Abstract

We have performed soft x-ray spectroscopy in order to study the photoirradiation time dependence of the valence band structure and chemical states of layered transition metal nitride chloride TiNCl. Under the soft x-ray irradiation, the intensities of the states near the Fermi level (E_F) and the Ti^{3+} component increased, while the Cl $2p$ intensity decreased. Ti $2p$ - $3d$ resonance photoemission spectroscopy confirmed a distinctive Fermi edge with Ti $3d$ character. These results indicate the photo-induced metallization originates from deintercalation due to Cl desorption, and thus provide a new carrier doping method that controls the conducting properties of TiNCl.

Introduction

TiNCl is an interesting layered material that belongs to a family of layered nitride halides MNX ($M = Ti, Zr, Hf$ and $X = Cl, Br, I$) systems with two polymorphs, the FeOCl-type crystal structure (α -form) and the SmSI-type crystal structure (β -form) [1, 2]. TiNCl is known to take only the FeOCl-type crystal structure [2], consisting of a stack of orthogonal M - N layers located between two X layers. TiNCl is a band insulator with a direct band gap of approximately 0.5-3 eV [3, 4], and theoretical studies have proposed its application to optoelectronic devices [4], photocatalysts [5], and spin devices [6]. Upon Na intercalation between TiNCl layers, TiNCl becomes a superconductor with a relatively high superconducting transition temperature of ~ 16 K [7]. As electron-doped

1 β -form HfNCl and ZrNCl [8-20], electron-doped TiNCl is considered a candidate for
2 unconventional superconductors, where exotic mediation forces for Cooper pairing other
3 than phonon are discussed [21-25].

4 In order to further explore the physical properties of this remarkable material, it is
5 essential to control carrier concentrations. In the β -form MNX , the carrier control has
6 been performed by intercalation of an alkali- or alkaline-earth-metal [8, 9, 15, 16], and/or
7 off stoichiometry or deintercalation of X [26]. As for TiNCl, to the best of our knowledge,
8 carrier control by neither element substitution nor off stoichiometry has been reported.
9 This may be due to the fact that TiNCl is easily thermally decomposed into TiN by
10 annealing[27-29]. The intercalation of alkali metal atoms and/or organic molecules
11 between layers is the only method way for doping carriers. However, intercalated samples
12 are unstable in a humid air, and precise carrier controlling is challenging, which prevents
13 the systematic investigations of physical properties systematically.

14 One of the techniques to create conductive samples is photo-irradiation-induce
15 metallization by breaking chemical bonds [30-36]. In SrTiO₃ and TiO₂, a metallic state
16 called two-dimensional electron gases is created on the surface by photoirradiation. Two-
17 dimensional electron gases have attracted extensive attention owing to unique physical
18 properties [30-35, 37-39], providing opportunities for the development of next generation
19 of electronic and photonic devices. If photo-induced bond breaking is also effective in
20 TiNCl, it can be established as a new method to control the physical properties of TiNCl.
21 Therefore, it is one of the important challenges to investigate whether TiNCl is metallized
22 by photoirradiation.

23 In this paper, we performed valence and core level photoelectron spectroscopy (PES),
24 x-ray absorption spectroscopy (XAS), and Ti $2p$ - $3d$ resonance photoelectron
25 spectroscopy (RPES) of layered transition metal nitride chloride TiNCl. It was found that
26 soft x-ray irradiation induced the metallization of TiNCl, and the metallization was
27 closely related to the Cl desorption. This is the first report of electron-doped TiNCl due
28 to Cl desorption.

30 **Experiment**

31 The highly crystalline TiNCl was grown by a method described elsewhere [7]. It was
32 pelletized into disk shape in an Ar filled glove box. Subsequently, the pellet was
33 transferred to an ultra-high vacuum chamber for photoelectron spectroscopy without
34 being exposed to the humid air for a long time. The experiments were performed at the
35 soft x-ray beam line BL23SU of SPring-8 [40] using a photoemission spectrometer
36 equipped with a Gammadata-Scienta SES-2002 electron analyzer. In the RPES

1 measurement, the energy resolution was set to 80 meV, and in the other PES
2 measurements, it was set to less than 200 meV. To reduce a possibility for pyrolysis of
3 TiNCl, we cooled down the sample and measured it at 100 K instead of at 300 K. We
4 performed PES measurements using a photon energy of 1000 eV. For calibration of the
5 binding energy, we used the Fermi edge of a gold film, which was located close to the
6 sample and had a good electrical contact to the sample.

