requiring smoothness of rotations and imposing motion
349 restrictions of joints²⁷, as animal poses are limited by both bone lengths and joint angle limits²⁶.
350 In addition, we generated ground truth data to quantify both the accuracy of the algorithm used to
351 fit the model skeleton to the behavioral data and also the performance of the ACM at estimating
352 limb and joint trajectories. Comparing the bone lengths of the fitted skeleton to the actual bone
353 lengths measured from anatomical MRI scans for animals of a range of sizes we showed that
354 accurate model fits could be obtained for animals with an order of magnitude difference in weight,
355 with equally good fitting results independent of animal size. By directly measuring the animals
356 paw positions and comparing with positions returned by the ACM, we showed that the
357 combination of both anatomical and temporal constraints significantly reduced the errors relative
358 to the naïve skeleton model or either constraint alone. This combination allowed accurate
359 estimation not only of the location and orientation of the paws but also the accelerations and
360 velocities of the joints during the measured behaviors. The ACM was capable of accurately
361 quantifying limb kinetics during cyclic gait behaviors and more complex behaviors, such as gap-
362 crossing, even when limbs were partially occluded.

363 Lastly, the ACM remained accurate over a large range of animal sizes, 72 g – 735 g, with the
364 expectation that the ACM approach would also work for smaller rodents, such as mice. Our
365 approach ushers in a suite of new possibilities for studying the biomechanics of motion during
366 complex behaviors in freely-moving animals and complements recent developments in detailed
367 surface tracking⁴². It opens up future investigations to also model forces applied by tendons and
368 muscles^{26,27} and starts bridging the gap between neural computations in the brain^{3-8,13} and the
369 mechanistic implementation of complex behavior⁹⁻¹¹, such as rodent emotion⁴³.

370 Recently, various studies relying on deep neural networks approached the problem of detecting
371 an animal's pose in the form of 2D features from an image without anatomically constrained
372 skeleton models^{21,23,24}. 3D poses can be inferred from these 2D features by means of classical
373 calibrated camera setups⁴⁴, however the 2D detection in one camera image does not benefit from
374 the information from other cameras and the triangulation may suffer from resulting mislabeling of

375 2D features as well as missing detections due to occluded features. A recent approach³²
376 overcomes many of these issues by mapping from recorded images directly to 3D feature
377 locations, again using deep learning, and is capable of classifying animal behaviors across many
378 species³². However, it does not possess explicit inherent temporal connections between frames
379 and thus no persistent skeletal model with fixed bone lengths over time or anatomical constraints
380 on joint angles. In contrast, the ACM uses a different approach: With DLC²⁴ we used an existing
381 method to detect 2D anatomical markers and inferred 3D positions and kinetics of movement with
382 the RTS smoother based on anatomical constraints and mechanistic knowledge of bone
383 rotations^{26,27}, considering the trajectory of 3D positions over time. While the goal of the current
384 study was to infer skeletal kinematics of freely behaving animals but not real-time behavior
385 tracking^{23,45}, we expect future work in the field of 3D animal pose estimation to combine both
386 supervised learning techniques^{32,42} and mechanistic model constraints^{26,27}, to simultaneously
387 capitalize on their different strengths, e.g. by applying a smoother with anatomical knowledge like
388 the ACM directly to 3D positions from an image-to-3D framework³². Our approach has the capacity
389 to extend existing methods and not only to enhance the detail in which animal behavior can be
390 studied and quantified, but it also provides an objective and accurate quantification of limb and
391 joint positions for comparison with neuronal recordings.

412

413 **Methods**

414 **Obtaining video data of behaving animals.** All experiments were performed in accordance with
415 German guidelines for animal experiments and were approved by the Landesamt für Natur,
416 Umwelt und Verbraucherschutz, North Rhine-Westphalia, Germany. Six Lister Hooded rats
417 (Charles River Laboratories), weighting 174 g (animal #1), 178 g (animal #2), 71 g (animal #3),
418 72 g (animal #4) , 735 g (animal #5) and 699 g (animal #6) on the day of the experiment, were
419 used. Anatomical landmarks for tracking limb and body positions consisted of black or white ink
420 spots (5-8 mm diameter, black markers: Edding 3300, white markers: Edding 751, Edding,
421 Ahrensburg, Germany) which were painted onto the fur in a stereotypical pattern that was near-
422 symmetrical around the animals' mid-sagittal axis (Supplementary Fig. 2). For application of the
423 anatomical markers, animals were anesthetized with isoflurane (2-3%) and body temperature
424 maintained around 37.5°C using a heating pad and temperature probe. After this labeling
425 procedure the animals were allowed to recover for approx. 45 min before datasets were acquired
426 on a gap-crossing track and open arena. The open arena was 80x105 cm² with 50 cm high walls
427 colored gray to promote contrast with the animals and markers. The gap-crossing track consisted
428 of two 50x20 cm² platforms, mounted 120 cm off the ground on a slide mechanism to allow manual
429 adjustment of the distance between the platforms in the range from 0 to 60 cm. The platforms
430 were positioned such that with the gap closed they met along one of the 20 cm edges. The edges
431 of the platform, apart from the edge along which the two platforms met, were equipped with a 2.5
432 cm tall wall. The floor of the platforms was covered with a layer of neoprene material to promote
433 a secure grip for the animals' feet. A water delivery spout was located in the center of the 20 cm
434 track edge opposite of where the platforms met. To encourage gap-crossing behavior, animals
435 were water-restricted, having full access to water two days per week, and otherwise having
436 access to water only on the gap-crossing track. Fifty to one hundred microliters of water was
437 available at the delivery spout after each successful cross of the gap. Animals received a minimum
438 of 50% of their daily *ad libitum* water consumption either during the training or recording sessions
439 or as a supplement after the last session of the day if they had not already consumed at least this
440 amount. Gap-crossing training commenced approximately two weeks prior to the recording, and
441 consisted of two daily sessions. Gap distances were pseudo-random, with the gap distance
442 reduced in cases where the animal refused to cross. Both setups were homogeneously
443 illuminated using eight 125 cm long white LED strips with 700 lm/m (PowerLED, Berkshire, United
444 Kingdom), arranged equidistantly in a patch of 125x80 cm² and 125x55 cm² at a distance of 130
445 cm and 150 cm above the ground of the open arena and the gap-crossing track, and data were
446 acquired using four synchronously triggered digital cameras (ace acA1300-200um, Basler,

447 Ahrensburg, Germany) mounted above the setups and set in such a way that all parts of the setup
448 were covered by at least two cameras, with the majority of both setups covered by all four.
449 Datasets consisted of 1280x1024 px² image frames with an acquisition time of 2.5 ms recorded
450 at 100 Hz for the gait dataset in the open arena and 200 Hz for the gap-crossing dataset. For
451 quantification of the animals' foot positions we used a custom-made FTIR plate, consisting of a
452 single sheet of 60x60 cm², along the edges of which an IR-LED strip (Solarox 850 nm LED strip
453 infrared 850 nm, Winger Electronics GmbH & Co. KG, Germany) was mounted such that IR light
454 could propagate through the FTIR plate from two opposing sites. Animal position data were
455 acquired from the overhead cameras at 200 Hz for these experiments, and paw placements were
456 recorded using two additional cameras (ace acA1300-200um, Basler, Ahrensburg, Germany),
457 synchronized with the overhead cameras, mounted underneath the plate and equipped with
458 infrared-highpass filters (Near-IR Bandpass Filter, part: BP850, useful range: 820-910 nm,
459 FWHM: 160 nm, Midwest Optical Systems, Inc., Palatine, USA). These cameras were set to
460 acquire 1280x1024 px² frames with an acquisition time of 2.5 ms recorded at 200 Hz. The total
461 FTIR dataset consisted of 29 sequences with a total of 36250 frames in each of the four cameras
462 and a total duration of 181.25 s. The gait dataset consisted of 27 sequences with a total of 14650
463 frames in each of the four cameras and a total duration of 146.5 s. The gap-crossing dataset
464 consisted of 44 sequences with a total of 8800 frames in each of the four cameras and a total
465 duration of 44 s.

466
467 **Obtaining MRI scans to evaluate learned skeleton models.** To locate labeled surface markers,
468 custom-made MRI markers (Premium sanitary silicone DSSA, fischerwerke GmbH & Co. KG,
469 Waldachtal, Germany) were attached to the respective positions on the surface of the animals'
470 bodies. MR imaging was performed at a field strength of 3T (Magnetom Prisma, Siemens
471 Healthineers, Erlangen, Germany), using the integrated 32-channel spine coil of the
472 manufacturer. The data was acquired *ex vivo* in six rats using a 3D turbo-spin-echo sequence
473 with variable-flip-angle echo trains (3D TSE-VFL). Detailed MR protocol parameters for 3D TSE-
474 VFL imaging with a turbo factor of 98 were as follows: a repetition time of 3200 ms, an effective
475 echo time of 284 ms, an echo train duration of 585 ms, and an echo spacing of 6.3 ms using a
476 readout bandwidth of 300 Hz/px for one slab with 208 slices covering the whole rat at an isotropic
477 resolution of 0.4x0.4x0.4 mm³.

478
479 **Calibrating multi-camera setups.** We based the calibration of multiple cameras on a pinhole
480 camera model with 2nd order radial distortions (Supplementary Text) and OpenCV⁴⁶ functions for

481 detection of checkerboard corners. The checkerboards we used had additional ArUco⁴⁷ markers
482 printed on them. To obtain the calibration an objective function penalizing mismatches between
483 detected and projected corners was defined and minimized via gradient descent optimization
484 using the Trust Region Reflective algorithm⁴⁸ (Supplementary Text).

485

486 **Defining a 3D skeleton model.** The generalized skeleton model consisted of joints, modeled as
487 vertices, and inter-joint segments, modeled as edges and which could represent multiple bones
488 from the true skeleton (Supplementary Fig. 1). The front limbs were modeled as four edges,
489 representing the clavicle, humerus, radius/ulna and metacarpal/phalanges. The associated
490 vertices corresponded to the shoulder, elbow and wrist, with the last vertex representing the tip of
491 the middle phalanx. The hind limbs were modeled as five edges representing the pelvis, femur,
492 tibia/fibula, tarsus and phalanges, with the associated vertices representing the hip, knee, ankle
493 and metatarsophalangeal joints, with the last vertex representing the tip of the middle tarsal. The
494 tail was modeled as five edges and five vertices, with the last vertex representing the tip of the
495 tail. The spine was modeled as four edges, representing the cervical, thoracic and lumbar spinal
496 regions and the sacrum, with three intervening vertices. The head was modeled as a single edge,
497 with a vertex at the tip to represent the nose, and a second vertex representing the joint to the
498 first cervical vertebra. The resting pose of the 3D skeleton model was defined as the pose
499 generated by the pose reconstruction scheme, when all the parameters encoding bone rotations
500 were set to zero. In this pose all edges (i.e. bones) pointed towards the positive z-direction of the
501 right-handed world coordinate system, except the four edges approximating the
502 clavicle/collarbone and sacrum/pelvis, where edges of the right limb faced towards and edges of
503 the left limb faced against the positive x-direction of the world coordinate system (Supplementary
504 Fig. 1). The configuration of these four edges was also kept constant during pose reconstruction,
505 so that edges representing the cervical and lumbar vertebrae were always orthogonal to the
506 edges representing the clavicle and sacrum. The y-coordinates of all vertices were equal to zero,
507 locating the entire 3D skeleton model in the world's xz-plane while situated in the resting pose.
508 Besides the world coordinate system each edge also had its own right-handed coordinate system
509 located at the start vertex of the corresponding edge, e.g. the coordinate system of the edge
510 representing the left humerus was located at the position of the vertex representing the left
511 shoulder joint. The z-direction of these edge coordinate systems were always identical to the
512 direction in which the associated edges faced. Additionally, anatomical rotations were defined in
513 the edge coordinate systems, so that a rotation around the x-direction became equivalent to

514 flexion/extension, rotations around the y-direction were identical to abduction/adduction and a
515 rotation around the z-direction coincided with internal/external rotation.

