10

11 Running head: Co-incorporation of waste and crop residues

12

1  
2  
3 **Abstract.** Return of high nitrogen (N) content crop residues to soil, particularly in  
4 autumn, can result in considerable environmental pollution resulting from gaseous and  
5 leaching losses of N. The EU Landfill Directive will require significant reductions in the  
6 amounts of biodegradable materials going to landfill. A field experiment was set up to  
7 examine the potential of using biodegradable waste materials to manipulate losses of N  
8 from high N crop residues in the soil. Leafy residues of sugar beet were co-incorporated  
9 into soil with materials of varying C:N ratios, including paper waste, cereal straw, green  
10 waste compost and molasses. The amendment materials were incorporated to provide  
11 approximately 3.7 t C ha<sup>-1</sup>. The most effective material for reducing N<sub>2</sub>O production and  
12 leaching loss of NO<sub>3</sub><sup>-</sup> was compactor waste, which is the final product from the recycling  
13 of cardboard. Adding molasses increased N<sub>2</sub>O and NO<sub>3</sub><sup>-</sup> leaching losses. Six months  
14 following incorporation of residues, the double rate application of compactor waste  
15 decreased soil mineral-N by 36 kg N ha<sup>-1</sup>, and the molasses increased soil mineral N by  
16 47 kg N ha<sup>-1</sup>. Compactor waste reduced spring barley grain yield by 73 % in the first of  
17 years following incorporation, with smaller losses at the second harvest. At the first  
18 harvest, molasses and paperwaste increased yields of spring barley by 20 and 10 %  
19 compared with sugar beet residues alone, and the enhanced yield persisted to the second  
20 harvest. The amounts of soil mineral-N in the spring and subsequent yields of a first  
21 cereal crop were significantly correlated to the lignin and cellulose contents of the  
22 amendment materials. Yield was reduced by 0.3 to 0.4 t ha<sup>-1</sup> for every 100 mg g<sup>-1</sup> increase  
23 in cellulose or lignin content. In a second year, cereal yield was still reduced and related  
24 to the cellulose content of the amendment materials but with one quarter of the effect.  
25 Additional fertiliser applied to this second crop did not mitigate this effect. Whilst

1 amendment materials were promising as tools to reduce N losses, further work will need  
2 to be carried out to reduce the negative effects on subsequent crops which was not  
3 mitigated by applying 60 kg ha<sup>-1</sup> of fertiliser N.

## 1 **Introduction**

2 The return of high nitrogen (N) content crop residues to soil, particularly in the autumn,  
3 can result in considerable environmental pollution. This can arise both from  $\text{NO}_3^-$   
4 leaching to water courses, and from the production of nitrous oxide, which has been  
5 implicated in global warming (Neeteson & Carton 2001). Crop residues containing high  
6 amounts of N are produced by a range of crops, including sugar beet and potatoes, and  
7 typically contain between 100 and 200 N kg ha<sup>-1</sup> (Sylvester-Bradley 1993); the residues  
8 of some vegetable brassicas, e.g. Brussels sprouts, can occasionally exceed 300 N kg ha<sup>-1</sup>  
9 (Rahn *et al.* 1992). On this basis it is estimated that sugar beet, potato and vegetable  
10 brassica residues, produced on 375,000 ha of land (DEFRA 2002) in the UK, contain  
11 45,000 t N. It is important that this valuable resource is retained and re-cycled into  
12 subsequent crops to prevent N losses to the environment. In organic production, there is  
13 an even greater need to retain and manage N from crop residues in the soil crop system  
14 (Watson *et al.* 2002). There is evidence that even when soils are cool, decomposition of  
15 crop residues can still occur rapidly and that mineral-N can be lost from the soil (Rahn *et*  
16 *al.* 2002). Further, where cover crops are planted late, their ability to take up N and  
17 reduce leaching can be small (Weinert *et al.* 2002).

18 Field studies have suggested that short-term rates of N mineralisation and subsequent  
19  $\text{NO}_3^-$  leaching can be minimised by the co-incorporation of paper waste with crop  
20 residues (Vinten *et al.* 1998). Their results demonstrated that there is scope to develop  
21 novel strategies for crop residue management based on the addition of substrates to  
22 directly influence the activities of the decomposer organisms. Such strategies could be  
23 used to either inhibit or stimulate short or long term mineralisation of N and to

1 synchronise N release to the needs of following crops, depending on the nature and  
2 quantity of amendment material added.