7 The irradiation light of $h\nu = 1000$ eV was used, and the detector angle was set to 90° .
8 Sets of Ti $2p$, N $1s$, Cl $2p$, and valence spectra were also measured at $h\nu = 1000$ eV in the
9 time interval of 25 minutes without changing the measured location of the sample surface.
10 The irradiation time includes the time of the PES measurements. Though it took 8 min to
11 take a set of Ti, N, Cl, and valence spectra, we refer to the irradiation time as the time
12 when we started the measurement of Ti. The spot size of the excitation light was $100 \times$
13 $200 \mu\text{m}^2$, and the photon flux was 2×10^{12} Photons/sec [40]. The illustration of the
14 experimental geometry is shown in Fig. 1. The intensity of PES spectra was normalized
15 by the area intensity of Ti $2p$ core-level spectra, while those of RPES were normalized by
16 the photocurrent. XAS spectrum was measured using the total electron yield (TEY) mode.
17 To obtain a clean surface, the TiNCl pellet was fractured at 100 K under an ultrahigh
18 vacuum of 1.5×10^{-8} Pa.

21

22 Results and discussion

23 Figure 2 shows the soft x-ray irradiation time dependence of the valence band PES

1 spectra of TiNCl. The background of an iterative Shirley method [41, 42] was subtracted
 2 from the raw spectra. The initial valence band spectrum of TiNCl had a peak at 6 eV with
 3 a shoulder structure at 4 eV, and there was almost no intensity in the near- E_F region. The
 4 overall spectral shape is consistent with that of the previous study [25], and thus the states
 5 of approximately 6 and 4 eV can be ascribed to Cl 3*p* and N 2*p* orbitals, respectively.

6 The peak intensities at 6 eV and 4 eV were decreased gradually. In contrast, the
 7 spectral intensity in the region between E_F and ~ 1.5 eV appears to be increased, as
 8 illustrated in the inset that shows a blowup of the spectra near E_F . The intensity near E_F
 9 of the initial spectrum can be ascribed to the states induced by the soft x-ray irradiation
 10 during the measurement and/or may be assigned to impurity states. In the spectrum after
 11 150 min irradiation, a clear Fermi edge structure was observed, suggesting the metallic
 12 nature of the measured region of the sample surface. The change in the valence band and
 13 the intensity near E_F due to the soft x-ray irradiation is very similar to the change due to
 14 the photoirradiation effect of SrTiO₃ [30].

15
 16 Figure 2. Soft x-ray irradiation time dependence of the valence band PES spectra of TiNCl,
 17 measured with a photon energy of 1000 eV at 100 K. Inset shows the enlargement of the
 18 spectra near E_F .

19
 20 To spectroscopically confirm the metallization and the character of the states at E_F ,
 21 we performed RPES of irradiated TiNCl at the Ti 2*p*-3*d* absorption threshold. The photon
 22 energies for the RPES measurement were chosen based on the Ti L_3 XAS spectrum, as
 23 shown in the inset of Fig. 3. Ti L_3 XAS spectrum had sharp absorption peaks at 457.4 eV,
 24 458.5 eV, and 460.1 eV in the region of Ti 2*p*_{3/2}-3*d* absorption edge. In the octahedral

1 structure, the $3d$ level was split into e_g and t_{2g} states by the crystal field effect. However,
 2 since the Ti ions in TiNCl are in a distorted octahedral structure [7], the degeneracy was
 3 further removed by the static Jahn-Teller effect, leading to the observed three-peak
 4 structure. We measured RPES spectra of TiNCl in the off-resonance ($h\nu = 454.0$ eV) and
 5 on-resonance ($h\nu = 457.4$ eV) conditions after the irradiation the soft x-rays for 4 h. While
 6 the spectral intensity at E_F in the off-resonance spectrum was almost negligible, the one
 7 in the on-resonance spectrum exhibited a distinctive Fermi edge, and was considerably
 8 enhanced. The resonance enhancement of the near- E_F structure indicates that its orbital
 9 character is Ti $3d$. Furthermore, the presence of the distinctive Fermi edge indicates that
 10 the soft x-ray irradiation indeed induces the metallization of TiNCl.

11
 12 Figure 3. ON (red) and OFF (blue) Ti $2p$ - $3d$ resonance photoemission spectra of the
 13 irradiated TiNCl measured with a photon energy of 457.4 eV and 454.0 eV, respectively.
 14 The inset shows the Ti $2p$ absorption spectrum where the employed photon energies for
 15 the resonance photoemission are indicated by arrows.

16
 17 To understand the mechanism of the metallization induced by soft x-ray irradiation in
 18 terms of chemical states, we have measured the core level spectra of TiNCl with different
 19 irradiation conditions. Figure 4 (a) shows soft x-ray irradiation time dependence of the Ti
 20 $2p$ core-level spectra, and Fig.4 (b) represents the initial and 150 min difference spectrum.