516

517 **Constraining poses based on joint angle limits.** We implemented joint angle limits based on
518 measured minimum and maximum values for flexion/extension, abduction/adduction and
519 internal/external rotation in domestic house cats²¹. A comparable set of measured values is to our
520 knowledge not available for rat. For vertices approximating head, spine or tail joints data for joint
521 angle limits was not available, so that we modeled corresponding edges without the capacity to
522 rotate around the z-direction of their associated edge coordinate systems, whereas joint angle
523 limits for rotations around the x- and y-direction were set to +/- 90°. This allowed a respective
524 child-vertex to reach any point within an area spanned by a hemisphere pointing in the direction
525 of the associated edge with radius identical to the length of this edge. Since the resting pose of
526 our 3D skeleton model was not necessarily identical to the pose in which the published joint angle
527 limits were measured in, we calculated the correct rotational limits which were consistent with our
528 resting pose based on the mean of the published values. The resulting joint angle limits were set
529 as follows:

530 joint	x (°)	y (°)	z (°)
531 left shoulder	[25,205]	[-85,25]	[-35,35]
532 right shoulder	[25,205]	[-25,85]	[-35,35]
533 left elbow	[2.5,145]	[0,0]	[-100,45]
534 right elbow	[2.5,145]	[0,0]	[-45,100]
535 left wrist	[-135,35]	[-12.5,37.5]	[0,0]
536 right wrist	[-135,35]	[-37.5,12.5]	[0,0]
537 left hip	[35,195]	[-65,25]	[-85,40]
538 right hip	[35,195]	[25,65]	[-40,85]
539 left knee	[-145,15]	[0,0]	[0,0]
540 right knee	[-145,15]	[0,0]	[0,0]
541 left ankle	[-10,145]	[0,0]	[0,0]
542 right ankle	[-10,145]	[0,0]	[0,0]
543 left metatarsophalangeal	[0,0]	[0,0]	[-15,35]
544 right metatarsophalangeal	[0,0]	[0,0]	[-35,15]

545 While the published joint angles referred to Euler angles, we used Rodrigues vectors to
546 parameterize rotations (Supplementary Text), since the latter are better suited for pose
547 reconstruction⁴⁹. However, both parameterizations become identical when only a single type of

548 rotation, e.g. flexion/extension, is present at a vertex, which was the case for the measured joint
549 angles⁴⁹. Parameterizing rotations with Rodrigues vectors therefore allowed us to obtain smooth
550 transitions between different types of bone rotations.

551

552 **Constraining surface marker positions based on body symmetry.** When learning surface
553 maker positions and bone lengths we constrained the former to comply with the symmetrically
554 applied surface marker pattern by enforcing box constraints for each spatial dimension, e.g.
555 markers on the left side of an animal were prevented from being placed on the right side. This
556 reduced the total number of free parameters during learning. To reduce this number further we
557 also mirrored surface marker positions in the yz-plane of the associated edge coordinate system
558 when there was a left/right correspondence, i.e. we only learned surface marker positions for the
559 left side which then also determined right-sided surface maker positions due to the mirroring
560 (Supplementary Text). Resulting box constraints for central and left-sided surface maker locations
561 were then defined in the coordinate system of the associated edges and set as follows
562 (Supplementary Fig. 1,2):

563 marker	attached joint	x	y	z
564 head #1	spine #5	[0,0]	[0,inf)	(-inf,inf)
565 head #2	spine #5	[0,0]	[0,inf)	(-inf,inf)
566 head #3	head (leaf)	[0,0]	[0,0)	[0,0]
567 spine #1	spine #2	[0,0]	[0,inf)	(-inf,inf)
568 spine #2	spine #2	[0,0]	[0,inf)	(-inf,inf)
569 spine #3	spine #3	[0,0]	[0,inf)	(-inf,inf)
570 spine #4	spine #3	[0,0]	[0,inf)	(-inf,inf)
571 spine #5	spine #4	[0,0]	[0,inf)	(-inf,inf)
572 spine #6	spine #5	[0,0]	[0,inf)	[0,0]
573 tail #1	tail #1 (leaf)	[0,0]	[0,0)	[0,0]
574 tail #2	tail #2	[0,0]	[0,inf)	(-inf,inf)
575 tail #3	tail #3	[0,0]	[0,inf)	(-inf,inf)
576 tail #4	tail #4	[0,0]	[0,inf)	(-inf,inf)
577 tail #5	tail #5	[0,0]	[0,inf)	(-inf,inf)
578 tail #6	spine #1	[0,0]	[0,inf)	(-inf,inf)
579 shoulder	shoulder	[0,0]	[0,inf)	[0,inf)
580 elbow	elbow	(-inf,0]	[0,0]	[0,0]
581 wrist	wrist	[0,0]	(-inf,0]	[0,0]

582	finger #1	finger (leaf)	(-inf,inf)	[0,0]	(-inf,inf)
583	finger #2	finger (leaf)	[0,0]	[0,0]	[0,0]
584	finger #3	finger (leaf)	(-inf,inf)	[0,0]	(-inf,inf)
585	side	spine #3	(-inf,0]	(-inf,inf)	(-inf,inf)
586	hip	hip	[0,0]	[0,inf)	[0,inf)
587	knee	knee	(-inf,0]	[0,0]	[0,0]
588	ankle	ankle	(-inf,0]	[0,0]	[0,0]
589	metatarsophalangeal	metatarsophalangeal	[0,0]	(-inf,0]	[0,0]
590	toe #1	toe (leaf)	(-inf,inf)	[0,0]	(-inf,inf)
591	toe #2	toe (leaf)	[0,0]	[0,0]	[0,0]
592	toe #3	toe (leaf)	(-inf,inf)	[0,0]	(-inf,inf)

593 The only exception from this was the upper bound of the left-sided surface marker on the shoulder
 594 in z-direction for the two large animals (animals #5 and #6), which was also set to 0 in order to
 595 prevent the bone lengths of the collarbones to become zero during learning.

596

597 **Constraining bone lengths based on allometry.** We applied loose constraints on the length of
 598 limb bones based on the published linear relationships between body weight and bone lengths in
 599 rats³⁵. The lengths of the following list of limb bones were constrained according to measured
 600 slope estimates³⁵. Box constraints for bone lengths were calculated from weight-matched lengths
 601 plus or minus 10 times the standard deviation, based on the following proportionality factors:

602	bone name	slope avg. +/- s.d. (cm/g)
603	humerus	0.0075 +/- 0.0005
604	radius	0.0069 +/- 0.0004
605	metacarpal	0.0023 +/- 0.0001
606	femur	0.0102 +/- 0.0006
607	tibia	0.0114 +/- 0.0006
608	metatarsal	0.0053 +/- 0.0003

609 For bones that were not part of the limbs no constraints were enforced, such that corresponding
 610 box constraints were set to [0,inf). To ensure that bone lengths of the left and right limbs were
 611 identical, we only learned bone lengths of the left-sided limbs, which then also determined right-
 612 sided limb bone lengths (Supplementary Text).

613

614 **Training deep neural networks to detect 2D locations of surface markers.** To automatically
 615 detect 2D locations of surface makers we used DeepLabCut²⁴. For each rat in each dataset an

616 individual neural network was trained on manually labeled images obtained from four different
617 cameras, six trained networks in total. For each image that was used for training a background-
618 subtracted image was generated by subtracting the image acquired 200 ms prior to the frame of
619 interest for the FTIR and gap-crossing datasets and 125 ms prior for the gait dataset.
620 Subsequently, approximate 2D locations of the recorded rats on the background-subtracted
621 images were obtained by calculating the median indices of pixels above a threshold-value of 5
622 times the standard deviation of each pixel, where the standard deviations were calculated from
623 the first 100 images of each recorded video, which were acquired with the arena or track empty
624 and free of any moving objects. These 2D locations were then used as a center-point to crop the
625 original images to 600x600 px². To minimize the influence of visible movements of the
626 experimentors on this center-point detection in the recorded FTIR data set, pixel values of pixels,
627 which did not show the FTIR plate, were set to zero for the recordings of animals #3 to #6. For
628 the FTIR datasets the networks were trained on 4068 images for animal #1, 3980 images for
629 animal #2, 752 images for animal #3, 1100 images for animal #4, 992 images for animal #5 and
630 1128 images for animal #6. For the gait and gap-crossing datasets 2404 and 3608 images were
631 used respectively for each analyzed animal (animal #1 and #2). Resulting images that did not
632 contain any manually annotated 2D positions of surface markers due to the preprocessing steps
633 not leading to correct cropping, were not used during training. We used DeepLabCut's default
634 settings, with the only two exceptions being that we changed the network architectures to ResNet-
635 152 and enabled mirroring of images for which we paired surface markers with a left/right
636 correspondence⁵⁰. Training was conducted via DeepLabCut 2.1.6.4 downloaded from GitHub
637 (<https://github.com/DeepLabCut/DeepLabCut/commit/2f5d32884da2e5c3e4b6ef2a2126f6bb61579060>).
638 Once the networks were trained, we used them to obtain 2D locations of surface markers
639 for images of analyzed behavioral sequences, where we set DeepLabCut's pcutoff-parameter⁵⁰
640 to 0.9 and treated detected marker positions below this value as missing measurements.

641
642 **Performing probabilistic pose reconstruction.** To perform probabilistic 3D pose
643 reconstruction, which allows for generating poses using non-linear mathematical operations and
644 where information of an entire behavioral sequence is processed, we implemented an unscented
645 Rauch-Tung-Striebel (RTS) smoother^{36,37}, whose fundamental principles are based on the
646 ordinary Kalman filter formulation³⁸. In this approach, time series data is modelled as a stochastic
647 process generated by a state space model where at each time point hidden states give rise to
648 observable measurements and fulfill the Markov property, i.e. each hidden state only depends on
649 the preceding one (Supplementary Fig. 12). This formalism allowed us to represent each pose as

650 a low-dimensional state variable, corresponding to the location of a reconstructed skeleton as well
651 as the individual bone rotations (dimension of hidden state variable: 50; 3 variables for 3D location
652 of the skeleton plus 47 variables for bone rotations). The measurable 2D locations of surface
653 markers (which were given by the outputs of the trained neural network) had a higher
654 dimensionality and were represented via measurement variables (dimension of measurement
655 variable: maximal 344; 43 surface markers times 4 cameras times 2 variables for the 2D location
656 of a surface marker). We assumed the hidden states to be (conditionally) normally distributed,
657 whereby temporal constraints are implicitly modeled through the transition kernel of the Markov
658 process (i.e. the probabilistic mapping between one state and the next). Our formalism allows for
659 non-linearities in our pose reconstruction scheme, e.g. introduced by the usage of trigonometric
660 functions when applying bone rotations. The unscented RTS smoother can be used to perform
661 probabilistic pose estimation in such a nonlinear state space model, considering both past and
662 future (Supplementary Text). We learned the unknown model parameters (i.e. the initial mean and
663 covariance of the state variables as well as the covariances of the transition and measurement
664 noise) via an expectation-maximization (EM) algorithm³⁹ (maximal 2944 model parameters total;
665 50 parameters for mean of initial hidden state variable plus 1275 parameters for covariance matrix
666 of initial hidden state variable plus 1275 parameters for covariance matrix of transition noise plus
667 maximal 334 parameters for diagonal covariance matrix of measurement noise), which aims to
668 maximize a lower bound of the state space model's evidence, i.e. the evidence lower bound
669 (ELBO), accounting for each pose within a behavioral sequence (Supplementary Text). This is
670 achieved by alternating between an expectation step (Supplementary Text), in which we obtain
671 the expected values of the state variables given a fixed set of model parameters via the unscented
672 RTS smoother, and a maximization step (Supplementary Text), in which these model parameters
673 are updated in closed form in order to maximize the ELBO⁵¹. After convergence of the EM
674 algorithm, final poses were obtained by applying the unscented RTS smoother using the learned
675 model parameters.

676

677 **Accounting for missing measurements during pose reconstruction.** Detecting 2D positions
678 of surface markers via a trained deep neural network was not always successful, e.g. due to
679 marker occlusions. As a result, we only had access to different subsets of all 2D positions during
680 smoothing. This forced us to apply modifications to the plain unscented RTS smoother formulation
681 and the EM algorithm, i.e. we set rows and/or columns of the measurement covariance matrices
682 to zero during the filtering path of the smoother^{52,53} and proceeded equivalently with the
683 covariance matrix of the measurement noise when maximizing the ELBO (Supplementary Text).

684

685 **Enforcing joint angle limits during pose reconstruction.** The plain formulation of the
686 unscented RTS smoother does not account for box constraints, so that state variables
687 representing bone rotations are not bounded. To still allow for anatomically constrained pose
688 estimation we instead optimized unbound state variables, which could be mapped onto the correct
689 lower and upper bounds for joint angle limits via sigmoidal functions, i.e. error functions
690 (Supplementary Text). These functions had slope one at the origin and were asymptotically
691 converging towards the lower and upper bounds of the respective joint angle limits.

692

693 **Learning bone lengths and surface marker positions.** To learn bone lengths and surface
694 marker positions we simultaneously fitted our generalized 3D skeleton model to manually labeled
695 2D positions of surface markers at different time points for each animal. Fitting of the generalized
696 3D skeleton model was achieved via gradient decent optimization using the L-BFGS-B algorithm⁵⁴
697 in order to minimize an objective function, which penalized mismatches between manually labeled
698 2D locations of surface markers and those generated via the pose reconstruction scheme
699 (Supplementary Text). Bone lengths, surface marker positions and pose parameters were
700 optimized, while only the pose parameters were unique for every time point and the rest were
701 shared throughout the entire sequence. For this we used sequences of freely-behaving animals
702 recorded via four different cameras totaling to 2404 training frames for animal #1 and #2, 752
703 training frames for animal #3, 1100 training frames for animal #4, 992 training frames for animal
704 #5 and 1128 training frames for animal #6. Bone lengths were initialized by the mean of their
705 upper and lower bounds or zero when there were no constraints and surface marker positions
706 were initialized to be identical to the joints they were attached too. Initial poses were identical to
707 the resting pose but global skeleton locations and rotations were adjusted prior to the fitting to
708 loosely align with the locations of an animal's body as seen by the cameras. Once values for bone
709 lengths and surface marker positions were learned, we used them for all further pose
710 reconstructions.