3 The addition of readily utilised sources of C to soil has been shown to stimulate  
4 denitrification (Weier *et al.* 1993). Adding amendments which reduce mineralisation of N  
5 might therefore reduce the potential for loss by leaching, at the expense of increased  
6 production of N<sub>2</sub>O. Incubation studies (Rahn *et al.* 2003; Motavalli & Diambra, 1997)  
7 suggested that materials with a high cellulose or lignin content had the greatest potential  
8 to reduce mineralisation of N from sugar beet residues without increasing nitrous oxide  
9 production.

10 The EU Landfill directive 1999/31/EC seeks to reduce the amounts of biodegradable  
11 materials being disposed of to landfill to 50 % of the 1995 values by 2013 which suggest  
12 that the UK will need to identify a different disposal route for between 6 million tonnes  
13 (Mt), by 2010, and 10 Mt by 2013 (The Composting Association 2003); one option is that  
14 the material should be spread on agricultural land. However there are constraints on  
15 application of such materials to agricultural land, (Directive 75/442/EEC amended by  
16 91/156/EEC). It must be shown that they are spread on land without endangering human  
17 health and that they provide an agricultural benefit to the soil. The application of some of  
18 these biodegradable wastes to agricultural land may not only have the potential to reduce  
19 NO<sub>3</sub><sup>-</sup> leaching to comply with the EU Nitrate directive (91/676/EC) but may also assist in  
20 helping to reduce the quantities of biodegradable wastes going to landfill. The effects of  
21 such materials need to be understood in designing appropriate Action Programmes in  
22 Nitrate Vulnerable Zones in fulfilment of this directive.

23 The objective of this research was to investigate the potential benefits of using  
24 biodegradable materials, including materials that might be diverted from landfill such as

1 paperwaste, as amendment materials to reduce N losses from high N content crop  
2 residues incorporated into agricultural soils.

3

#### 4 **Materials and methods**

##### 5 *Experimental site and soil properties*

6 A field experiment was set up to test the effects of the most promising treatments from an  
7 earlier laboratory incubation experiment (Rahn *et al.* 2003) which investigated the effect  
8 of a broader range of materials on potential N losses from sugar beet leaf residues  
9 incorporated into soil. The experiment was carried out at Wellesbourne, Warwickshire,  
10 England on a sandy loam soil of Dunnington Heath series (Whitfield 1974), chromic  
11 luvisol (FAO 1998). The soil had a pH of 6.4 with exchangeable P and K concentrations  
12 of 83 and 160 mg l<sup>-1</sup>, respectively, as determined using standard analytical methods  
13 (MAFF 1986). The experimental area had been cropped with winter barley and winter  
14 wheat in 1997/8 and 1998/9 respectively. The site was fertilised with compound fertiliser  
15 supplying 60 kg/ha P<sub>2</sub>O<sub>5</sub> in autumn of each year and 60 K<sub>2</sub>O in 98 and 90 in 99 and 75 in  
16 2000.

17

##### 18 *Experimental design*

19 The experiment was set up to investigate the effect of co-incorporation of sugar beet  
20 leaves with 6 organic amendments. The treatments were as follows:

- 21 1. No residues or amendment material
- 22 2. Sugar beet residues only (control)
- 23 3. Molasses (a by-product from sugar beet refining)
- 24 4. Compactor waste (a recalcitrant waste product of waste paper recycling)

- 1           5. Double rate compactor waste (7.5 t ha<sup>-1</sup> C)
- 2           6. Compost (composted local authority green waste)
- 3           7. Paper waste (from the paper recycling industry).
- 4           8. Wheat straw (grown at Warwick WHRI)

5           Treatments 3-8 also received the same amount of sugar beet residues as treatment 2.

6           Amendments were incorporated on the 7th October 1999 with all treatments and on  
7 14 January 2000 where treatments 1, 2 3 and 5 were applied to different plots..

8           For the first season treatments were arranged in four randomised blocks and each plot  
9 was 8 \* 3.6m . In the second season, 2001 two of the experimental blocks received  
10 fertiliser and two blocks remained unfertilised.

11           Statistical analysis was carried out using Genstat (Payne et al 2007) In the first  
12 season the analysis was based on 11 treatments and 4 replicates providing 33 df for the  
13 estimation of error. In the second season where N was applied to the blocks a spit plot  
14 analysis was used where the number of degrees of freedom for fertiliser applied was 2,  
15 and for the amendment treatments was 22.