1 The peaks at 457.5 eV and 463.5 eV are spin-orbit split Ti $2p$, namely Ti $2p_{3/2}$ and Ti $2p_{1/2}$,
2 respectively [43]. The initial Ti $2p$ spectrum showed a sharp Ti^{4+} peak at 457.5 eV [25]
3 and a small shoulder structure at 456.5 eV. In the Ti $2p$ spectrum, as the irradiation time
4 increased, the peak area of Ti^{4+} decreased compared to the initial value. In addition, the
5 intensity of the shoulder structure at 456.5 eV clearly increased gradually. This binding
6 energy is different from that of TiN (455.2 ± 0.2 eV) [44, 45], but is very similar to the
7 weak Ti $2p$ spectral component of electron-doped $SrTiO_3$ and electron-doped anatase-
8 TiO_2 , which is assigned to the component of Ti^{3+} state [30, 31, 46-48]. Thus, the
9 observation indicates that the soft x-ray irradiation on TiNCl induces the changes Ti^{4+} in
10 the valence state of the Ti ion from the Ti^{3+} state to the Ti^{4+} state. We performed spectral
11 fitting using two components. The area intensities of Ti^{3+} and Ti^{4+} components at each
12 irradiation time are summarized in Table 1.

13 Figure 4 (c) compares the spectra of the N $1s$ core level at each soft x-ray irradiation
14 time. These spectra had peaks at 396.5 eV, and were almost identical, suggesting that
15 there was no significant change in the spectral shape due to soft x-ray irradiation. The Cl
16 $2p$ core-level spectra consist of Cl $2p_{3/2}$ (198.4 eV) and Cl $2p_{1/2}$ (200.1 eV) spin-orbit split
17 peaks. The intensity of the Cl $2p$ spectrum after the soft x-ray irradiation of 150 min
18 decreased gradually, which suggests the desorption of Cl atoms from the surface is
19 induced by the soft x-ray irradiation. This is consistent with the observed reduction of the
20 valence band spectra, which reflects a dominant Cl $3p$ contribution.

Here, we discuss the relationship between the observed results. Figure 5 shows the soft x-ray irradiation time dependence of the intensity of N 1s and Cl 2p core-level PES spectra, the PES intensity between E_F and 1.5 eV, and the Ti^{3+} ratio ($Ti^{3+} / (Ti^{4+} + Ti^{3+})$) of Ti 2p core-level PES spectrum. We normalized their initial values to unity. The intensity of N 1s core-level PES does not show a marked change depending on the soft x-ray irradiation time of soft x-ray. In a comparison with that of the N 1s core-level PES, the intensity of the Cl 2p core-level PES decreased more rapidly with increasing irradiation time. Furthermore, simultaneously with a decrease in Cl, the areas of the Ti^{3+} component and of the states near E_F increased in a similar manner. A smaller increase in near E_F intensity may be attributed to a more complicated orbital character of states near E_F than that of the Ti^{3+} core level. These observations suggest the close relationship of the desorption of Cl atoms and an increase in the intensity near E_F with an increase in the Ti^{3+} component. We consider that the desorption of a portion of the Cl atoms from the TiNCl layers introduces electron carriers into the layers, making the layer conductive, which is inferred from the observation of the metallic Fermi edge. Therefore, to estimate the time of change, the data for Ti^{3+} and Cl 2p, which are more intense than the near- E_F data, were fitted with an exponential function ($A\exp(-t/\lambda)+B$ for Ti^{3+} and $C\exp(t/\lambda)+D$ for Cl 2p, where t and λ are time and lifetime, respectively.). The obtained lifetimes of Ti^{3+} and Cl 2p were 119 ± 29 and 96 ± 31 min, respectively. This provided a value of 100 min as the order estimate of the time of change for this experiment.

22

1 Figure 5. Soft x-ray irradiation time dependence of the core-level and near- E_F intensities
2 of TiNCl. Area intensity of N 1s and Cl 2p core-level spectra (left axis), and an increase
3 ratio in area intensity of near E_F and Ti^{3+} in Ti 2p core level spectra (right axis). The initial
4 values were normalized to 1.