711

712 **Comparison of skeleton parameters with MRI data.** To estimate the quality of these skeleton
713 parameters, we aligned learned 3D skeleton models to manually labeled 3D locations of surface
714 markers obtained from an MRI scan for each animal (Fig. 1b, bottom). To determine the 3D
715 positions of the respective spine joints in the MRI scan, we counted vertebrae such that each
716 modeled spine segment matched its anatomical counterpart with respect to the number of
717 contained vertebrae³³. One MRI surface marker was not recoverable in the MRI dataset from one

718 animal (right metatarsophalangeal marker, animal #1), and in this case we labeled the 3D location
719 on the animal's body closest to the position of the missing marker. Again, we used gradient decent
720 optimization of an objective function, so that manually labeled 3D markers locations were matched
721 with the ones given by our model. Skeleton parameters were kept constant and only pose
722 parameters changed during optimization. All ground truth joint positions except those for the
723 metatarsophalangeal joints could be identified manually in the MRI scan (4 joint locations total).
724 These missing locations were assumed to be identical to the positions of the corresponding
725 metatarsophalangeal markers.

726

727 **Defining four different models to evaluate the influence of anatomical and temporal**
728 **constraints.** In the ACM anatomical and temporal constraints were enforced and poses were
729 reconstructed using the unscented RTS smoother together with the EM algorithm. This was also
730 the case for the temporal model but joint angle limits of limb joints, which were not equal to $[0^\circ, 0^\circ]$,
731 were set to $[-180^\circ, 180^\circ]$, effectively allowing full 360° rotations at the respective joints. Pose
732 parameters for these two models were initialized by fitting the pose of the first time point of a
733 behavioral sequence equivalently to how we learned the skeleton parameters with the only
734 exception that automatically detected instead of manually labeled 2D locations of surface markers
735 were used. The covariance matrices for the initial state variables as well as the state and the
736 measurement noise, which were learned via the EM algorithm, were initialized by setting all
737 diagonal entries to 0.001 and off-diagonal entries to zero, while the latter were also kept constant
738 for the measurement noise covariance matrix during the maximization step of the EM algorithm.
739 For the joint angle and the naïve skeleton model, where only anatomical or no constrains were
740 enforced, we did not use the unscented RTS smoother but reconstructed every pose in the same
741 way we initialized the ACM and the temporal model. Here poses within a behavioral sequence at
742 a certain time point were initialized with the reconstructed pose of the previous time point and
743 joint angle limits of limb joints were set to $[-180^\circ, 180^\circ]$ in the naïve skeleton model.

744

745 **Evaluating pose reconstruction accuracy via a FTIR touch sensing system.** To obtain ground
746 truth data paw centers and three individual fingers/toes were manually labeled for each limb in
747 every 40th frame of the FTIR dataset. Images from the calibrated underneath cameras were used
748 and paw centers were identified as the interpolated intersection of the three fingers/toes. Manually
749 labeled marker locations were then projected onto the surface of the transparent floor and xy-
750 positions were calculated as the intersection between this surface and the corresponding epipolar
751 lines. Paw positions and orientation errors were then calculated in the coordinate system of the

752 transparent floor based on these xy-coordinates. Velocity and acceleration values for the four
753 different models were derived from central finite differences (order of accuracy: 8) based on the
754 reconstructed 3D positions of the metatarsophalangeal/wrist and finger/toe markers. Paw position
755 errors of undetected markers were obtained by only using paw position errors of surface markers
756 that were not detected by the trained neural network (i.e. pcutoff < 0.9). When ordering these
757 errors according to the time spans that passed since a respective marker was successfully
758 detected, differentiating between the ACM/temporal and joint angle/naïve skeleton model was
759 necessary. As the unscented RTS smoother incorporates information from the past as well as
760 from the future, time spans until the next detection need to be treated equally to time spans since
761 the last detection, i.e. the direction of the time axis becomes irrelevant. For the ACM/temporal
762 model time spans were calculated as the minimum of the time spans since the last or until the
763 next detection, whereas for the joint angle/naïve skeleton model only time spans since the last
764 detection were relevant, as the smoother was not used here. For the resulting analysis we only
765 included errors for which the corresponding sample size was at least 10.

766

767 **Analyzing gait data.** In order to extract gait periodicity, we normalized reconstructed poses by
768 applying a coordinate transformation on 3D joint locations, such that the new origin was identical
769 to the joint which connects lumbar vertebrae with the sacrum and the new x-direction pointed
770 towards the xy-position of the joint linking cervical with thoracic vertebrae. Given the new joint
771 coordinates we calculated normalized x-positions and bone angles as well as their first temporal
772 derivatives (i.e. normalized x-velocity and angular velocity) of limb joints, where bone angles were
773 defined as the angle between the new x-direction and a respective bone. To model auto-
774 correlations of normalized x-positions, we minimized an objective function penalizing mismatches
775 between data from the four different traces of each limb and the corresponding estimate
776 calculated using a single damped sinusoid via gradient decent optimization. To obtain population
777 averages of normalized x-positions, bone angles and their temporal derivatives, we detected
778 midpoints of swing phases by identifying maximum peaks of normalized x-velocities above 25
779 cm/s. An individual trace was extracted containing data up to +/- 200 ms around each peak. These
780 traces were then aligned with respect to their associated velocity peaks and then averaged across
781 the entire population. To obtain traces from only tracking surface markers alone, 3D positions of
782 surface markers were interpolated based on their inferred 2D locations given by the trained
783 neural network, whereas for each 3D position only the two most likely 2D locations were taken
784 into account, i.e. the two 2D locations with the highest pcutoff-value.

785

786 **Analyzing gap-crossing data.** Each of the 44 gap-crossing sequences was 1 s long and
787 contained 200 frames per camera totaling 35200 frames. Due to the limited number of gap-
788 crossing events and recorded frames, we used 20% of the frames to train the neural network, i.e.
789 we took every 5th frame of the recorded gap crossing sequences for its training and deployed it
790 to automatically process all frames once training was completed. Similar to the analysis of gait
791 data, velocity values were derived from central finite differences (order of accuracy: 8) of
792 reconstructed 3D joint positions and joint angles were defined as the angle between two
793 connected bones. To obtain start-, mid- and end-point for each jump we averaged joint angles of
794 all spine and hind limb joints and identified the time point where this averaged metric reached its
795 global minimum for each gap-crossing sequence. The averaged metric was characteristic for each
796 jump, i.e. distinct peaks were always present in the following order: local minimum, local
797 maximum, global minimum, local maximum, local minimum. This allowed us to extract the start-
798 and end-point of each jump by finding the first and last local minimum of this sequential pattern.
799 Resulting jump start- and end-points were in close agreement with those obtained from manual
800 assessments of gap crossing sequences by a human expert. Jump distances were calculated as
801 the absolute xy-difference of the average hind paw positions, i.e. average of left/right ankle,
802 metatarsophalangeal and toe joint positions, at the start- and end-point of each jump. To obtain
803 population averaged poses for the jump start-, mid- and end-points, we normalized each pose
804 equivalently to the analysis of gait data. This aligned the resulting poses at their origin and we
805 were able to calculate characteristic jump poses by averaging them across the entire population.
806 For the population averaged mean angle traces we aligned each individual trace according to the
807 mid-point of each jump and then averaged across the entire population. To highlight the diversity
808 of the data given by the reconstructed poses, we calculated distance- and auto-correlations of
809 several different metrics and joints: jump distances were correlated with spatial z-velocities and
810 angular velocities of spine joints at time points up to 400 ms before the end of a jump and absolute
811 spatial velocities and angular velocities of hind limbs joints were correlated with each other at the
812 start-point of a jump. Since differences in bone lengths for each animal dominated the correlation
813 for spatial position and joint angle we only focused on their first temporal derivatives.

814

815 **Computing hardware.** All pose reconstructions and analyzes were conducted on a workstation
816 equipped with an AMD Ryzen 7 2700x CPU, 32 GB DDR4 RAM, Samsung 970 EVO 500 GB
817 SSD, and a single NVIDIA GeForce RTX 1080 Ti (11 GB) GPU. The installed operating system
818 was Ubuntu 18.04.5 LTS. Training DeepLabCut was either conducted on a NVIDIA GeForce RTX
819 1080 Ti (11 GB) GPU, using CUDA version 10.0 and NVIDIA driver version 410.48, or a NVIDIA

820 GeForce RTX 2080 Ti (11 GB) GPU, using CUDA version 11.0 and NVIDIA driver version
821 450.80.02.

822

823 **Code availability.** Code for performing pose reconstructions will be made publicly available on

824 GitHub: <https://github.com/bbo-lab/ACM>

825

826 **Data availability.** Raw data available on request.

1 Parameterizing rotations

We choose to parameterize rotations with Rodrigues vectors as they are well suited for the description of bone rotations with three rotational degrees of freedom [10]. A Rodrigues vector r is formed by combining the axis of rotation $\omega \in \mathbb{R}^3$ and the rotation angle $\theta \in \mathbb{R}$:

$$r = \theta\omega = \theta(\omega_1, \omega_2, \omega_3)^T \quad (1)$$

where $\|\omega\| = 1$. To calculate the associated rotation matrix R from a given Rodrigues vector r we can use the following function:

$$f_{\mathbb{R} \rightarrow \mathbb{R}}(r) = I + \hat{\omega} \sin(\theta) + \hat{\omega}^2 (1 - \cos(\theta)) = \begin{pmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{pmatrix} = R \quad (2)$$

where $I \in \mathbb{R}^{3 \times 3}$ is the identity matrix and $\hat{\omega} \in \mathbb{R}^{3 \times 3}$ is given by:

$$\hat{\omega} = \begin{pmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{pmatrix}. \quad (3)$$

2 Camera calibration

2.1 Pinhole camera model

To project an arbitrary three-dimensional joint or surface marker location $m_{3D} \in \mathbb{R}^3$ onto a camera sensor to obtain the corresponding two-dimensional data point $m_{2D} \in \mathbb{R}^2$, we are using a pinhole camera model [6], which gives the following relationship between the two:

$$f_{3D \rightarrow 2D}(m_{3D}, \tilde{r}, \tilde{t}, \tilde{k}, \tilde{A}) = \tilde{A} f_{\text{distort}}(f_{\mathbb{R} \rightarrow \mathbb{R}}(\tilde{r}) m_{3D} + \tilde{t}, \tilde{k}) = m_{2D} \quad (4)$$

where $\tilde{r} \in \mathbb{R}^3$ is the Rodrigues vector and $\tilde{t} \in \mathbb{R}^3$ the translation vector of the respective camera, such that the expression $f_{\mathbb{R} \rightarrow \mathbb{R}}(\tilde{r}) m_{3D} + \tilde{t}$ maps m_{3D} from the world coordinate system into the coordinate system of the camera. Given the camera's distortion vector $\tilde{k} \in \mathbb{R}^2$, the function f_{distort} applies radial distortions according to

$$f_{\text{distort}}(y, \tilde{k}) = \begin{pmatrix} \frac{y_1}{y_3} \left(1 + \tilde{k}_1 \tilde{c} + \tilde{k}_2 \tilde{c}^2\right) \\ \frac{y_2}{y_3} \left(1 + \tilde{k}_1 \tilde{c} + \tilde{k}_2 \tilde{c}^2\right) \\ 1 \end{pmatrix} \quad (5)$$

with $y = (y_1, y_2, y_3)^T$ and $\tilde{c} = \left(\frac{y_1}{y_3}\right)^2 + \left(\frac{y_2}{y_3}\right)^2$. The final mapping onto the two-dimensional camera sensor is done using the camera matrix $\tilde{A} \in \mathbb{R}^{2 \times 3}$ given by

$$\tilde{A} = \begin{pmatrix} \tilde{A}_{11} & 0 & \tilde{A}_{13} \\ 0 & \tilde{A}_{22} & \tilde{A}_{23} \end{pmatrix} \quad (6)$$

where \tilde{A}_{11} and \tilde{A}_{22} are the focal lengths and \tilde{A}_{13} and \tilde{A}_{23} are the x- and y-location of the camera's optical center.