16

#### 17           *Amendment materials*

18           The amendment materials were selected for their differences in biochemical quality  
19 and their potential N immobilising ability (Table 1). Materials with a wide C:N ratio were  
20 selected to immobilise N and those of a narrow C:N to stimulate net mineralisation.  
21 Materials were also chosen because of ready availability. Two types of paperwaste were  
22 selected for their potential N immobilising capacity; these were 'compactor' waste and  
23 'paper' waste, which were obtained from the cardboard and paper recycling industry  
24 respectively. Wheat straw was collected from a recently harvested field at WHRI

1 Wellesbourne. For narrow C:N materials, compost was obtained from Worcestershire  
2 County Council and liquid molasses from the sugar beet refining industry. Although also  
3 sold as an animal feed, molasses was chosen for its high carbohydrate content and  
4 potential to stimulate rapid microbial growth and decomposition.

5

6 The amendment materials were applied at amounts intended to supply 3.7 t C ha<sup>-1</sup>,  
7 although the actual rate varied between 3.2 and 3.8 t C ha<sup>-1</sup> (Table 1). It was assumed that  
8 only one third of the carbon would be biochemically active and that the soil microbial  
9 biomass had a C:N ratio of 7:1, similar to that used for unamended soils (Joergensen &  
10 Raubach, 2003; Ocio & Brooks 1990, Jenkinson 1988), so it was calculated that 181 kg of  
11 N would be immobilised by adding the amendment materials. Dry amendment materials  
12 were spread by hand while the molasses was diluted with water and sprayed on to ensure  
13 even coverage. The amendment materials were co-incorporated with 42 t ha<sup>-1</sup> of fresh  
14 sugar beet leaves (containing 117 kg ha<sup>-1</sup> N) in October 1999. Treatments 1, 2, 3 and 5,  
15 were repeated in January 2000 with 41 t ha<sup>-1</sup> as fresh sugar beet leaves (containing 191 kg  
16 ha<sup>-1</sup> N). The leaves of sugar beet were obtained from a commercial crop grown on a  
17 neighbouring farm. The chemical composition of the two batches of leaves did not differ  
18 significantly. The quality characteristics of the sugar beet used in October 1999 is shown  
19 in Table 1. Materials were co-incorporated to a depth of 20 cm using a mechanical  
20 spading machine. Treatments were arranged in four randomised blocks and each plot was  
21 8 x 3.6 m.

22

23 *Chemical quality of amendment materials*

1 The characteristics of each material were determined by measuring carbohydrates,  
2 cellulose and lignin content using a proximate analysis based on H<sub>2</sub>SO<sub>4</sub> hydrolysis, as  
3 described by Rahn *et al.* (1999). Water-soluble phenolics and total C:N ratio were  
4 determined as described in Bending *et al.* (1998). The analyses were carried out on  
5 triplicate samples. The characteristics of materials used for the October and January  
6 incorporation dates were similar. Data from material used for the October incorporation  
7 date is shown in Table 2.

8

### 9 *Soil sampling and analysis*

10 Levels of mineral-N to 90 cm were measured on all plots on 4<sup>th</sup> October, 21<sup>st</sup>  
11 October, 7<sup>th</sup> December in 1999, 10<sup>th</sup> January, 14<sup>th</sup> April, 1<sup>st</sup> and 15<sup>th</sup> November in 2000,  
12 14<sup>th</sup> of March and 20<sup>th</sup> of August 2001. Two soil cores were taken from three layers (0-30,  
13 30-60 and 60-90 cm) per plot. Nitrate and ammonium concentrations were determined  
14 using continuous flow analysis (MAFF 1986) after extraction with 0.5 M K<sub>2</sub>SO<sub>4</sub>.

15 Following the October incorporation, overwinter leaching was estimated using  
16 porous cups (three per plot) on treatments 1-4 which allowed the NO<sub>3</sub><sup>-</sup> concentration of  
17 water draining below 60 cm to be determined during the winters of 1999/2000, 2000/2001  
18 and 2001/2002. Cups were sampled after every 25 mm rainfall after the onset of field  
19 capacity and drainage volume was assumed to equal rainfall after field capacity had been  
20 reached. The results were interpreted using methods described in Lord *et al.* (1993).

21 Losses of N<sub>2</sub>O were assessed following the October and January incorporation dates  
22 using four automated closed chambers provided by Scottish Agricultural College with  
23 single chambers being used on treatments, 1, 2, 3 and 5 following the incorporation of

1 residues and amendments in October and January. The procedures for operation of these  
2 units and analysis of samples were as described by Scott *et al.* (1999).

