Introduction: Berberine (BBR) is an isoquinoline plant alkaloid with demonstrated anti-inflammatory, anti-tumor and immunosuppressive pharmacological properties that functions via multiple signaling pathways and epigenetic modulators. Numerous studies have proposed BBR as a promising therapeutic agent for joint cartilage degeneration, and other connective tissue diseases.

Purpose and Methods: This work aimed to evaluate the effects of BBR on the growth and differentiation of embryonic skeletal progenitors using the limb mesoderm micromass culture assay.

Results: Our findings show that at difference of its apoptotic influence on a variety of tumor tissues, cell death was not induced in skeletal progenitors by the addition of 12 or 25 μ M BBR concentration to the culture medium. Morphological and transcriptional analysis revealed dual and opposite effects of BBR treatments on chondrogenesis depending on the stage of differentiation of the cultured progenitors. At early stage of culture, BBR was a potent chondrogenic inhibitor, while chondrogenesis was intensified in treatments at advanced stages of culture. The chondrogenic promoting effect was accompanied by a moderate upregulation of gene markers of prehypertrophic cartilage, including *ColXa1*, alkaline phosphatase *Alpl*, *Runx2*, and Indian Hedgehog *Ihh*. We further observed a positive transcriptional influence of BBR in the expression of DNA methyltransferase genes, *Dnmt1*, *Dnmt3a* and *Dnmt3b*, suggesting a potential involvement of epigenetic factors in its effects.

Conclusion: Our study uncovers a new pharmacological influence of BBR in cartilage differentiation that must be taken into account in designing clinical protocols for its employment in the treatment of cartilage degenerative diseases.

Keywords: chondrogenesis, osteoarthritis, cartilage differentiation, DNA methyltransferases

Introduction

The degenerative pathology of the locomotor system shows a high prevalence in occidental society due to the aging of the population, to the sedentary lifestyle, and to the practice of highly competitive sports. Joint cartilage, ligaments and tendons are major targets of such degenerative diseases. Regenerative medicine offers great expectations for the treatment of these diseases. However, the development of this therapy requires a detailed knowledge of the mechanisms that regulate the differentiation and functional maintenance of skeletal tissues. Epigenetic regulators are emerging as major factors responsible for these functions.¹

The embryonic limb provides a useful model for analyzing differentiation of skeletal tissues and for testing new therapeutic approaches. The early developing

limb is formed by a core of skeletal progenitors of somatopleural origin covered by ectoderm. During the development, progenitors are segregated into a core region that aggregate to form the cartilage templates of the skeleton and a peripheral population that remains undifferentiated under the influence of the ectodermal cover.² The peripheral cell population forms the connective tissues associate with joints and muscles,³ or are eliminated by cell death.⁴ Most evidence indicate that the structural diversification of limb skeletal progenitors in vivo is regulated by epigenetic modifications via Wnt/ β -catenin signaling or by functional regulation of DNA methyl transferases.^{2,5,6} In vitro studies analyzing the chondrogenic differentiation of stem cells revealed important and precocious transcriptional changes in the expression of pro-chondrogenic factors such as *Sox9*, *Sox5*, *Sox6*, and *Runx2* via epigenetic modifications.^{7,8} In addition, SOX9 that is a master chondrogenic factor regulates itself the methylation status of downstream chondrogenic markers.⁹ Transcriptional changes regulated by epigenetic modifications are also associated with tendon differentiation and aging,^{10,11} and with the progress of cartilage differentiation.^{12,13}

Berberine (BBR) is a botanical alkaloid employed in traditional Chinese medicine that has been characterized as a promising therapeutic agent for numerous degenerative and inflammatory diseases, and also as anti-tumoral treatment for a variety of cancers.^{14–16} Among the pharmacological applications proposed for BBR are skeletal degenerative diseases, including joint cartilage degeneration and osteoarthritis,^{14–18} intervertebral disc degeneration,^{19,20} and abnormal fibrosis.²¹

It is believed that the signaling pathways associated with inflammation are major molecular targets for the pharmacological effects of BBR.²² However, there is increasing evidence showing that transcriptional gene regulations via epigenetic modifications sustain, at least in part, its pharmacological effects.^{23–26} It has been reported that BBR ameliorates cartilage degeneration via Wnt/ β -catenin signal pathway,²⁷ and exerts a potent antitumoral effect on multiple myeloma inducing the degradation of UHRF1 via the ubiquitin-dependent proteasome system.²⁵ Considering that both β -catenin signaling and UHRF1 are important regulators of differentiation of limb chondroprogenitors,^{2,28,29} and the proposed beneficial effect of BBR on cartilage degeneration,²⁷ the aim of our study was to explore its effect on embryonic limb skeletal progenitors at different stages of differentiation.