2.2 Calibration of multiple cameras

Given a multi-camera setup with several cameras and overlapping fields of view, we need to infer the initially unknown location and camera parameters of every individual camera in the setup as this allows us to predict where a three-dimensional point in space will be visible on each camera sensor.

structure and dimensions are known to us. Hereby, the images are taken synchronously in all cameras, such that the spatial location and orientation of the shown object is identical for a given set of images at a certain time point. For this purpose checkerboards are suited objects as edges of individual tiles can be detected automatically in recorded image frames and the description of their spatial structure requires only a single parameter, i.e. the length of a quadratic tile. Given a multi-camera setup with n_{cam} cameras and n_{time} time points at which we used each camera to record images, which show a checkerboard that has a total of n_{edge} detectable edges, we can calibrate the setup by minimizing a respective objective function via gradient decent optimization using the Trust Region Reflective algorithm [2]:

$$\arg \min_{\substack{\tilde{r}_i, \tilde{t}_i, \tilde{k}_i, \tilde{A}_i, \hat{r}_\tau, \hat{t}_\tau \\ \forall i \in \{1, \dots, n_{\text{cam}}\} \\ \forall \tau \in \{1, \dots, n_{\text{time}}\}}} \sum_{\tau=1}^{n_{\text{time}}} \sum_{i=1}^{n_{\text{cam}}} \sum_{j=1}^{n_{\text{edge}}} \delta_{\tau ij} \left\| m_{\tau ij} - f_{3D \rightarrow 2D} \left(f_{R \rightarrow R}(\hat{r}_\tau) \hat{m}_j + \hat{t}_\tau, \tilde{r}_i, \tilde{t}_i, \tilde{k}_i, \tilde{A}_i \right) \right\|^2 \quad (7)$$

where \tilde{r}_i is the Rodrigues vector, \tilde{t}_i is the translation vector, \tilde{k}_i is the distortion vector and \tilde{A}_i is the camera matrix of camera i . The Rodrigues vector \hat{r}_τ and the translation vector \hat{t}_τ encode the orientation and translation of the checkerboard at time point τ . Since the checkerboard is a planar object each edge j is given by a three-dimensional point $\hat{m}_j = c_{\text{tile}}(x_j, y_j, 0)^T$ with the known length of a single tile c_{tile} and $x_j \in \mathbb{N}$ as well as $y_j \in \mathbb{N}$. Furthermore, the two-dimensional edge j in camera i at time point τ is denoted as $m_{\tau ij} \in \mathbb{R}^2$ and the delta function $\delta_{\tau ij}$ indicates whether this edge is detected successfully, i.e. $\delta_{\tau ij} = 1$, or not, i.e. $\delta_{\tau ij} = 0$.

3 Skeleton model

3.1 Modifying the skeleton model to obtain new poses

Given a three-dimensional skeleton model, we need to adjust joint locations by rotating each bone of the model, such that resulting three-dimensional positions of rigidly attached surface markers match the respective two-dimensional locations in our video data. Assuming our skeleton model has a total of n_{bone} bones and n_{marker} surface markers, we want to generate the three-dimensional locations of the joints $p \in \mathbb{R}^{n_{\text{bone}} \times 3}$ and surface markers $m \in \mathbb{R}^{n_{\text{marker}} \times 3}$, which can be obtained according to Algorithm 1.

Algorithm 1

```

1: function  $f_{\text{pose}}(t, r, l, v)$ 
2:   for  $j \in \{1, \dots, n_{\text{bone}}\}$  do
3:      $R_j \leftarrow I$  ▷ Initialize each bone rotation  $R_j$ 
4:   for  $i \in \{1, \dots, n_{\text{bone}}\}$  do
5:     for  $j \in \{1, \dots, n_{\text{bone}}\}$  do
6:       if  $j_1$  is child of  $i_0$  then ▷ Check if rotation of bone  $i$  affects end joint  $j_1$ 
7:          $R_j \leftarrow f_{R \rightarrow R}(r_i)^T R_j$  ▷ Update rotation of bone  $j$ 
8:   for  $j \in \{1, \dots, n_{\text{bone}}\}$  do
9:      $R_j \leftarrow R_j^T \bar{R}_j$  ▷ Apply bone rotation  $R_j$  to resting pose  $\bar{R}_j$ 
10:   $p_{1_0} \leftarrow t$  ▷ Initialize root joint location  $p_{1_0}$ 
11:  for  $j \in \{1, \dots, n_{\text{bone}}\}$  do
12:     $p_{j_1} \leftarrow p_{j_0} + (R_{j_{13}}, R_{j_{23}}, R_{j_{33}})^T l_j$  ▷ Calculate end joint location  $p_{j_1}$  of bone  $j$ 
13:    for  $k \in \{1, \dots, n_{\text{marker}}\}$  do
14:      if  $j_1$  is connected to  $k$  then ▷ Check if end joint  $j_1$  is connected to marker  $k$ 
15:         $m_k \leftarrow p_{j_1} + R_j v_k$  ▷ Calculate absolute marker location  $m_k$ 
16:  return  $m$ 

```

Here, it is assumed that the set i_0 is sorted such that one iterates through the skeleton graph beginning with the bone whose start joint is the root joint i_0 and then proceed with the bones further down the skeleton graph. Thus, it is always guaranteed that for $j > i$, the start joint i_0 of bone i is never a child of the start joint j_0 of bone j . It is also assumed that the bone coordinate systems of the skeleton model are constructed such that their z-directions encode the directions in which the respective bones are pointing. Furthermore, the global translation vector $t \in \mathbb{R}^3$ corresponds to the three-dimensional location of the skeleton's root joint, the rows of the tensor $r \in \mathbb{R}^{n_{\text{bone}} \times 3}$ contain Rodrigues vectors encoding the bone rotations, the vector $l \in \mathbb{R}^{n_{\text{bone}}}$ contains the bone lengths and the rows of the tensor $v \in \mathbb{R}^{n_{\text{marker}} \times 3}$ contain the relative marker locations, i.e. the locations of the markers when the position of the attached joints are assumed to be the origin. The resting pose $\bar{R} \in \mathbb{R}^{n_{\text{bone}} \times 3 \times 3}$ of the animal describes the orientation of the bones when no additional rotations are applied, i.e. $r_i = (0, 0, 0)^T \forall i \in \{1, \dots, n_{\text{bone}}\}$. Here, the frequent usage of the transpose operation allows to first rotate bones, which are the closest to the leaf joints of the skeleton graph [4]. This has the advantage that we can enforce constraints on bone rotations with reference to a global coordinate system that corresponds to the three main axes of the animal's body. Assume we only model a single front limb where we only have rotations around the shoulder, elbow and wrist, i.e. R_{shoulder} , R_{elbow} and R_{wrist} , and would like to obtain the new orientation R_{new} of the bone whose start joint is identical to the animal's wrist given its resting pose \bar{R}_{wrist} while iterating through the skeleton graph starting from the root joint, i.e. the shoulder. Then we can obtain R_{new} according to

$$R_{\text{new}} = (R_{\text{wrist}}^T R_{\text{elbow}}^T R_{\text{shoulder}}^T)^T \bar{R}_{\text{wrist}} = R_{\text{shoulder}} R_{\text{elbow}} R_{\text{wrist}} \bar{R}_{\text{wrist}} \quad (8)$$

Thus, we can iterate through the skeleton graph from the root to the leaf joints but actually apply the respective bone rotations in the reversed order.

3.2 Inferring bone lengths and surface marker positions

Reconstructing poses for n_{time} time points can be archived equivalently to the calibration of a multi-camera setup as discussed in Section 2.2, i.e. we need to minimize a respective objective function via gradient decent optimization using the L-BFGS-B algorithm [3]:

$$\arg \min_{\substack{t_\tau, r_\tau, l, v \\ \forall \tau \in \{1, \dots, n_{\text{time}}\}}} \sum_{\tau=1}^{n_{\text{time}}} \sum_{i=1}^{n_{\text{cam}}} \sum_{j=1}^{n_{\text{marker}}} \delta_{\tau ij} \|m_{\tau ij} - \hat{m}_{\tau ij}\|^2 \quad (9)$$

where $m_{\tau ij}$ is the two-dimensional location of marker j in camera i at time point τ and $\delta_{\tau ij}$ indicates whether this marker location was successfully detected, i.e. $\delta_{\tau ij} = 1$, or not, i.e. $\delta_{\tau ij} = 0$. The corresponding projected two-dimensional marker location $\hat{m}_{\tau ij}$ can be obtained by propagating the absolute marker positions calculated via Algorithm 1 through the projection function $f_{3\text{D} \rightarrow 2\text{D}}$:

$$\hat{m}_{\tau ij} = f_{3\text{D} \rightarrow 2\text{D}} \left(f_{\text{pose}}(t_\tau, r_\tau, l, v)_j, \tilde{r}_i, \tilde{t}_i, \tilde{k}_i, \tilde{A}_i \right) \quad (10)$$

where $t_\tau \in \mathbb{R}^3$ and $r_\tau \in \mathbb{R}^{n_{\text{bone}} \times 3}$ denote the translation vector and the bone rotations at time point τ . Note how there is a set of pose-encoding parameters t_τ and r_τ for each time point τ whereas the bone lengths l and the relative surface marker positions v , which encode the animal's skeletal structure and configuration, are shared across all time points. Thus, if we provide enough time points where the animal is visible in many different poses, which ideally cover the entire spectrum of the animal's behavioral space, we can not only reconstruct the pose of the animal for the given time points but are also able to learn the structure of the animal's skeleton, by inferring the unknown parameters l and v .

3.3 Scaling of input and output variables

In general, we always scale the translation vector t and the bone rotations r as well as the resulting two-dimensional marker locations \hat{m} , such that all of them roughly lie within the same range, i.e.

Particularly, we define the normalization constants c_t and c_r as well as $c_1 = 640$ px and $c_2 = 512$ px, which we use to normalize t and r as well as \hat{m} . The choice for c_t was based on the dimensions of the largest arena we used in our experiments, where the maximum distance to an arena's edge from the origin of the world coordinate system, located at the center of the arena, was around 50 cm. The choice for c_r was based on the maximum bone rotation of the naively constrained spine and tail joints in our skeleton model, which was equal to $\frac{\pi}{2}$ rad. The choice for c_1 and c_2 were based on the sensor sizes of the cameras we used in our experiments, which were all equal to 1280×1024 px². Using the normalization constants we obtain the normalized translation vector $t^* = \frac{t}{c_t}$ and the normalized bone rotations $r^* = \frac{r}{c_r}$ as well as the normalized two-dimensional marker locations

$$\hat{m}^* = \begin{pmatrix} \hat{m}_1^* \\ \hat{m}_2^* \end{pmatrix} = \begin{pmatrix} \frac{\hat{m}_1}{c_1} - 1 \\ \frac{\hat{m}_2}{c_2} - 1 \end{pmatrix} \quad (11)$$

for a single two dimensional marker location $\hat{m} \in \mathbb{R}^2$, such that \hat{m}_1 represents its x- and \hat{m}_2 its y-coordinate. These normalized variables were used instead of their non-normalized counterparts in all depicted optimization and pose reconstruction steps.

3.4 Enforcing body symmetry

To improve the inference of bone lengths and surface marker positions we took advantage of the symmetric properties of an animal's body, i.e. for every left-sided limb there exists a corresponding limb on the right side. Furthermore, we also placed the surface markers onto the animal's fur, such that the marker-pattern itself was symmetrical, e.g. for a marker that was placed to a position close to the left hip joint there was a corresponding marker on the right side of the animal. By incorporating this knowledge into Algorithm 1 we reduced the number of free parameters, i.e. we only optimized the reduced bone lengths $l^* \in \mathbb{R}^{n_{\text{bone}}^*}$ and relative marker positions $v^* \in \mathbb{R}^{n_{\text{marker}}^* \times 3}$, where n_{bone}^* is the number of asymmetrical bones, i.e. bones along the head, spine and tail, plus the number of limb bones on the animal's left side and, equivalently, n_{marker}^* denotes the number of the asymmetrical and left-sided markers. The excluded right-sided limb bones were then enforced to have the same lengths as the corresponding limb bones on the left side. Additionally, we also applied this concept for the relative marker locations by mirroring the x-component of the left-sided markers at the yz-plane to obtain the relative marker locations of the markers on the right side. To implement this we defined Algorithm 2, which maps the reduced bone lengths l^* to the original parameter l .

Algorithm 2

```

1: function  $f_{l^* \rightarrow l}(l^*)$ 
2:    $c \leftarrow 1$                                      ▷ Initialize counter  $c$  for right-sided bones
3:   for  $i \in \{1, \dots, n_{\text{bone}}^*\}$  do
4:      $l_i \leftarrow l_i^*$                              ▷ Set asymmetric/left-sided bone length  $l_i$ 
5:     if  $i$  is left-sided bone then
6:        $l_{n_{\text{bone}}^*+c} \leftarrow l_i^*$                  ▷ Set right-sided bone length  $l_{n_{\text{bone}}^*+c}$ 
7:        $c \leftarrow c + 1$                              ▷ Increase counter  $c$  for right-sided bones
8:   return  $l$ 

```

Equivalently, we also defined the corresponding Algorithm 3, which maps the reduced relative marker positions v^* to their original counterpart v .