3

#### 4 *Crop growth and uptake of N following residue and amendment incorporation*

5 The mineral-N remaining after two consecutive winters was assessed by drilling spring  
6 barley on 4<sup>th</sup> of May 2000 (cv. chariot) and 19<sup>th</sup> April 2001 (cv. Pearl), respectively. No N  
7 fertiliser was applied in 2000, but in 2001, 60 kg ha<sup>-1</sup> N as NH<sub>4</sub>NO<sub>3</sub> was applied to two of  
8 the four experimental blocks on 27<sup>th</sup> April 2001.

9 Yield and total N uptake of the two cereal crops was determined in order to estimate the  
10 recovery of N from the co-incorporated materials and soil samples were used to assess the  
11 continuing potential of the amendment materials to immobilise N mineralised during the  
12 spring and early summer of 2001.

13 Yield was determined by plot combine on 29/08/00 and 16/08/01, harvesting at least  
14 11.2 m<sup>2</sup> per plot, from which area all grain straw and stubble was collected and weighed.  
15 Sub-samples of at least 100 g were taken for drying at 80°C for 48 hours. The N content  
16 of the dried material was determined by total combustion using a C/N autoanalyser (Leco  
17 Corporation, Michigan, USA).

18

## 19 **Results**

### 20 *Soil mineral-N*

21 Prior to the incorporation of the amendment materials in October 1999, mineral-N in the  
22 0-30 layer was 29.7 kg ha<sup>-1</sup> (Figure 1). Within a month of the incorporation of sugar beet  
23 residues, soil mineral-N levels had increased by over 6 kg ha<sup>-1</sup> in comparison to soils  
24 receiving no residue, and levels remained elevated until April 2000. Where molasses were

1 co-incorporated with the sugar beet residues, there was rapid mineralisation, with  
2 mineral-N levels being 10 to 15 kg ha<sup>-1</sup> higher than the sugar beet alone treatment  
3 between a month and 6 months following incorporation. Levels of mineral-N following  
4 co-incorporation of compactor waste were 20 kg ha<sup>-1</sup> lower than the soil receiving sugar  
5 beet residues alone by mid November 1999, although by April 2000 amounts of mineral-  
6 N at 0-30 cm depth had returned to levels found in the sugar beet alone treatment.

7 In April 2000, six months following incorporation, analysis of soil mineral-N at 0-90  
8 cm depth showed that the addition of sugar beet residue had increased mineral-N levels  
9 by 16 kg ha<sup>-1</sup> (Table 2). In comparison to soil receiving sugar beet residues alone, co-  
10 amendment with straw and compactor waste reduced soil mineral-N by 25 and 15 kg ha<sup>-1</sup>  
11 respectively, with the double compactor waste reducing mineral-N by 36 kg ha<sup>-1</sup>.  
12 Paperwaste had no net effect on mineral-N, while molasses and compost increased soil  
13 mineral-N by 46 and 11 kg ha<sup>-1</sup>, respectively. The January incorporation of molasses and  
14 compactor waste had similar effects on soil mineral-N as the October incorporation.  
15 Amounts of mineral-N in April following the October incorporation were significantly  
16 correlated ( $p > 0.05$ ) with concentrations of lignin and cellulose in the amendment  
17 materials ( $r = -0.91$  and  $-0.86$  respectively).

18 Following the October incorporation, soil mineral-N levels to 90 cm depth were around  
19 60 kg ha<sup>-1</sup> N, in the November/March of 2000/01 and were not significantly affected by  
20 the amendment materials or sugar beet residues incorporated in the autumn of 1999.  
21 Similarly following harvest in August 2001 there were no significant effects of  
22 amendments, or fertiliser on the mineral-N level in the 0-90 cm soil layer, which  
23 remained around 60 kg ha<sup>-1</sup> N (data not shown).

24

1 *Leaching losses*

2 For the October incorporation, compared to soil which received no residues, incorporation  
3 of sugar beet alone reduced amounts of N leached between Nov-Dec 1999, but increased  
4 amounts leached between Jan-Feb 2000 (Table 3). Compared to the sugar beet alone  
5 treatment, molasses increased, and compactor waste decreased, the N concentration of  
6 leachate. The increased leaching following molasses incorporation was evident from the  
7 first sampling date in November 1999 and continued until February 2000. For compactor  
8 waste, leaching losses were higher than the sugar beet alone treatment until December  
9 2000, and subsequently declined to between a half and a third of levels in the sugarbeet  
10 alone treatment.