Materials and Methods

Micromass Cultures

The study was performed in high density cultures of skeletal progenitors (micromass cultures) obtained from the undifferentiated mesoderm of the distal margin of the limb bud (“progress zone”) of chick (Rhode Island) embryos at 4.5 day of incubation, equivalent to stages 24 and 25 HH. Fertilized eggs were obtained from a commercial farm (Granja Santa Isabel, Cordoba Spain) and embryo extraction was performed at the appropriate stage following the ethical recommendations of the European Communities Council. Embryos were washed in cold PBS and the most distal part of the hindlimb bud was dissected out. The tissue fragments were dissociated to single-cell level by treatment with 0.25% trypsin and 0.25% collagenase for 6 and 12 min respectively. The cellular suspension was then filtered through a 100 μ m membrane and resuspended in Dulbecco’s Modified Eagle Medium (DMEM, Lonza) supplemented with 10% fetal bovine serum (FBS), 100 units/mL penicillin and 100mg/mL streptomycin. 10 μ L drops of cell suspension at a concentration of 2×10^4 cells/ μ L were pipetted into each well of a 48 well plate. Cells were allowed to attach for 2 hours and then 200 μ L of DMEM was added to each well. “Short term cultures” were incubated for 2 days in DMEM with or without 10% FBS. “Long-term cultures” were incubated for 12 days in DMEM plus 10% FBS and 50mg/mL of ascorbic acid added to the medium from day 7 of culture. We have previously reported,³⁰ that these culture periods corresponds to pre-chondrogenic and pre-hypertrophic stages of cartilage differentiation.

At the end of the initial culture period, both short-term and long-term cultures were cultured for additional 6 hr in a medium containing 12.5 or 25 μ M Berberine (BBR, Sigma-Aldrich) dissolved in DMSO. Control cultures were maintained for the same period in fresh medium lacking BBR but containing the same amount of DMSO. At the end of this period, cell proliferation and apoptosis were studied by flow cytometry and transcriptional changes were analyzed by Real-time quantitative PCR (qPCR). The phenotypic outcome of control and experimental cultures was analyzed by cartilage specific staining with Alcian Blue or by histology after an additional 3 days of culture in drug-free medium.

Morphological Analysis

The chondrogenic differentiation of the cultures was analyzed by whole mount staining with 0.5% Alcian blue at

pH1.0 of cultures fixed in Kahle's solution. The intensity of Alcian blue staining was quantified by colorimetric analysis at 600nm after dye extraction with 6 M guanidine-HCl (pH 5.8). Each sample was a pool of 4 micromasses. Data were analyzed by ANOVA followed by Bonferroni test for post-hoc comparisons and statistical significance was set at $p < 0.05$.

For histology, micromasses were detached from the wells and embedded in araldite. 1 μ m thick sections were obtained and stained with Toluidine blue.

Cell senescence was evaluated detecting β -galactosidase activity at pH 6 (SA β -gal) after overnight fixation in 4% glutaraldehyde following the recommendations of Debacq-Chainiaux et al.³¹ The SA β -gal positive area in the central region of each culture was measured with Image J default tools and values were analyzed by ANOVA followed by Bonferroni test.

Apoptosis was evaluated by the terminal deoxynucleotidyl transferase-mediated dUTP-TRIC nick end labeling (TUNEL) assay using the in situ cell death detection kit (Roche).