Algorithm 3

```

1: function  $f_{v^* \rightarrow v}(v^*)$ 
2:    $c \leftarrow 1$  ▷ Initialize counter  $c$  for right-sided markers
3:   for  $j \in \{1, \dots, n_{\text{marker}}^*\}$  do
4:      $v_j \leftarrow v_j^*$  ▷ Set asymmetric/left-sided rel. marker position  $v_j$ 
5:     if  $j$  is left-sided marker then ▷ Check if marker  $j$  is on the left side
6:        $v_{n_{\text{marker}}^*+c} \leftarrow (-v_{j1}^*, v_{j2}^*, v_{j3}^*)^T$  ▷ Set right-sided rel. marker position  $v_{n_{\text{marker}}^*+c}$ 
7:        $c \leftarrow c + 1$  ▷ Increase counter  $c$  for right-sided markers
8:   return  $v$ 

```

To learn the underlying three-dimensional skeleton model while also enforcing body symmetry, we then redefined $\hat{m}_{\tau ij}$ from equation 10 as follows:

$$\hat{m}_{\tau ij} = f_{3D \rightarrow 2D} \left(f_{\text{pose}}(t_{\tau}, r_{\tau}, f_{l^* \rightarrow l}(l^*), f_{v^* \rightarrow v}(v^*))_j, \tilde{r}_i, \tilde{t}_i, \tilde{k}_i, \tilde{A}_i \right) \quad (12)$$

and minimized equation 9 with respect to the parameters l^* and v^* instead of l and v .

4 Probabilistic pose estimation

4.1 Using a state space model to describe behavioral time series'

To allow for probabilistic pose reconstruction of entire behavioral sequences of length T , which ensures that poses of consecutive time points are similar to each other, we deploy a state space model, given by a transition and an emission equation

$$z_t = z_{t-1} + \epsilon_z \quad (13)$$

$$x_t = g(z_t) + \epsilon_x \quad (14)$$

where at time point $t \in \{1, \dots, T\}$ the state variable $z_t \in \mathbb{R}^{n_z}$ encodes the position of the animal as well as the bone rotations and the measurement variable $x_t \in \mathbb{R}^{n_x}$ represents the two-dimensional surface marker locations in all cameras given by a trained neural network. Thus, the state variable z_t contains the global translation vector t as well as the pose-encoding tensor r for time point t and the measurement variable x_t is a constant quantity given for all time points t . The function g , given by Algorithm 4, computes the noise-free measurements of the two-dimensional surface marker locations x_t^* given the state variable z_t . At this point the bone lengths l and relative marker locations v are already inferred and therefore given. The same applies to the Rodrigues vector \tilde{r}_i , the translation vector \tilde{t}_i , the distortion vector \tilde{k}_i and the camera matrix \tilde{A}_i of camera i , which we obtained from calibrating the multi-camera setup. The normalization constants c_t , c_r as well as c_1 and c_2 are the same as in Section 3.3. The probabilistic nature of the model is given by incorporating the two normally distributed random variables $\epsilon_z \sim \mathcal{N}(0, V_z)$ and $\epsilon_x \sim \mathcal{N}(0, V_x)$, simulating small pose changes over time and measurement noise, as well as the initial state $z_0 \sim \mathcal{N}(\mu_0, V_0)$, which is also assumed to be a normally distributed random variable. Thus, the state space model is entirely described by the model parameters $\Theta = \{\mu_0, V_0, V_z, V_x\}$. This allows for inferring a set of expected state variables $z = \{z_1, \dots, z_T\}$ given our measurements $x = \{x_1, \dots, x_T\}$ in case we have a good estimate for the model parameters Θ . Alternatively, we are also able to calculate a set of model parameters Θ , which, given an estimate for the state variables z , maximizes a lower bound of the model's evidence, i.e. the evidence lower bound (ELBO). The former is equivalent to the expectation step (E-step) of the expectation-maximization (EM) algorithm, which can be performed by applying the unscented Rauch-Tung-Striebel (RTS) smoother, whereas the latter is identical to the algorithm's maximization step (M-step), in which new model parameters are calculated in closed form to maximize the ELBO [8].

Algorithm 4

```

1: function  $g(z_t)$ 
2:    $t \leftarrow c_t(z_{t1}, z_{t2}, z_{t3})^T$                                 ▷ Obtain global translation  $t$ 
3:    $r_0 \leftarrow c_r(z_{t3}, z_{t4}, z_{t5})^T$                             ▷ Obtain global translation  $r_0$ 
4:   for  $i \in \{1, \dots, n_{\text{bone}}\}$  do
5:      $k \leftarrow 3(i + 1)$                                           ▷ Calculate correct index  $k$ 
6:      $r_i \leftarrow (z_{tk}, z_{tk+1}, z_{tk+2})^T$                     ▷ Obtain bone rotation  $r_i$ 
7:      $m_{3D} \leftarrow f_{\text{pose}}(t, r, l, v)$                           ▷ Obtain 3D marker locations given  $l$  and  $v$ 
8:     for  $i \in \{1, \dots, n_{\text{cam}}\}$  do
9:       for  $j \in \{1, \dots, n_{\text{marker}}\}$  do
10:         $k \leftarrow 2n_{\text{marker}}(i - 1) + j$                     ▷ Calculate correct index  $k$ 
11:         $m_{2D} \leftarrow f_{3D \rightarrow 2D}(m_{3Dj}, \tilde{r}_i, \tilde{t}_i, \tilde{k}_i, \tilde{A}_i)$   ▷ Obtain 2D marker locations given  $\tilde{r}$ ,  $\tilde{t}$ ,  $\tilde{k}$  and  $\tilde{A}$ 
12:         $x_{tk}^* \leftarrow \frac{m_{2D1} - 1}{c_1}$                             ▷ Normalize x-coordinates
13:         $x_{tk+n_{\text{marker}}}^* \leftarrow \frac{m_{2D2} - 1}{c_2}$           ▷ Normalize y-coordinates
14:   return  $x_t^*$ 

```

4.2 Theory of the expectation-maximization algorithm

While the EM algorithm was first introduced by Dempster et al. [5], we follow the concepts and notations stated by Bishop [1] and Murphy [9]. To derive a formulation of the ELBO we first note that the model's joint distribution $p(x, z)$ is equal to the product of the model's likelihood $p(x|z)$ and prior $p(z)$:

$$p(x, z) = p(x|z)p(z). \quad (15)$$

Additionally, we also note that the mutual dependency of the model's marginal likelihood $p(x)$, posterior $p(z|x)$, likelihood $p(x|z)$ and prior $p(z)$ is given by Bayes' theorem:

$$p(z|x)p(x) = p(x|z)p(z). \quad (16)$$

We now define an arbitrary probability density function $q(z)$ over our state variables z , for which we know the following statement is true by definition:

$$\int q(z) dz = 1. \quad (17)$$

Multiplying equation 17 with an arbitrary constant c yields:

$$c \int q(z) dz = \int c q(z) dz = c. \quad (18)$$

We can now replace the constant c with a function independent from the state variables z without loss of generality. If we choose this function to be the model's marginal log-likelihood $\ln p(x)$, we obtain:

$$\int q(z) \ln p(x) dz = \ln p(x) \quad (19)$$

and note that, due to equation 17 and 18 respectively, the marginal log-likelihood $\ln p(x)$ is actually independent of the probability density function $q(z)$. Next, we can use equation 15 and 16 to derive a relationship between the marginal log-likelihood $\ln p(x)$, the Kullback–Leibler (KL) divergence

$$\ln p(x) = \int q(z) \ln p(x) dz \quad (20)$$

$$= \int q(z) \ln \frac{p(z|x) p(x)}{p(z|x)} dz \quad (21)$$

$$= \int q(z) \ln \frac{p(x|z) p(z)}{p(z|x)} dz \quad (22)$$

$$= \int q(z) \ln \frac{p(x, z)}{p(z|x)} dz \quad (23)$$

$$= \int q(z) \ln \frac{p(x, z) q(z)}{p(z|x) q(z)} dz \quad (24)$$

$$= \int q(z) \left(\ln \frac{p(x, z)}{q(z)} - \ln \frac{p(z|x)}{q(z)} \right) dz \quad (25)$$

$$= \int q(z) \ln \frac{p(x, z)}{q(z)} dz - \int q(z) \ln \frac{p(z|x)}{q(z)} dz \quad (26)$$

$$= \mathcal{L} + \text{KL}(q||p) \quad (27)$$

with $\mathcal{L} = \int q(z) \ln \frac{p(x, z)}{q(z)} dz$ and $\text{KL}(q||p) = - \int q(z) \ln \frac{p(z|x)}{q(z)} dz$. The KL divergence is a distance measure between the probability density functions q and p and as such always larger or equal to zero:

$$\text{KL}(q||p) \geq 0 \quad (28)$$

with equality $\text{KL}(q||p) = 0$ if $q = p$. When we add the ELBO \mathcal{L} to equation 28 and combine the result with the derived definition of $\ln p(x)$, it becomes clear that the ELBO \mathcal{L} is a lower bound of the marginal log-likelihood:

$$\ln p(x) = \mathcal{L} + \text{KL}(q||p) \geq \mathcal{L}. \quad (29)$$

If we now acknowledge that we also require the model parameters Θ to compute the above quantities, i.e.

$$\ln p(x|\Theta) = \mathcal{L}(q, \Theta) + \text{KL}(q||p) \quad (30)$$

$$= \int q(z) \ln \frac{p(x, z|\Theta)}{q(z)} dz - \int q(z) \ln \frac{p(z|x, \Theta)}{q(z)} dz \quad (31)$$

$$= \left(\int q(z) \ln p(x|\Theta) dz + \int q(z) \ln \frac{p(z|x, \Theta)}{q(z)} dz \right) - \int q(z) \ln \frac{p(z|x, \Theta)}{q(z)} dz \quad (32)$$

$$\geq \mathcal{L}(q, \Theta) \quad (33)$$

$$= \int q(z) \ln p(x|\Theta) dz - \text{KL}(q||p), \quad (34)$$

we can start building an understanding for how the EM algorithm works. In the E-step we are holding Θ constant and maximize $\mathcal{L}(q, \Theta)$ with respect to q , i.e. given a current estimate for the model parameters Θ_k we infer the probability density functions of our state variables $p(z|x, \Theta_k)$, such that $q(z) = p(z|x, \Theta_k)$, making the KL divergence $\text{KL}(q||p)$ become zero, i.e. $\text{KL}(q||p) = \text{KL}(p||p) = 0$, and the marginal log-likelihood $\ln p(x|\Theta_k)$ become equal to the ELBO $\mathcal{L}(q, \Theta)$. Here, setting $q(z) = p(z|x, \Theta_k)$ maximizes the ELBO $\mathcal{L}(q, \Theta)$ due to the equality given by equation 34 and the previously mentioned fact that the marginal log-likelihood $\ln p(x)$ is actually independent of the probability density function $q(z)$. Subsequently, in the M-step we are holding q constant and maximize $\mathcal{L}(q, \Theta)$ with respect to Θ in order to obtain a new set of model parameters Θ_{k+1} , leading to an increased marginal log-likelihood $\ln p(x|\Theta_{k+1})$, as the KL divergence becomes greater than zero again, i.e. $\text{KL}(q||p) \geq 0$

$$\ln p(x|\Theta) \geq \mathcal{L}(q, \Theta) \quad (35)$$

$$= \int p(z|x, \Theta_k) \ln \frac{p(x, z|\Theta)}{p(z|x, \Theta_k)} dz \quad (36)$$

$$= \int p(z|x, \Theta_k) \ln p(x, z|\Theta) dz - \int p(z|x, \Theta_k) \ln p(z|x, \Theta_k) dz \quad (37)$$

$$= \mathcal{Q}(\Theta, \Theta_k) - \int p(z|x, \Theta_k) \ln p(z|x, \Theta_k) dz \quad (38)$$

with $\mathcal{Q}(\Theta, \Theta_k) = \int p(z|x, \Theta_k) \ln p(x, z|\Theta) dz$. We note that the latter term is independent of Θ and can be omitted since our goal is to optimize the ELBO $\mathcal{L}(q, \Theta)$ with respect to Θ . Therefore, instead of maximizing the ELBO $\mathcal{L}(q, \Theta)$ directly, we can just maximize the function $\mathcal{Q}(\Theta, \Theta_k)$. We furthermore notice that $\mathcal{Q}(\Theta, \Theta_k)$ has the form of an expectation value, i.e. we can obtain $\mathcal{Q}(\Theta, \Theta_k)$ by taking the expectation of $\ln p(x, z|\Theta)$ with respect to z :

$$\mathcal{Q}(\Theta, \Theta_k) = \mathbb{E}[\ln p(x, z|\Theta)] \quad (39)$$

where $\mathbb{E}[\ln p(x, z|\Theta)]$ is conditioned on x and Θ_k , i.e. both quantities are given. With this we finally arrive at the essence of what is done during the M-step, i.e. maximizing $\mathcal{Q}(\Theta, \Theta_k)$ with respect to Θ to obtain new model parameters Θ_{k+1} :

$$\Theta_{k+1} = \arg \max_{\Theta} \mathcal{Q}(\Theta, \Theta_k) \quad (40)$$

4.3 The unscented transformation

We are required to approximate expectation values to perform the E-step, i.e. when applying the unscented Kalman filter and the unscented Kalman smoother (Algorithm 7 and 9), as well as the M-step, i.e. when maximizing $\mathcal{Q}(\Theta, \Theta_k)$ (equation 39), as we can not compute them analytically [8]. These expectation values are of the form:

$$\mathbb{E}[h(y)] = \int p(y) h(y) dy \quad (41)$$

where h is an arbitrary function and $y \in \mathbb{R}^d$ an arbitrary normally distributed random variable, i.e. $y \sim \mathcal{N}(m, \Sigma)$. We can obtain such approximations using the unscented transformation f_{ut} , which was first introduced by Julier et al. [7] and is defined in Algorithm 5. Given the mean m and the covariance Σ , the unscented transformation f_{ut} generates so called sigma points $\mathcal{Y} \in \mathbb{R}^{2d+1 \times d}$, whose locations are systematically spread around the mean m based on the covariance Σ :