11 Overall, in the 1999/2000 season there was no significant difference in amounts of N  
12 leached in the no residue and sugarbeet alone treatments, with 56 and 60 kg N ha<sup>-1</sup> lost  
13 respectively. However, leaching losses in the molasses and compacter treatments were  
14 significantly (P<0.001) different to the other treatments, at 72 and 38 kg N ha<sup>-1</sup>. In the  
15 following winter the total amounts of leaching ranged from 29 to 36 kg N ha<sup>-1</sup> with no  
16 significant treatment differences in 299 mm of drainage. There were no significant  
17 differences between treatments. In the 2001/02 the second winter after the amendments  
18 were applied the leaching amounts varied from 23 – 33 kg N ha<sup>-1</sup> and not significantly  
19 different in 124 mm of drainage. The application of 60 kg N ha<sup>-1</sup> did not significantly  
20 affect the amounts of N leached.

21 *Gaseous losses of N*

22 N<sub>2</sub>O losses were monitored for both the October 1999 and January 2000 incorporation  
23 dates on selected treatments using un-replicated chambers. Treatment effects on N<sub>2</sub>O  
24 losses were similar at the two sampling dates, and only data from January 2000 is shown

1 (Fig 2). Following January incorporation, there were peaks in evolution of N<sub>2</sub>O from the  
2 soil alone treatment after 36 and 72 hours, with peaks of 300-400 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup> . In the  
3 sugar beet treatment, there were peaks in N<sub>2</sub>O production evolution after 72 and 144 h,  
4 with peaks of 700 and 350 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup> evolved. In the sugar beet plus compactor  
5 treatment, there was a single peak 150 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup> after 72 h, with. In contrast, N<sub>2</sub>O  
6 losses in the molasses treatment were substantial, with a peak of over 1500 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup>  
7 <sup>1</sup> after 36 h, with levels remaining above 200 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup> until 120 h, when there was  
8 a sharp increase to 2800 µg N<sub>2</sub>O m<sup>2</sup> hr<sup>-1</sup>. Levels of N<sub>2</sub>O returned to those seen in the other  
9 treatments only after 218 h. The overall amounts of N lost as N<sub>2</sub>O were at most 3 kg ha<sup>-1</sup>  
10 over the entire period of monitoring where molasses had been co-incorporated.

11

### 12 *Grain Yield*

13 Following the October incorporation, sugar beet residues increased grain yield by 12 %  
14 relative to unamended soil at the first season after incorporation, in 2000 (Table 4). Co-  
15 incorporation of paperwaste and molasses with sugar beet increased yield by a further 11  
16 and 20 %, respectively. Straw and compactor waste reduced grain yield by 47 and 21 %,   
17 respectively, while the double compactor treatment reduced grain yields by 63 %  
18 compared to sugar beet residue alone. Following January incorporation, yield in the  
19 absence of residues or amendments was only 1.6 compared with 2.1 t ha<sup>-1</sup> with October  
20 cultivations. Yield was increased markedly by sugar beet incorporation. Compactor waste  
21 reduced yield by 53 % and the application of molasses increased yield, but only by 8 %  
22 compared with residues alone.

23 Cellulose and lignin content of the amendment materials were significantly (P<0.05)  
24 correlated with grain yield (r= -0.85 and -0.83 respectively). Variations in yield were

1 significantly correlated ( $r=0.90$ ,  $P<0.05$ ) with soil mineral-N in April which were also  
2 related to lignin and cellulose contents. As the concentrations of cellulose and lignin in the  
3 amendment materials increased, yield decreased by  $0.4 (\pm 0.1)$  and  $0.3 (\pm 0.09)$  t ha<sup>-1</sup>  
4 respectively, for 100 mg g<sup>-1</sup> cellulose and lignin respectively, (Figure 3a, 3b).

5 In 2001, where no new N fertiliser had been applied there was a 21 % decrease in  
6 barley yield where no sugar beet residues had been incorporated in 1999, relative to soil  
7 that had received sugar beet residues (Table 4). Where the single rate of compactor and  
8 straw were incorporated, grain yield was reduced by 20 %. However, where the double  
9 rate of compactor was applied, yield was only reduced by 3 %. Incorporation of molasses,  
10 compost and paper waste increased grain yield by 28, 41 and 38 %, respectively. Where  
11 amendments and residues had been incorporated in January the patterns were different,  
12 with yield being boosted by both molasses (+239 %) and compactor waste (+50 %).