5
6 There are two possible causes of the desorption of Cl atoms. One of them is a
7 pyrolysis. TiNCl has been reported to be decomposed completely into TiN when it is
8 heated above 550°C [27-29]. In the present experiment, however, the sample was kept at
9 100 K during the measurement, and therefore this possibility can be ruled out. The other
10 possible cause is photon stimulated desorption [49-51]. There are primarily two
11 mechanisms for photon stimulated desorption, which are distinguished by the process
12 induced by photon irradiation: The Menzel, Gomer, and Redhead (MGR) model and the
13 Knotek and Feibelman (KF) model [49, 50]. The MGR model involves the excitation of
14 valence electrons and works reasonably well for covalent bonds. The KF model involves
15 the excitation of core electrons and is applicable to ion bonding. Since the TiNCl is
16 considered to be an ionic insulator composed of TiN^+ and Cl^- [23], we assumed that this
17 mechanism is involved in the Cl desorption of TiNCl. In the case of TiO_2 , photoinduced
18 desorption is explained by the KF model in terms of Coulomb expulsion between Ti^{4+}
19 and O^+ that are induced by emitting Auger electrons after the relaxation of electrons in O
20 2p levels to create photo-holes in the Ti 3p levels [48]. If the KF mechanism is involved
21 in the present case, the electron transfer that leads to Coulomb expulsion may occur from
22 Cl 3p (valence band) to Ti 3p. Further experiments are needed to confirm the KF
23 mechanism, as it is we think beyond the scope of the present study.

24 With photon stimulated Cl desorption, the final products may be TiN or Cl deficient
25 $TiNCl_{1-\delta}$, depending on the amount of Cl deficiency. However, from the Ti 2p
26 photoelectron spectrum, no sharp TiN peak was observed at 455 ± 0.3 eV [44, 45],
27 suggesting the formation of $TiNCl_{1-\delta}$, rather than TiN. In β -(Hf or Zr) NCl, Cl deficiency
28 is called deintercalation, which is one of the methods of electron doping to the system.
29 Deintercalated $HfNCl_{0.7}$ is a metallic system that also exhibits superconductivity below
30 24 K [26]. However, since electron doping utilizing the Cl deintercalation into α - MNX
31 has never been reported, the present study is the first experimental realization of
32 deintercalated electron doped α - MNX . Further Cl deintercalation by the soft x-ray
33 irradiation would make the system superconductive, like β -form compounds.

34 Lastly, we discuss the benefits of methodologies and findings. Regarding pyrolysis,
35 bond breaking by heat cannot be confined within a small area because of the diffusion of
36 heat in a solid. In addition, temperature controlling of a sample is severe for a target

1 material located in a narrow temperature region of a complicated phase diagram. In
2 contrast, bond breaking by light irradiation occurs only in the place where light is
3 irradiated. In particular, when core-levels excitation are important in the bond-breaking
4 process as in the KF model, element/chemical site-selective bond breaking is possible by
5 setting the excitation energy to a specific element/chemical site [52, 53]. This site-
6 selective bond breaking is called a molecular scalpel and is mainly studied in surface
7 adsorption molecular systems. Such a characteristic, combined with sub-micrometer scale
8 spot sizes in third-generation synchrotron facilities, might be used to make sub-micron
9 scale conducting paths at any place on the surface. Photo-induced metallization of TiNCl
10 has enabled detailed electronic-structure investigation studies of metallic (even
11 superconductive) TiNCl by controlling the carrier concentration in a small single crystal
12 region on the surface, which shed light on the exotic properties of TiNCl.

13 14 **Conclusion**

15 In summary, the irradiation time dependence of the valence band and core-level
16 spectra of TiNCl was studied by PES and Ti $2p$ - $3d$ RPES. Using soft x-ray irradiation,
17 the intensity of the valence band structure origination from Cl $3p$ and N $2p$ states
18 decreased while the intensity near E_F increased. The intensity near E_F exhibited resonant
19 enhancement, and the Fermi edge was clearly observed by Ti $2p$ - $3d$ RPES. The analyses
20 of core-level and near- E_F PES spectral intensities as a function of the soft x-ray irradiation
21 time revealed that the desorption of Cl atoms, the increase in the intensity of the Ti^{3+}
22 component, and increase of the spectral weight in the vicinity of E_F exhibit strong
23 correlations. These results indicate that photoirradiation induced metallization of TiNCl
24 occurs due to electron doping through Cl desorption. As estimated from Cl $2p$ and Ti^{3+}
25 data, the order of the time-of-changes is 100 min. This technique can be used to further
26 explore the conducting properties, especially the unconventional superconductivity, of
27 TiNCl.

- 33 43. The binding energies of Ti 2*p* and Cl 2*p* of the present study are slightly lower by 0.4
34 eV and 0.2 eV than those in Ref. 25, respectively. The two experiments were
35 performed in SPring-8 but on the different beam lines BL23SU (present study) and
36 BL25SU (Ref. 25). We assume that there are three reasons for this difference:

1 charging up, difference in metallization, and calibration of the spectrometer. Since
2 the photon flux density of BL25SU is higher than that of BL23SU, larger binding
3 energies of BL25SU data may be explained by charging up and/or difference in
4 metallization. We do not have the clear answer, however the difference does not
5 change the conclusion of the present study.