Algorithm 5

```

1: function  $f_{\text{ut}}(m, \Sigma)$ 
2:    $L \leftarrow f_{\text{cholesky}}(\Sigma)$ 
3:    $\mathcal{Y}_1 \leftarrow m$ 
4:   for  $i \in \{2, \dots, d+1\}$  do
5:      $\mathcal{Y}_i \leftarrow m + \sqrt{d+\lambda} L^T_i$ 
6:   for  $i \in \{d+2, \dots, 2d+1\}$  do
7:      $\mathcal{Y}_i \leftarrow m - \sqrt{d+\lambda} L^T_i$ 
8:   return  $\mathcal{Y}$ 

```

Here $f_{\text{cholesky}}(\Sigma)$ denotes the Cholesky decomposition of matrix Σ , which computes a lower triangular matrix L such that $LL^T = \Sigma$, and λ can be calculated as follows:

$$\lambda = \alpha^2 (d + \kappa) - d \quad (42)$$

where we set the parameters $\alpha = 1$ and $\kappa = 0$ such that $\alpha = 1$. Using the sigma points \mathcal{Y} , we can approximate $\mathbb{E}[h(y)]$ as follows:

$$\mathbb{E}[h(y)] \approx \sum_{i=1}^{2d+1} w_i h(\mathcal{Y}_i) = \sum_{i=1}^{2d+1} w_i h(f_{\text{ut}}(m, \Sigma)_i) \quad (43)$$

with the weights w :

$$w_1 = \frac{\lambda}{d + \lambda} \quad (44)$$

$$w_i = \frac{1}{2(d + \lambda)} \forall i \in \{2, \dots, 2d + 1\}. \quad (45)$$

which due to our choice of α and κ simplifies to:

$$w_1 = 0 \quad (46)$$

$$w_i = \frac{1}{2d} \forall i \in \{2, \dots, 2d + 1\}. \quad (47)$$

4.4 Expectation step

In the E-step we need to infer the probability density function of the latent variable z_t for all time points t of a behavioral sequence, given the set of all measurements x and the model parameters Θ , noted as $p(z_t|x, \Theta)$. Since all random variables of the model are assumed to be normally distributed, this property is maintained for the latent variable z_t as well. Therefore, z_t is drawn from a normal distribution with mean μ_t and covariance V_t , i.e. $z_t \sim \mathcal{N}(\mu_t, V_t)$. By using all measurements x of the sequence for the inference of $p(z_t|x, \Theta)$ at time point t , information of the past as well as of the future is processed, which is what the unscented RTS smoother is used for. However, to derive the equations of the smoother we first need to focus on the inference when only information of the past is available, i.e. we want to infer $p(z_t|x_1, \dots, x_t, \Theta)$ where only measurements until time point t are given, which can be achieved by utilizing the unscented Kalman filter. To avoid confusions, we denote mean values and covariance matrices obtained from the unscented Kalman smoother as $\tilde{\mu}_t$ and \tilde{V}_t , whereas those calculated via the unscented RTS smoother are denoted as $\hat{\mu}_t$ and \hat{V}_t .

4.4.1 The unscented Kalman filter

The unscented Kalman filter is an iterative algorithm, which calculates the filtered values for the mean $\tilde{\mu}_t$ and covariance \tilde{V}_t at a time point t , based on the filter output for these values $\tilde{\mu}_{t-1}$ and \tilde{V}_{t-1} at the previous time point $t - 1$ as well as the measurement variable x_t for time point t . The inference scheme for obtaining $p(z_t|x_1, \dots, x_{t-1}, \Theta)$ is given by Algorithm 6 and 7 [11, 12]:

Algorithm 6

```

1: function  $f_{ukf_0}(\tilde{\mu}_{t-1}, \tilde{V}_{t-1}, V_z, V_x)$ 
2:    $\mathcal{Z} \leftarrow f_{ut}(\tilde{\mu}_{t-1}, \tilde{V}_{t-1})$  ▷ Form sigma points  $\mathcal{Z}$ 
3:    $\bar{z} \leftarrow \sum_{i=1}^{2n_z+1} w_i \mathcal{Z}_i$  ▷ Compute predicted mean  $\bar{z}$ 
4:    $P \leftarrow V_z + \sum_{i=1}^{2n_z+1} w_i (\mathcal{Z}_i - \bar{z})(\mathcal{Z}_i - \bar{z})^T$  ▷ Compute predicted covariance  $P$ 
5:    $\mathcal{Z} \leftarrow f_{ut}(\bar{z}, P)$  ▷ Form sigma points  $\mathcal{Z}$ 
6:    $\mathcal{X} \leftarrow g(\mathcal{Z})$  ▷ Propagate sigma points through emission function  $g$ 
7:    $\bar{x} \leftarrow \sum_{i=1}^{2n_z+1} w_i \mathcal{X}_i$  ▷ Compute predicted mean  $\bar{x}$ 
8:    $S \leftarrow V_x + \sum_{i=1}^{2n_z+1} w_i (\mathcal{X}_i - \bar{x})(\mathcal{X}_i - \bar{x})^T$  ▷ Compute predicted covariance  $S$ 
9:   for  $i \in \{1, \dots, n_x\}$  do
10:    if  $x_{t_i}$  is missing measurement then
11:      for  $j \in \{1, \dots, n_x\}$  do
12:         $S_{ij} \leftarrow 0$  ▷ Set rows of missing measurements to 0
13:         $S_{ji} \leftarrow 0$  ▷ Set columns of missing measurements to 0
14:         $S_{ii} \leftarrow 1$  ▷ Set diagonal entries to 1 to allow computing  $S^{-1}$ 
15:       $C \leftarrow \sum_{i=1}^{2n_z+1} w_i (\mathcal{Z}_i - \bar{z})(\mathcal{X}_i - \bar{x})^T$  ▷ Compute cross-covariance  $C$ 
16:      for  $i \in \{1, \dots, n_x\}$  do
17:        if  $x_{t_i}$  is missing measurement then
18:          for  $j \in \{1, \dots, n_z\}$  do
19:             $C_{ji} \leftarrow 0$  ▷ Set columns of missing measurements to 0
20:           $K \leftarrow CS^{-1}$  ▷ Compute filter gain  $K$ 
21:           $\bar{x} \leftarrow x_t - \bar{x}$ 
22:          for  $i \in \{1, \dots, n_x\}$  do
23:            if  $x_{t_i}$  is missing measurement then
24:               $\bar{x}_i \leftarrow 0$  ▷ Set entries of missing measurements to 0
25:             $\tilde{\mu}_t \leftarrow \bar{z} + K\bar{x}$  ▷ Compute filtered mean  $\tilde{\mu}_t$ 
26:             $\tilde{V}_t \leftarrow P - KC^T$  ▷ Compute filtered covariance  $\tilde{V}_t$ 
27:   return  $\tilde{\mu}_t, \tilde{V}_t$ 

```

To obtain values for filtered means $\tilde{\mu} = \{\tilde{\mu}_0, \dots, \tilde{\mu}_T\}$ and covariances $\tilde{V} = \{\tilde{V}_0, \dots, \tilde{V}_T\}$ for all time points one needs to iterate through the entire behavioral sequence:

Algorithm 7

```

1: function  $f_{ukf}(\mu_0, V_0, V_z, V_x)$ 
2:    $\tilde{\mu}_0 \leftarrow \mu_0$ 
3:    $\tilde{V}_0 \leftarrow V_0$ 
4:   for  $t \in \{1, \dots, T\}$  do
5:      $\tilde{\mu}_t, \tilde{V}_t \leftarrow f_{ukf_0}(\tilde{\mu}_{t-1}, \tilde{V}_{t-1}, V_z, V_x)$ 
6:   return  $\tilde{\mu}, \tilde{V}$ 

```

4.4.2 The unscented RTS smoother

The unscented RTS smoother is also an iterative algorithm, which calculates the smoothed values for the mean $\hat{\mu}_t$ and covariance \hat{V}_t at a time point t , based on the smoother output for these values $\hat{\mu}_{t+1}$ and \hat{V}_{t+1} at the next time point $t+1$ as well as the corresponding output from the unscented Kalman filter $\tilde{\mu}_t$ and \tilde{V}_t for time point t . The inference scheme for obtaining $p(z_t|x, \Theta)$ is given by Algorithm 8 and 9 [12]:

Algorithm 8

```

1: function  $f_{uks0}(\tilde{\mu}_t, \tilde{V}_t, \hat{\mu}_{t+1}, \hat{V}_{t+1}, V_z)$ 
2:    $\mathcal{Z} \leftarrow f_{ut}(\tilde{\mu}_t, \tilde{V}_t)$  ▷ Form sigma points  $\mathcal{Z}$  (1)
3:    $\bar{z} \leftarrow \sum_{i=1}^{2n_z+1} w_i \mathcal{Z}_i$  ▷ Compute predicted mean  $\bar{z}$  (3.1)
4:    $P \leftarrow V_z + \sum_{i=1}^{2n_z+1} w_i (\mathcal{Z}_i - \bar{z})(\mathcal{Z}_i - \bar{z})^T$  ▷ Compute predicted covariance  $P$  (3.2)
5:    $D \leftarrow \sum_{i=1}^{2n_z+1} w_i (\mathcal{Z}_i - \tilde{\mu}_t)(\mathcal{Z}_i - \bar{z})^T$  ▷ Compute cross-covariance  $D$  (3.3)
6:    $G_t \leftarrow DP^{-1}$  ▷ Compute smoother gain  $G_t$  (4.1)
7:    $\hat{\mu}_t \leftarrow \tilde{\mu}_t + G_t(\hat{\mu}_{t+1} - \bar{z})$  ▷ Compute smoothed mean  $\hat{\mu}_t$  (4.2)
8:    $\hat{V}_t \leftarrow \tilde{V}_t + (G_t \hat{V}_{t+1} - D) G_t^T$  ▷ Compute smoothed covariance  $\hat{V}_t$  (4.3)
9:   return  $\hat{\mu}_t, \hat{V}_t, G_t$ 

```

To obtain values of the smoothed means $\hat{\mu} = \{\hat{\mu}_0, \dots, \hat{\mu}_T\}$ and covariances $\hat{V} = \{\hat{V}_0, \dots, \hat{V}_T\}$ for all time points one needs to run the forward filtering path and then iterate backwards through the entire behavioral sequence:

Algorithm 9

```

1: function  $f_{uks}(\mu_0, V_0, V_z, V_x)$ 
2:    $\tilde{\mu}, \tilde{V} \leftarrow f_{ukf}(\mu_0, V_0, V_z, V_x)$ 
3:    $\hat{\mu}_T \leftarrow \tilde{\mu}_T$ 
4:    $\hat{V}_T \leftarrow \tilde{V}_T$ 
5:   for  $t \in \{T-1, \dots, 0\}$  do
6:      $\hat{\mu}_t, \hat{V}_t, G_t \leftarrow f_{uks0}(\tilde{\mu}_t, \tilde{V}_t, \mu_{t+1}, V_{t+1}, V_z)$ 
7:   return  $\hat{\mu}, \hat{V}, G$ 

```

Here, the set of all smoother gains $G = \{G_0, \dots, G_{T-1}\}$ is needed for performing the M-step later on.

4.4.3 Enforcing anatomical constraints

The plain formulation of the unscented RTS smoother does not allow constraining the state variables. However, in order to enforce joint angle limits we need to ensure that Rodrigues vectors encoding bone rotations stay within specified limits. Therefore, we introduce a mapping function $f_{z^* \rightarrow z}$, which allows for mapping a redefined state variable $z_t^* \in \mathbb{R}^{n_z}$ onto the original one $z_t \in \mathbb{R}^{n_z}$, while enforcing that entries of z_t corresponding to bone rotations stay within their respective lower and upper bounds. The respective mapping function $f_{z^* \rightarrow z}$ is given by Algorithm 10.