13 Where 60 kg ha<sup>-1</sup> N fertiliser had been applied to the October 1999 treatments, the  
14 effects of the amendments on yield were smaller compared to where no N had been  
15 added, with the differences in grain yield compared with sugar beet residues alone -14, -  
16 13, -16, +6, +16, -1, -4 % for no residue, compactor waste, double rate compactor,  
17 molasses, paper waste compost and wheat straw, respectively. With January incorporation  
18 there were increases in yield of 4 and 27 % respectively where compactor and molasses  
19 had been applied.

20 Following October incorporation variations in yield in the second cereal crop in 2001  
21 were again significantly ( $P<0.05$ ) correlated with the cellulose content of the amendment  
22 materials ( $r= -0.90$ ). Figure 5a shows the effect of increasing concentrations of cellulose  
23 in the amendment materials on yield, with and without fertiliser applied. The slope of the  
24 relationships was not affected by the application of fertiliser N. When both lines are taken

1 into account over 96% of the variance in yield is accounted for (df =9). For every 100 mg  
2 g<sup>-1</sup> increase in concentration of cellulose, yield was reduced by 0.11 (± 0.02) t ha<sup>-1</sup>,  
3 correspondingly increased lignin contents reduced yield by 0.12 (± 0.04) t ha<sup>-1</sup>. This data  
4 indicates that the amendment materials were still having an effect on yield in 2001, but  
5 that it was up to four times less than seen in 2000.

6

7

#### 8 *N Uptake*

9 At the first harvest of spring barley in 2000 the variation in plant N uptake was closely  
10 related to grain yield (r<sup>2</sup>=0.94). Compared to application of sugarbeet alone, compost,  
11 compactor, double compactor and straw reduced N uptake by 9, 25 63, and 48 %  
12 respectively (Table 5). In contrast, molasses increased N uptake by almost 32 %.  
13 Paperwaste had no effect on N uptake. Where sugar beet had been incorporated in  
14 January, N uptake was similar to that taken up following the October incorporation.  
15 Compactor waste reduced N uptake by 55 %, and molasses stimulated N uptake by 9%  
16 Plant N uptake at the 2000 harvest was significantly (P<0.05) correlated with lignin and  
17 cellulose (r=-0.88 and -0.83 respectively) N uptake was reduced by increasing  
18 concentrations of lignin or cellulose, falling by 9 (±2) and 6 (±2) kg ha<sup>-1</sup> for each 100 mg  
19 g<sup>-1</sup> change in concentration respectively.

20 At the second harvest in 2001, N uptake was reduced by 24% where no residue had been  
21 incorporated, compared to the control with sugar beet alone (Table 5). Incorporation of  
22 compactor and double compactor reduced N uptake by 13 and 15% respectively. Addition  
23 of paperwaste and compost increased N uptake by 31 %, and molasses by 21%. Where

1 amendments and residues had been applied in January, compactor and molasses increased  
2 crop N uptake by 30 and 106 % respectively.

3 Where 60 kg ha<sup>-1</sup> N fertiliser had been applied, N uptake was significantly increased,  
4 and the effects of the amendment materials on N uptake were smaller relative to when no  
5 fertiliser had been applied. Where residues had been incorporated in October, molasses  
6 and paperwaste increased N uptake by 4 and 16 % respectively. Single and double  
7 compactor waste reduced N uptake by 14 and 18 % respectively. Where amendments  
8 were incorporated in January, compactor and molasses waste increased N uptake by 14 %  
9 and 33 % respectively.

10 N uptake at the 2001 harvest, like yield, was significantly correlated to cellulose content,  
11  $r = -0.93$ ,  $P < 0.01$ ). Similarly the relationships were not affected by the addition of  
12 fertiliser N, although the influence of the concentration of cellulose on N uptake at the  
13 2001 harvest was lower than at 2000, with an change in N uptake of 2 ( $\pm 0.4$ ) kg N ha<sup>-1</sup> for  
14 each 100 mg g<sup>-1</sup> change in cellulose concentration (Figure 4b).

15

#### 16 *N Balance during growing season*

17 During 2000, straw, compactor waste and paperwaste had no effect on the net N balance  
18 between April and harvest (Table 6). However for the molasses and compost treatments  
19 there was a large negative N balance, which amounted to -33 and -27 kg N ha<sup>-1</sup>  
20 respectively, indicating that large amounts of net immobilisation had occurred. Net N  
21 balance was significantly correlated with % N, cellulose and lignin content ( $r = -0.88$ ,  $-0.82$   
22 and  $-0.88$  respectively). More N was immobilised following incorporation of materials in  
23 January although there were no significant differences between treatments.