Flow Cytometry

Control and BBR-treated cell cultures were dissociated with trypsin EDTA (Lonza). For propidium iodide (PI) staining, cells were washed with PBS, and fixed in 90% ethanol and stained overnight at 4°C with 0.1 mg/mL PI with 0.1% sodium citrate and 0.01% Triton X-100. The cell suspensions were subjected to flow cytometry in a Cytotflex (Beckman Coulter) with Cytexpert software for data collection and analysis. One million cells were used in each test. The gating strategy was made by deselecting impurities (debris) using an SSC-A/IP-PE dot plot and then selecting the populations of apoptotic and living cells in a logarithmic scale IP-PE histogram (see [Supplementary Figure 1](#)). Data were analyzed by ANOVA followed by Bonferroni test for post-hoc comparisons. Statistical significance was set at $p < 0.05$.

Real-Time Quantitative PCR (qPCR) for Gene Expression Analysis

For transcriptional analysis we selected a panel of genes including: master transcription factors of distinct connective tissues (*Sox9*, *Scleraxis*, *Runx2*, *Tgfr1*, *Ihh* and *Alpl*); epigenetic regulators (*Uhrf1*, *Uhrf2*, *Dnmt1*, *Dnmt3a*, *Dnmt3b* and *Tet3*); cell senescence (*p16*, *p21*, *p53*, *p63* and *p73*); Tumor suppressor genes (*Btg1* and *Btg2*); apoptotic markers (*Bak1*); TGF β ligands (*Tgfb2* and *Tgfb3*);

and a variety of extracellular matrix constituents and regulatory factors (*Col1a1*, *Col2a1*, *ColXa1*, *Col27a1*, *Aggrecan*, *Decorin*, the matricellular proteins *Ccn1* and *Ccn3*, and the metalloprotease *Mmp2*).

Total RNA from Control or BBR-treated cultures was extracted using the NucleoSpin RNA Kit (Macherey-Nagel). RNA samples were quantified using a spectrophotometer ND-1000 (Nanodrop Technologies). First-strand cDNA was synthesized by RT-PCR using the RevertAid RT Kit (Thermo Scientific). The cDNA concentration measured in a spectrophotometer ND-1000 was adjusted to 0.5 μ g/ μ L. SYBR Green qPCRs were performed using the StepOne system (Life Technologies), with automation attachment, and the SYBR[®] Select Master Mix (Applied Biosystems). *Gapdh* had no significant variation in expression across the sample set and therefore was chosen as the normalizer in our experiments. Mean values for fold changes were calculated for each gene. Each value in this work represents the mean \pm SD of at least five independent samples obtained under the same conditions from at least 3 distinct experiments. Samples consisted of four micromass cultures. Student's *t*-test was employed to analyze the statistical significance when control and experimental sample values differed more than 1.5 folds. Primers for qPCR are included in [Supplementary Table S1](#).

Results

The micromass culture assay is a precursor of what we now term organoid cultures.^{32,33} Dissociated limb undifferentiated skeletal progenitors cultured at high density in serum-free minimum essential medium or in medium containing 10% fetal bovine serum recapitulates the events leading to the formation of the skeletal primordia except for the absence of the specific morphological shape of cartilages in vivo.^{34,35} After two days of culture, cells aggregate forming small SOX9 and Alcian blue positive nodules. Cells in the perinodular regions maintain a fibroblastic appearance. Consistent with this differentiation pattern, both *Scleraxis* and *Sox9* genes are robustly expressed at these stages. *Scleraxis* is a marker of connective tissues that in vivo surround the differentiating cartilaginous skeleton, including tendons, joint tissues, and aponeurosis.³⁶ In subsequent days of culture, the chondrogenic nodules expand both in number and in size at expense of reducing the amount of peripheral fibroblastic tissue. The progression of chondrogenesis is intense in cultures containing FBS and more limited when cultures are grown only in minimum essential

medium. After 10 days of culture in medium lacking FBS, and some days earlier in cultures containing FBS, cartilage specifically stainable by Alcian blue is the predominant tissue in the culture. In a previous study we observed that cultures of 2 and 12 days represent two distinct stages of cartilage differentiation. 2 days cultures contain prechondrogenic cells in course of aggregation while 12 days cultures contain maturing cartilage in a prehypertrophic stage of differentiation.³⁰ Consistent with these data, expression of *Collagen type 2 alpha 1 (Col2a1)* and *Aggrecan* genes, that are master markers of chondrodifferentiation increased by 5 and 7 folds respectively between day 2 and day 12 of culture (Fig. Supplementary 1). Considering these stages of cartilage differentiation, we performed treatments at early (short-term) and late stages (long-term) of culture to monitor the differences in the influence of BBR over the immature chondroprogenitors versus differentiating chondrocytes. We analyzed the outcome and differentiation of the cultures and the transcriptional regulation that precede differences in chondrodifferentiation.