Algorithm 10

```

1: function  $f_{z^* \rightarrow z}(z_t^*)$ 
2:    $t^* \leftarrow (z_{t^*1}^*, z_{t^*2}^*, z_{t^*3}^*)^T$  ▷ Obtain normalized global translation  $t^*$ 
3:    $r_0^* \leftarrow (z_{t^*4}^*, z_{t^*5}^*)^T$  ▷ Obtain normalized global rotation  $r_0^*$ 
4:   for  $i \in \{1, \dots, n_{\text{bone}}\}$  do
5:      $k \leftarrow 3(i+1)$  ▷ Calculate correct index  $k$ 
6:      $r_i^* \leftarrow (z_{t^*k}^*, z_{t^*k+1}^*, z_{t^*k+2}^*)^T$  ▷ Obtain normalized bone rotation  $r_i^*$ 
7:     for  $j \in \{1, \dots, 3\}$  do
8:        $n \leftarrow \text{erf}\left(\frac{\sqrt{\pi}}{2} r_{i^*j}^*\right)$  ▷ Map  $r_{i^*j}^* \in (-\text{inf}, \text{inf})$  to  $n \in (-1, 1)$ 
9:        $r_{ij} \leftarrow b_{0ij} + \frac{1}{2}(b_{1ij} - b_{0ij})(1+n)$  ▷ Compute  $r_{ij} \in (b_{0ij}, b_{1ij})$ 
10:     $z_t \leftarrow (t^*, r_0^*, r_1, \dots, r_{n_{\text{bone}}})^T$  ▷ Obtain  $z_t$  via concatenation
11:   return  $z_t$ 

```

Here, $\theta_{i,0}$ and $\theta_{i,1}$ denote the lower and upper bound corresponding to entry i of the Rodrigues vector r_i , which encodes the rotation of bone i , and erf is a sigmoidal function, i.e. the error function given by:

$$\text{erf}(y) = \frac{2}{\sqrt{\pi}} \int_0^y \exp(-t^2) dt \quad (48)$$

for $y \in \mathbb{R}$. In order to enforce joint angle limits we just replace the original transmission and emission equation in our state space model given by equations 13 and 14 with:

$$z_t^* = z_{t-1}^* + \epsilon_z \quad (49)$$

$$x_t = g(f_{z^* \rightarrow z}(z_t^*)) + \epsilon_x. \quad (50)$$

In the following we always refer to the state space model given by equations 49 and 50 and therefore also to the redefined state variables z^* but we drop $*$ in the notation.

4.5 Maximization step

In the M-step we find a new set of model parameters Θ_{k+1} by maximizing the ELBO \mathcal{L} , given the smoothed means $\hat{\mu}$ and covariances \hat{V} as well as the smoother gains G , which we obtained in the E-step using a current estimate of the model parameters Θ_k .

4.5.1 Obtaining new model parameters by maximizing the evidence lower bound

We can take advantage of the specific structure of the state space model when maximizing the ELBO \mathcal{L} [8]. In the state space model the state variables fulfill the Markov property, i.e. each state variable z_t only depends on the previous one z_{t-1} . Based on this we can compute the model's joint distribution:

$$p(x, z) = p(z_0) \prod_{t=1}^T p(z_t | z_{t-1}) p(x_t | z_t). \quad (51)$$

When we now take the logarithm of the joint distribution and acknowledge that the model parameters Θ are also required for computing the joint distribution we obtain:

$$\ln p(x, z | \Theta) = \ln p(z_0 | \mu_0, V_0) + \sum_{t=1}^T \ln p(z_t | z_{t-1}, V_z) + \sum_{t=1}^T \ln p(x_t | z_t, V_x). \quad (52)$$

However, to maximize $\mathcal{Q}(\Theta, \Theta_k)$ we actually need to consider the expectation value of $\ln p(x, z | \Theta)$:

$$\mathcal{Q}(\Theta, \Theta_k) = \mathbb{E}[\ln p(x, z | \Theta)] \quad (53)$$

$$= \mathbb{E}[\ln p(z_0 | \mu_0, V_0)] + \sum_{t=1}^T \mathbb{E}[\ln p(z_t | z_{t-1}, V_z)] + \sum_{t=1}^T \mathbb{E}[\ln p(x_t | z_t, V_x)] \quad (54)$$

$$= I_0 + I_z + I_x \quad (55)$$

with $I_0 = \mathbb{E}[\ln p(z_0 | \mu_0, V_0)]$, $I_z = \sum_{t=1}^T \mathbb{E}[\ln p(z_t | z_{t-1}, V_z)]$ and $I_x = \sum_{t=1}^T \mathbb{E}[\ln p(x_t | z_t, V_x)]$. If we now acknowledge that all random variables in our state space model are normally distributed, i.e. $z_t \sim \mathcal{N}(\hat{\mu}_t, \hat{V}_t)$, it becomes clear that computing $\mathcal{Q}(\Theta, \Theta_k)$ only involves evaluating the expectation values of log-transformed normal distributions (see Appendix A). Consequently, we can obtain simplified terms for the individual components I_0 , I_z and I_x of $\mathcal{Q}(\Theta, \Theta_k)$ using the smoothed means $\hat{\mu}$ and covariances \hat{V} as well as the smoother gains G . For I_0 we get:

$$I_0 = -\frac{1}{2} \ln \det(2\pi V_0) - \frac{1}{2} \text{tr} \left(V_0^{-1} \mathbb{E} \left[(z_0 - \mu_0)(z_0 - \mu_0)^T \right] \right) \quad (56)$$

$$= -\frac{1}{2} \ln \det(2\pi V_0) - \frac{1}{2} \text{tr} \left(V_0^{-1} \left(\hat{V}_0 + (\hat{\mu}_0 - \mu_0)(\hat{\mu}_0 - \mu_0)^T \right) \right). \quad (57)$$

bioRxiv preprint doi: <https://doi.org/10.1101/2021.11.03.466906>; this version posted November 4, 2021. To obtain a simplified expression for I_z , we need to form pairwise sigma points \mathcal{P}_t as there are always two random variables involved simultaneously, $z_t \sim \mathcal{N}(\hat{\mu}_t, \hat{V}_t)$ and $z_{t-1} \sim \mathcal{N}(\hat{\mu}_{t-1}, \hat{V}_{t-1})$, when evaluating the expectation values of the underlying log-transformed normal distributions in I_z . For each of the T transition steps we generate the pairwise mean vector $\check{\mu}_t \in \mathbb{R}^{2n_z}$:

$$\check{\mu}_t = \begin{pmatrix} \hat{\mu}_t \\ \hat{\mu}_{t-1} \end{pmatrix} \quad (58)$$

as well as the pairwise covariance matrix $\check{V}_t \in \mathbb{R}^{2n_z \times 2n_z}$:

$$\check{V}_t = \begin{pmatrix} \hat{V}_t & \hat{V}_t G_{t-1}^T \\ G_{t-1} \hat{V}_t & \hat{V}_{t-1} \end{pmatrix} \quad (59)$$

and calculate the pairwise sigma points \mathcal{P}_t as follows:

$$\mathcal{P}_t = \begin{pmatrix} \mathcal{B}_t \\ \mathcal{A}_t \end{pmatrix} = f_{\text{ut}}(\check{\mu}_t, \check{V}_t) \quad (60)$$

where concatenating the incomplete pairwise sigma points $\mathcal{B}_t \in \mathbb{R}^{4n_z+1 \times n_z}$ and $\mathcal{A}_t \in \mathbb{R}^{4n_z+1 \times n_z}$ gives $\mathcal{P}_t \in \mathbb{R}^{4n_z+1 \times 2n_z}$. Consequently, the weights \check{w} associated with the pairwise sigma points \mathcal{P}_t are then given in accordance with the concepts discussed in Section 4.3:

$$\check{w}_1 = 0 \quad (61)$$

$$\check{w}_i = \frac{1}{4n_z} \forall i \in \{2, \dots, 4n_z + 1\} \quad (62)$$

A simplified term for I_z is then given by:

$$I_z = -\frac{T}{2} \ln \det(2\pi V_z) - \frac{1}{2} \sum_{t=1}^T \text{tr} \left(V_z^{-1} \mathbb{E} \left[(z_t - z_{t-1})(z_t - z_{t-1})^T \right] \right) \quad (63)$$

$$= -\frac{T}{2} \ln \det(2\pi V_z) - \frac{T}{2} \text{tr} \left(V_z^{-1} \left(\frac{1}{T} \sum_{t=1}^T \mathbb{E} \left[(z_t - z_{t-1})(z_t - z_{t-1})^T \right] \right) \right) \quad (64)$$

$$\approx -\frac{T}{2} \ln \det(2\pi V_z) - \frac{T}{2} \sum_{t=1}^T \text{tr} \left(V_z^{-1} \left(\frac{1}{T} \sum_{i=1}^{4n_z+1} \check{w}_i (\mathcal{B}_{ti} - \mathcal{A}_{ti})(\mathcal{B}_{ti} - \mathcal{A}_{ti})^T \right) \right). \quad (65)$$

To evaluate the expectation value in I_x it is sufficient to just use the normal sigma points $\mathcal{Z}_t = f_{\text{ut}}(\hat{\mu}_t, \hat{V}_t)$ and propagate them through our emission function g :

$$I_x = -\frac{T}{2} \ln \det(2\pi V_x) - \frac{1}{2} \sum_{t=1}^T \text{tr} \left(V_x^{-1} \mathbb{E} \left[(x_t - g(z_t))(x_t - g(z_t))^T \right] \right) \quad (66)$$

$$= -\frac{T}{2} \ln \det(2\pi V_x) - \frac{T}{2} \text{tr} \left(V_x^{-1} \left(\frac{1}{T} \sum_{t=1}^T \mathbb{E} \left[(x_t - g(z_t))(x_t - g(z_t))^T \right] \right) \right) \quad (67)$$

$$\approx -\frac{T}{2} \ln \det(2\pi V_x) - \frac{T}{2} \sum_{t=1}^T \text{tr} \left(V_x^{-1} \left(\frac{1}{T} \sum_{i=1}^{2n_z+1} w_i (x_t - g(\mathcal{Z}_{ti}))(x_t - g(\mathcal{Z}_{ti}))^T \right) \right). \quad (68)$$

To finally obtain new model parameters $\Theta_{k+1} = \{\mu_{0,k+1}, V_{0,k+1}, V_{z,k+1}, V_{x,k+1}\}$ we still need to differentiate $\mathcal{Q}(\Theta, \Theta_k)$ with respect to μ_0, V_0, V_z and V_x , set the resulting derivatives to zero and solve them

$$\frac{d}{d\mu_0} \mathcal{Q}(\Theta, \Theta_k) = \frac{d}{d\mu_0} I_0 \quad (69)$$

$$= V_0^{-1} (\hat{\mu}_0 - \mu_0) \quad (70)$$

$$\frac{d}{dV_0} \mathcal{Q}(\Theta, \Theta_k) = \frac{d}{dV_0} I_0 \quad (71)$$

$$= -\frac{1}{2} V_0^{-1} + \frac{1}{2} V_0^{-1} \left(\hat{V}_0 + (\hat{\mu}_0 - \mu_0) (\hat{\mu}_0 - \mu_0)^T \right) V_0^{-1} \quad (72)$$

$$\frac{d}{dV_z} \mathcal{Q}(\Theta, \Theta_k) = \frac{d}{dV_z} I_z \quad (73)$$

$$= -\frac{T}{2} V_z^{-1} + \frac{T}{2} \sum_{t=1}^T V_z^{-1} \left(\frac{1}{T} \sum_{i=1}^{4n_z+1} \check{w}_i (\mathcal{B}_{ti} - \mathcal{A}_{ti}) (\mathcal{B}_{ti} - \mathcal{A}_{ti})^T \right) V_z^{-1} \quad (74)$$

$$\frac{d}{dV_x} \mathcal{Q}(\Theta, \Theta_k) = \frac{d}{dV_x} I_x \quad (75)$$

$$= -\frac{T}{2} V_x^{-1} + \frac{T}{2} \sum_{t=1}^T V_x^{-1} \left(\frac{1}{T} \sum_{i=1}^{2n_z+1} w_i (x_t - g(\mathcal{Z}_{ti})) (x_t - g(\mathcal{Z}_{ti}))^T \right) V_x^{-1}. \quad (76)$$

Setting these derivatives to zero and solving for μ_0 , V_0 , V_z and V_x yields the following:

$$\mu_0 = \hat{\mu}_0 \quad (77)$$

$$V_0 = \hat{V}_0 + (\hat{\mu}_0 - \mu_0) (\hat{\mu}_0 - \mu_0)^T \quad (78)$$

$$V_z = \frac{1}{T} \sum_{t=1}^T \sum_{i=1}^{4n_z+1} \check{w}_i (\mathcal{B}_{ti} - \mathcal{A}_{ti}) (\mathcal{B}_{ti} - \mathcal{A}_{ti})^T \quad (79)$$

$$V_x = \frac{1}{T} \sum_{t=1}^T \sum_{i=1}^{2n_z+1} w_i (x_t - g(\mathcal{Z}_{ti})) (x_t - g(\mathcal{Z}_{ti}))^T. \quad (80)$$

The resulting values for $\mu_{0,k+1}$, $V_{z,k+1}$ and $V_{x,k+1}$ are then given by equations 77, 79 and 80. To obtain $V_{0,k+1}$ we need to substitute $\mu_{0,k+1}$ into equation 78, giving $V_{0,k+1} = \hat{V}_0$. Lastly, we still need to adjust the solution for $V_{x,k+1}$ to also account for missing measurements. Besides that, we note that it is sufficient to only compute the diagonal entries of $V_{x,k+1}$, since we enforce the covariance matrix of the measurement noise V_x to be a diagonal matrix. Thus, the final solution for a diagonal entry $j \in \{1, \dots, n_x\}$ of $V_{x,k+1}$ is given by:

$$\text{diag}(V_{x,k+1})_j = \frac{1}{T_j} \sum_{t=1}^T \delta_{tj} \sum_{i=1}^{2n_z+1} w_i (x_{tj} - g(\mathcal{Z}_{ti})_j)^2 \quad (81)$$

where the function diag gives the diagonal entries of the input matrix, δ_{tj} indicates if at time point t the entry j of x_t is associated with a missing measurement, i.e. $\delta_{tj} = 0$, or not, i.e. $\delta_{tj} = 1$, and T_j is the total number of successful measurements for entry j in the entire behavioral sequence, i.e. $T_j = \sum_{t=1}^T \delta_{tj}$.