1 In the 2001 season, in the absence of fertiliser-N all treatments showed a positive net N  
2 balance. In the October treatments, in plots without N fertiliser, N balance for compost  
3 and compactor were 12 and 14 kg ha<sup>-1</sup> higher than for the sugarbeet alone treatment, but  
4 there was no significant difference with the other treatments. N balance was higher for the  
5 January incorporation, and both molasses and compactor waste resulted in an elevated n  
6 balance relative to the sugarbeet alone treatment.

7 Applying fertiliser-N led to largely negative N balances, suggesting N immobilisation,  
8 although netN was still mineralised where sugar beet or sugar beet and paperwaste had  
9 been incorporated. With October incorporation more N was immobilised where  
10 compactor waste had been incorporated or in the absence of residues. Similar results  
11 were seen for the January incorporation.

12

### 13 **Discussion**

14 The data clearly demonstrates that co-incorporation in the field of crop residue  
15 materials with a broad range of materials with different chemical properties can have a  
16 significant impact on soil N cycling processes, and in particular, that the size and  
17 direction of the impact is predictable and largely dependent on the lignin and cellulose  
18 content of the amendment material.

19 Several laboratory studies have investigated the effect of amendments of varying  
20 composition and complexity on mineralization of N from crop residues. Vinten *et al.*  
21 (2002), used incubation experiments in which residues were co-incorporated with pure  
22 cellulose, glucose or straw as sources of C. In common with high C:N ratio materials in  
23 our study, they noticed substantial initial immobilisation of mineral-N which was largest

1 from glucose followed by cellulose and straw. In contrast, lower C:N materials such as  
2 molasses showed no such immobilisation.

3 The effects of the amendment materials on net N mineralization following  
4 incorporation of sugarbeet residues were similar to those in an earlier laboratory  
5 incubation study (Rahn *et al.* 2003). Decreased net mineralization caused by several  
6 materials, including compactor waste, was explained, at least in part, by increasing  
7 immobilisation of N into the biomass. In the experiments of Vinten *et al.* (2002) the  
8 immobilisation of all N could not be explained by bacterial biomass, but where cellulose  
9 content was higher more fungal biomass appeared to have been responsible for the  
10 immobilisation.

11 Our data confirm the results from earlier laboratory incubation experiments using the  
12 same materials (Rahn *et al.* 2003) and those of Motavalli & Diambra (1997), in which  
13 total N, lignin, cellulose, C:N and cellulose:N ratios were shown to be appropriate to  
14 estimate net mineralisation following co-incorporation of paperwaste and other waste  
15 materials with crop residues into soil. In addition our findings support those of Vinten *et*  
16 *al.* (1998) where the release of N was based on the decomposability of carbon compounds  
17 contained in paper mill sludge, and not simply on C:N ratio.

18 In common with our study, Vinten *et al.* (1998) also identified large reductions in N  
19 leaching with the addition of paper mill waste to soils in the first season after application.  
20 There is clearly some potential for longer term consequences of repeated application of  
21 such wastes, with the possibility that immobilised N could stimulate out of season  
22 mineralisation and increase NO<sub>3</sub><sup>-</sup> leaching in the longer term. However our data showed  
23 no evidence that any of the materials stimulated additional leaching in the second winter.

1 In earlier laboratory incubation experiments with these amendment materials, Rahn *et*  
2 *al.* (2003) showed that co-incorporation of molasses with sugarbeet residuess stimulated  
3 N<sub>2</sub>O formation for less than 24 h relative to soil receiving sugar beet residues, with  
4 amounts of N<sub>2</sub>O produced depending on soil type, with higher quantities in a sandy-loam  
5 relative to a clay-loam. Similarly, Yang *et al.* (2002) found rapid increases in N<sub>2</sub>O  
6 emissions immediately following incorporation of composts and manures into soil.  
7 Furthermore, in laboratory incubation studies Chaves *et al.* (2005) found that a variety of  
8 high C:N materials including sawdust and green compost compost reduced N<sub>2</sub>O  
9 production during decomposition of celery residues, although a low C:N ratio paperwaste  
10 material increased N<sub>2</sub>O production. Increased emission of N<sub>2</sub>O following co-  
11 incorporation of narrow C:N paperwastes with crop residues has been shown several  
12 times (Vinten *et al.* 1988; Baggs *et al.*, 2002). Denitrification is dependant on various  
13 parameters, including the availability of NO<sub>3</sub><sup>-</sup>, labile organic compounds, and the  
14 N<sub>2</sub>O/NO<sub>3</sub><sup>-</sup> ratio (Weier *et al.* 1993). The stimulated production of N<sub>2</sub>O by low C:N  
15 substrates, including molasses in the current study, clearly reflects the rapidly  
16 decomposable nature of these materials. The reduced denitrification that can occur  
17 following addition of high C:N ratio materials, including compactor waste (Rahn *et al.*,  
18 2003; Chaves *et al.* 2005) probably reflects immobilisation of NO<sub>3</sub><sup>-</sup> within the microbial  
19 biomass during decomposition (Beauchamp, 1997). Whilst the losses measured in our  
20 study were agronomically small even where molasses was applied N<sub>2</sub>O is a potent  
21 greenhouse gas IPCC (2006)