BBR Decreased Initial Stages of Chondrogenesis Favoring Fibroblastic Differentiation of Progenitors

Although the differentiation of the micromass cultures progressed much quicker in the presence of FBS than in its absence, in both cases, a 6hr treatment of BBR at the end of the second day of culture caused an intense inhibition of chondrogenesis detectable 3 days later. As shown in Figure 1, after three days of additional culture in BBR-free medium, the number, size, and staining intensity of the Alcian blue-positive nodules were reduced in BBR-treated micromasses (Figure 1A and C). Notably, the perinodular fibroblastic tissue increased in a dose-dependent fashion in parallel with the reduction of the size of the Alcian blue positive nodules (Figure 1B, D, F–H). In tissue sections of control micromasses, cartilage nodules exhibit a well structural organization and are separated of each other by a reduced amount of internodular tissue (Figure 1B and F). In contrast, chondrogenic regions of BBR-treated cultures appeared less organized with zones having a rather fibrocartilaginous appearance with rounded chondrocytes rich in extracellular matrix intermingled with regions of dark cells lacking the morphological appearance of chondrocytes (Figure 1G–H). Quantification of the Alcian blue extracted by guanidine-HCl showed a 50% fall of chondrogenesis in cultures treated with 12.5 μ M

BBR (hereafter, “low-dose” of BBR) and 70% fall in 25 μ M BBR treatments (hereafter “high-dose” of BBR) (Figure 1I).

Changes in cell proliferation, cell senescence and cell death together with transcriptional modifications preceding the different outcome of the treated cultures were analyzed at the end of the 6 hr period of BBR treatment in cultures growing in DMEM without FBS. Not statistically significant changes in cell cycle, cell senescence or cell death between control and treated cultures were appreciated in this period, even in high-dose BBR treatments (Figure 1J, K, and Fig. Supplementary 2).

As shown in Table 1, we observed mild but significant transcriptional changes in genes associated with for cell differentiation, cell senescence, cell death, and epigenetic regulation. Independent of the doses selected, *Tgfb2* and *Scleraxis* were up regulated. Other genes belonging to the TGF β pathway involved in fibrogenesis or the transcription factor *Runx2*, which play a role at initial and at advanced stages of chondrogenic differentiation,^{35,37} were not regulated. *p21* and *p53* genes, but not p16, that are developmental senescence central factors,³⁸ were moderately up-regulated although the pattern of SA β -gal staining appeared only moderately intensified without reaching statistical significance (Fig. Supplementary 2). Tumor suppressor genes and the pro-apoptotic factor *Bak1* were neither regulated at significant levels. Among the epigenetic regulators, *Dnmt1*, 3a, and 3b were all significantly up regulated, but other epigenetic modulators were not. Extracellular matrix factors were not significantly regulated.

BBR Promotes Cartilage Maturation at Advanced Stages of Culture

Cartilage is the predominant component of micromasses cultured for 12 days. At this stage, the cultures were widely positive for Alcian blue staining showing nodules of intensified staining (Figure 2A). At difference of treatments at earlier stages of culture (short-term), chondrogenesis appeared strongly intensified in cultures treated with low-dose BBR, (Figure 2B) and in a less intense fashion after treatment at high-dose of BBR (Figure 2C). In tissue sections, control and the low-dose treated experimental cultures showed similar appearance (Figure 2D–E). The high dose-dose treated cultures showed a slight prehypertrophic morphology (Figure 2F). Quantification of chondrogenesis after guanidine-HCl extraction of Alcian blue

confirmed and 50% of increased staining in cultures subjected to low-dose of BBR (Figure 2G). The intensification of staining after high-dose BBR treatment was less intense reaching only a 25% (Figure 2G).