4.6 Convergence of the expectation-maximization algorithm

We calculate the changes in the model parameters Θ in each iteration k of the EM algorithm to check for convergence [1]. Particularly, we are computing the vectors $\Delta\mu_0 \in \mathbb{R}^{n_z}$, $\Delta \text{diag}(V_0) \in \mathbb{R}^{n_z}$, $\Delta \text{diag}(V_z) \in \mathbb{R}^{n_z}$ and $\Delta \text{diag}(V_x) \in \mathbb{R}^{n_x}$, which contain the relative changes of μ_0 , V_0 , V_z and V_x at

$$\Delta\mu_{0i} = \text{abs} \left(\frac{\mu_{0,k_i} - \mu_{0,k-1_i}}{\mu_{0,k-1_i}} \right) \quad \forall i \in \{1, \dots, n_z\} \quad (82)$$

$$\Delta \text{diag} (V_0)_i = \text{abs} \left(\frac{V_{0,k_{ii}} - V_{0,k-1_{ii}}}{V_{0,k-1_{ii}}} \right) \quad \forall i \in \{1, \dots, n_z\} \quad (83)$$

$$\Delta \text{diag} (V_z)_i = \text{abs} \left(\frac{V_{z,k_{ii}} - V_{z,k-1_{ii}}}{V_{z,k-1_{ii}}} \right) \quad \forall i \in \{1, \dots, n_z\} \quad (84)$$

$$\Delta \text{diag} (V_x)_i = \text{abs} \left(\frac{V_{x,k_{ii}} - V_{x,k-1_{ii}}}{V_{x,k-1_{ii}}} \right) \quad \forall i \in \{1, \dots, n_x\} \quad (85)$$

where `abs` is a function returning the absolute value of its input argument and $\mu_{0,k}$, $V_{0,k}$, $V_{z,k}$ and $V_{x,k}$ are the model parameters at iteration k whereas $\mu_{0,k-1}$, $V_{0,k-1}$, $V_{z,k-1}$ and $V_{x,k-1}$ are those at iteration $k-1$. We only focus on the diagonal entries of the covariances V_0 and V_z since a fraction of their off-diagonal entries is expected to be zero. Using these relative changes we construct a vector $\Delta v \in \mathbb{R}^{3n_z+n_x}$ containing all relative changes via concatenation:

$$\Delta v = (\Delta\mu_0, \Delta \text{diag} (V_0), \Delta \text{diag} (V_z), \Delta \text{diag} (V_x))^T \quad (86)$$

and assume convergence is reached when the mean $\Delta\bar{v}$ of Δv falls below a threshold ϵ_{tol} :

$$\Delta\bar{v} = \frac{1}{3n_z + n_x} \sum_{i=1}^{3n_z+n_x} \Delta v_i < \epsilon_{\text{tol}} \quad (87)$$

where we set $\epsilon_{\text{tol}} = 0.05$.

4.7 Implementation of the expectation-maximization algorithm

We initialize the mean of the state variables μ_0 by minimizing the objective function given by equation 9 but keep the bone lengths l and the surface marker positions v constant and set $n_{\text{time}} = 1$, i.e. we only include a single time point in the optimization, which is identical to the first time point of a respective behavioral sequence. The covariances V_0 , V_x and V_z are initialized as matrices whose diagonal elements all equal 0.001 and off-diagonal entries are set to zero. To learn new model parameters μ_0 , V_0 , V_x and V_z we run the EM algorithm, given by Algorithm 11, with the stated initial values using measurements x obtained from the behavioral sequence. Finally, once the EM algorithm converged, we use the unscented RTS smoother with the resulting learned model parameters to reconstruct poses of the behavioral sequence.

Algorithm 11

```

1: function  $f_{\text{EM}}(\mu_0, V_0, V_z, V_x)$ 
2:    $k \leftarrow 0$  ▷ Initialize iteration number  $k$ 
3:    $\mu_{0,k} \leftarrow \mu_0$  ▷ Initialize state mean
4:    $V_{0,k} \leftarrow V_0$  ▷ Initialize state covariance
5:    $V_{z,k} \leftarrow V_z$  ▷ Initialize covariance of transition noise
6:    $V_{x,k} \leftarrow V_x$  ▷ Initialize covariance of measurement noise
7:    $\Delta\bar{v} \leftarrow \text{inf}$ 
8:   while  $\Delta\bar{v} \geq \epsilon_{\text{tol}}$  do
9:      $\hat{\mu}, \hat{V}, G \leftarrow f_{\text{uks}}(\mu_{0,k}, V_{0,k}, V_{z,k}, V_{x,k})$  ▷ Perform E-step
10:     $\mu_{0,k+1}, V_{0,k+1}, V_{z,k+1}, V_{x,k+1} \leftarrow f_{\text{M}}(\hat{\mu}, \hat{V}, G)$  ▷ Perform M-step
11:     $k \leftarrow k + 1$  ▷ Increase iteration number  $k$ 
12:     $\Delta\bar{v} \leftarrow f_{\text{tol}}(\mu_{0,k-1}, V_{0,k-1}, V_{z,k-1}, V_{x,k-1}, \mu_{0,k}, V_{0,k}, V_{z,k}, V_{x,k})$  ▷ Compute change in  $\Theta$ 
13: return  $\mu_{0,k}, V_{0,k}, V_{z,k}, V_{x,k}$ 

```

Here, in accordance to the concepts stated in Section 4.5 and 4.6, function f_{ut} , given by Algorithm 12, performs the M-step and function f_{tol} , given by Algorithm 13, computes the mean $\Delta \bar{v}$ of the relative changes of the model parameters Θ .

Algorithm 12

```

1: function  $f_{\text{M}}(\hat{\mu}, \hat{V}, G)$ 
2:   for  $t \in \{1, \dots, T\}$  do
3:      $\begin{pmatrix} \mathcal{B}_t \\ \mathcal{A}_t \end{pmatrix} \leftarrow f_{\text{ut}} \left( \begin{pmatrix} \hat{\mu}_t \\ \hat{\mu}_{t-1} \end{pmatrix}, \begin{pmatrix} \hat{V}_t & \hat{V}_t G_{t-1}^T \\ G_{t-1} \hat{V}_t & \hat{V}_{t-1} \end{pmatrix} \right)$ 
4:      $\mathcal{Z}_t \leftarrow f_{\text{ut}}(\hat{\mu}_t, \hat{V}_t)$ 
5:      $\mu_{0,k+1} \leftarrow \hat{\mu}_0$ 
6:      $V_{0,k+1} \leftarrow \hat{V}_0$ 
7:      $V_{z,k+1} \leftarrow \frac{1}{T} \sum_{t=1}^T \sum_{i=1}^{4n_z+1} \tilde{w}_i (\mathcal{B}_{ti} - \mathcal{A}_{ti}) (\mathcal{B}_{ti} - \mathcal{A}_{ti})^T$ 
8:     for  $j \in \{1, \dots, n_x\}$  do
9:        $V_{x,k+1,jj} \leftarrow \frac{1}{T_j} \sum_{t=1}^T \delta_{tj} \sum_{i=1}^{2n_z+1} w_i (x_{tj} - g(\mathcal{Z}_{ti})_j)^2$ 
10:  return  $\mu_{0,k+1}, V_{0,k+1}, V_{z,k+1}, V_{x,k+1}$ 

```

Algorithm 13

```

1: function  $f_{\text{tol}}(\mu_{0,k-1}, V_{0,k-1}, V_{z,k-1}, V_{x,k-1}, \mu_{0,k}, V_{0,k}, V_{z,k}, V_{x,k})$ 
2:   for  $i \in \{1, \dots, n_z\}$  do
3:      $\Delta \mu_{0i} \leftarrow \text{abs} \left( \frac{\mu_{0,k,i} - \mu_{0,k-1,i}}{\mu_{0,k-1,i}} \right)$ 
4:      $\Delta \text{diag}(V_0)_i \leftarrow \text{abs} \left( \frac{V_{0,k,ii} - V_{0,k-1,ii}}{V_{0,k-1,ii}} \right)$ 
5:      $\Delta \text{diag}(V_z)_i \leftarrow \text{abs} \left( \frac{V_{z,k,ii} - V_{z,k-1,ii}}{V_{z,k-1,ii}} \right)$ 
6:   for  $i \in \{1, \dots, n_x\}$  do
7:      $\Delta \text{diag}(V_x)_i \leftarrow \text{abs} \left( \frac{V_{x,k,ii} - V_{x,k-1,ii}}{V_{x,k-1,ii}} \right)$ 
8:    $\Delta v \leftarrow (\Delta \mu_0, \Delta \text{diag}(V_0), \Delta \text{diag}(V_z), \Delta \text{diag}(V_x))^T$ 
9:    $\Delta \bar{v} \leftarrow \frac{1}{3n_z+n_x} \sum_{i=1}^{3n_z+n_x} \Delta v_i$ 
10:  return  $\Delta \bar{v}$ 

```

A Evaluating expected values of log-transformed normal distributions

Given a d -dimensional normal distribution p_{norm} with mean $\mu_y \in \mathbb{R}^d$ and covariance $V_y \in \mathbb{R}^{d \times d}$, evaluating it for a normally distributed random variable $y \sim \mathcal{N}(m, \Sigma)$ takes the following form:

$$p_{\text{norm}}(y|\mu_y, V_y) = (2\pi)^{-\frac{d}{2}} \det(V_y)^{-\frac{1}{2}} \exp\left(-\frac{1}{2}(y - \mu_y)^T V_y^{-1} (y - \mu_y)\right) \quad (88)$$

where $\det(V_y) \in \mathbb{R}$ denotes the determinant of matrix V_y . Applying a logarithmic transformation yields:

$$\ln p_{\text{norm}}(y|\mu_y, V_y) = -\frac{1}{2} \ln \det(2\pi V_y) - \frac{1}{2} \text{tr}\left(V_y^{-1} (y - \mu_y)(y - \mu_y)^T\right) \quad (89)$$

where $\text{tr}(V_y) \in \mathbb{R}$ denotes the trace of matrix V_y . Noticing that $\mathbb{E}[yy^T] = \Sigma + mm^T$ [8], we can take the expected value of equation 89 with respect to y and obtain:

$$\mathbb{E}[\ln p_{\text{norm}}(y|\mu_y, V_y)] = -\frac{1}{2} \ln \det(2\pi V_y) - \frac{1}{2} \text{tr}\left(V_y^{-1} \mathbb{E}\left[(y - \mu_y)(y - \mu_y)^T\right]\right) \quad (90)$$

$$= -\frac{1}{2} \ln \det(2\pi V_y) - \frac{1}{2} \text{tr}\left(V_y^{-1} \left(\Sigma + (m - \mu_y)(m - \mu_y)^T\right)\right) \quad (91)$$

B Derivatives

Given a d -dimensional vector $v \in \mathbb{R}^d$, two symmetric matrices $M \in \mathbb{R}^{d \times d}$ and $C \in \mathbb{R}^{d \times d}$ as well as a scalar $c \in \mathbb{R}$, we can obtain the following derivatives:

$$\frac{d}{dv} \text{tr}(Cvv^T) = Cv + C^T v = 2Cv \quad (92)$$

$$\frac{d}{dM} \ln \det(cM) = M^{-1} \quad (93)$$

$$\frac{d}{dM} \text{tr}(M^{-1}C) = -(M^T)^{-1} C^T (M^T)^{-1} = -M^{-1} C M^{-1}. \quad (94)$$