As observed in earlier stages of culture, no significant changes in cell death were appreciated after either low- or

high-dose BBR treatments (Figure 2H). At difference of treatments at early stage of culture, a moderated slowing at phase S of the cell cycle, that not reached statistically significance, was appreciated after low-dose BBR treatments (Figure 2I). We choose low-dose treatments for analyzing transcriptional changes (Table 2). *Scleraxis*, *Tgfb2*, *Tgfb3* and *Sox9* were all up regulated. Markers of cartilage hypertrophic maturation,^{39,40} including Collagen type X (*ColXa1*), *Runx2*, *Ihh* and alkaline phosphatase gene (*Alpl*), appeared also positively regulated. The epigenetic marker *Dnmt3b*, but not other epigenetic regulators, appeared up regulated. Finally, senescence (*p16*, *p21*) apoptotic (*Bak1*) and the tumor suppressor *Btg1* were also upregulated. Detection of SA β -gal activity appeared moderately intensified after BBR treatments, but without reaching statistically significant differences (Fig. Supplementary 2).

Discussion

The embryonic limb mesodermal micromass culture assay is a powerful model for analyzing drugs of potential influence on the differentiation and maintenance of skeletal tissues. Limb skeletal progenitors are originated from the somatopleura and have potential to generate all the connective tissues of the limb including, cartilage, tendons, ligaments, fasciae, joint capsules and intramuscular connective tissue.^{3,41} Furthermore, in the absence of appropriate differentiation signals, skeletal progenitors are eliminated by senescence and massive cell death.⁴ Importantly, the diversification of progenitors to form specialized cartilages, fibrous (dense) connective tissue, or being eliminated by cell death appears to be associated with epigenetic changes regulated by local signaling cascades.^{2,6,13,42}

BBR has been characterized as a chondroprotective drug that ameliorates cartilage degeneration and joint rigidity in experimental models of osteoarthritis.^{43–45} These findings together with other experimental approaches proposed that BBR could be effective for osteoarthritis treatment,^{17,22,27,46,47} intervertebral disc degeneration,²⁰ and pathological fibrotic processes.⁹ Abundant evidence indicates that the anti-inflammatory effect of BBR relays in the regulation of signaling pathways associated with inflammation.^{15,22} Cell death and cell cycle arrest of activated rheumatoid arthritis fibroblast-like synoviocytes in combination with an anti-apoptotic influence on chondrocytes were proposed to

contribute also to the pharmacological effects of BBR on joint cartilage.^{44,48} Remarkably, the induction of cell cycle arrest and apoptosis constitutes the basis for the anti-tumoral pharmacological application of BBR in a variety of tumors.¹⁵ These pharmacological effects have been associated with transcriptional regulation of the pro-apoptotic and tumor suppressor genes, such as *p53*, *p21*, or *Bax* via inducing epigenetic modifications.^{15,24,48} These modifications included changes in DNA methylation,²³ inhibition of histone deacetylases binding,²⁴ inhibition of the epigenetic regulatory factor *Uhrf1*,²⁵ and transcriptional up-regulation of demethylation (TET) enzymes.²⁶

Three major findings concerning the pharmacological properties of BBR can be deduced from our results: 1) firstly, at difference of the apoptotic influence of BBR on a variety of tumoral tissues, no changes in cell death were detected in the micromass culture assay; 2) secondly, in concert with previous studies performed on a variety of normal or pathological tissues,⁴³ we found that transcriptional and phenotypic changes of treated cultures caused by BBR administration are associated with the stage of differentiation of cultured progenitors; and, 3), treatments with low doses of BBR performed in cultures at stages of cartilage maturation increased the chondrogenic process.

It has been found that the pro-apoptotic and anti-proliferative effects of BBR in breast cancer cells are not observed in non-malignant breast epithelial cells.⁴⁹ The absence of increased cell death in our experimental assay is

consistent with the reported chondroprotective influence of BBR,⁴⁴ and supports the specificity of the dying influence of BBR on different cell lineages. As reported in different experimental studies,^{22,48,50} we have observed a mild, but significant, transcriptional influence of BBR on genes associated with cell death and developmental cell senescence,^{51,52} including *p21* and *Bak1*, *p53* and the tumor suppressor gene *Btg1*. This moderate gene up-regulation in our in vitro assay appeared insufficient to induce apoptosis or increased SA β -gal activity in early or late cultures at the end of the 6 hr period of treatment.

The increased chondrogenesis observed after treatments of cultures at advanced stages of cartilage differentiation might be important when considering the therapeutic influence of BBR on joint cartilage degeneration.²² In our experimental model, BBR at initial stages of culture inhibited chondrogenesis, up-regulating pro-fibrogenic genes (*Tgfb2* and *Scleraxis*) but not *Sox9*, and maintained progenitors into a fibroblastic-like state. However, the addition of BBR to the culture medium at advanced stages of culture promoted chondrogenesis, deduced by the intensification of Alcian blue specific cartilage staining and by the transcriptional up-regulation of *Sox9*.

From a clinical point of view, a major question about the suitability of joint cartilage regenerative therapy concerns the nature of the cartilaginous tissue resulting by the treatment.⁵³ Our results do not presuppose that the influence of BBR in the micromass assay replicates its pharmacological effects on adult pathologic cartilage but may be of help to uncover effects on degenerating cartilage of interest for therapeutics. The natural outcome of differentiating cartilages in the course of skeletogenesis in vivo and in vitro is a sequential process evolving from prechondrogenic condensation to overt hypertrophy that is followed by osteogenic differentiation.⁵³ We observed that *ColXa1*, *Runx2*, *Ihh*, and even *Alpl* genes, that are considered cartilage prehypertrophic markers, appeared up regulated in the late-stage treated cultures. However, the histological appearance of the cultures together with the twofold increased expression of *Scleraxis*, and the over-expression of *Ccn1* (*Cyr61*) genes, that are associated with the differentiation of progenitors in the contour of the developing cartilage,⁵⁴ indicate that chondrogenic intensification was not fully dependent of a hypertrophic progression of cartilage differentiation. Consistent with this interpretation *Sox9* gene, that is believed to counteract

cartilage hypertrophy in the growth plate of long bones,⁵⁵ is maintained at high expression levels.

The regulation of *Runx2* in later BBR treatments, merits especial attention. At the beginning of chondrogenic differentiation *Runx2* is required to sustain chondrogenesis, while once the cartilage is formed *Runx2* promotes hypertrophy.⁴⁰ Therefore, the differential regulation of *Runx2* in early and late cultures may reflect the stage-dependent opposite influence of BBR on chondrogenesis.

A further task of our study was to identify epigenetic factors as potential targets activated by BBR treatments. We identified *Dnmt3b* as an epigenetic target potentially implicated in the transcriptional influence of BBR in late cultures and also *Dnmt1* and *Dnmt3a* in early cultures. However, at difference with studies on the anti-tumor influence of BBR,²³ we detected a significant up-regulation, rather than down-regulation, of *Dnmt3b*. In addition, no transcriptional regulation of other epigenetic markers was appreciated in pro-chondrogenic treatments of BBR. Further studies are required to clarify this question.

Conclusion

Our study uncovers a pharmacological influence of BBR in the differentiation of the limb skeletal progenitors in vitro. The possibility that these effects were also induced in adult tissues during cartilage degenerative diseases is a tempting hypothesis that may help to design protocols for the treatment of cartilages diseases.

Abbreviations

BBR, Berberine; DMEM, Dulbecco's Modified Eagle Medium; FBS, fetal bovine serum; PBS, phosphate buffered saline; PI, propidium iodide; qPCR, Real-time quantitative PCR.

Acknowledgments

We thank Montse Fernandez Calderon, Susana Dawalibi, and Sonia Perez Mantecon for excellent technical assistance. We are grateful to Dr. J. Hurlé for comments and suggestions to this study. A Grant (BFU2017-84046-P) from the Spanish Science and Innovation Ministry to J. A.M supported this work.

Journal of Inflammation Research

Dovepress

Publish your work in this journal

The Journal of Inflammation Research is an international, peer-reviewed open-access journal that welcomes laboratory and clinical findings on the molecular basis, cell biology and pharmacology of inflammation including original research, reviews, symposium reports, hypothesis formation and commentaries on: acute/chronic inflammation; mediators of inflammation; cellular processes; molecular

mechanisms; pharmacology and novel anti-inflammatory drugs; clinical conditions involving inflammation. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/journal-of-inflammation-research-journal>