22 In the study of Aitken *et al.* (1998) the application of 100 t ha<sup>-1</sup> of de-inked paper mill  
23 sludge (DPMS) with C:N of 86 reduced cereal yield one year after application. However,  
24 in the second year there were no significant effects on grain yield, and by the third season

1 more soil N was seen where DPMS had been applied suggesting some remineralisation of  
2 N. Vagstad *et al.* (2001) showed that barley yields increased following the incorporation  
3 of static piles of paper waste into soil in Norwegian field studies, although these materials  
4 had a narrow C:N ratio (20:1). Where paperwaste materials had a wider C:N ratio (30:1),  
5 grain yields of the following crop were reduced. These effects were only observed in the  
6 first year after incorporation, and yield effects were small in following seasons. In our  
7 experiments, where high C:N compactor waste had been applied there were still  
8 reductions in yield at the second crop harvest even where fertiliser had been applied.  
9 However, there was evidence for remineralisation and enhanced grain yield in soil  
10 receiving materials of lower lignin content such as paperwaste, molasses and green  
11 compost. Motavallii *et al.* (2000) also found that where wide C:N (1235) paperwastes had  
12 been incorporated into field soils there were similar yield reductions, with an estimated  
13 fertiliser N application of over 250 kg ha<sup>-1</sup> needed to overcome the yield reduction.

14 In the second growing season the correlations between the quality of the organic  
15 matter in the amendments and net N mineralisation were less clear, which suggests the  
16 increasing effects of other factors on N dynamics. One of the factors is likely to be  
17 remineralisation of N. Eriksen (1999) did see increased amounts of remineralisation of N  
18 in his experiments where the highest rates of municipal solid waste had been applied to  
19 soils. Mitchell *et al.* (2000) also showed that seasonal effects on can have a large effect  
20 on N mineralisation with complex interactions between temperature and soil processes.

21 The amounts of carbon incorporated with crop residues needs to be adjusted for  
22 effective reduction of leaching and also to reduce any negative effects on yield and to  
23 control later remineralisation of N. De Neve *et al* (2004) found that the addition of  
24 molasses could be used to stimulate remineralisation of immobilised N in a laboratory

1 study but Chaves *et al.* (2007) demonstrated that it is not easy to stimulate  
2 remineralisation of immobilised materials in the field. Beauchamp (2002) indicated that  
3 there were other aspects of the chemical quality of paperwastes such as their content of  
4 fatty acids and PCBs which should be considered prior to application to land, although in  
5 their samples of deinked paper waste these components were not at a significant level and  
6 composting reduced the levels further.

7

8

## 9 **Conclusions**

- 10 • Where low quality amendment materials were co-incorporated with sugar beet  
11 residues the concentration and amount of N leached in the first winter was  
12 significantly reduced.
- 13 • Where  $\text{NO}_3^-$  leaching was reduced where low quality amendment materials had been  
14 co-incorporated, grain yield of the subsequent cereal crops was reduced.
- 15 • The grain yields and nitrogen uptake in the first season were more closely related to  
16 the quality of the amendment materials as measured by the contents of cellulose and  
17 lignin rather than simple assessment of N or C:N ratio.
- 18 • The cellulose and lignin content in the amendment materials also affected the yields  
19 and N uptake of a second cereal crop but the effects were about a third to a quarter  
20 those seen in the first season. The effect was not mitigated by the application of 60  
21 kg/ha fertiliser N.
- 22 • Whilst the application of amendment materials have the potential to reduce losses of  
23 N, before its wider use experiments will need to be carried out testing the effects of

1 different rates and methods of mixing so that excess N can be immobilised but not in  
2 competition with plant requirement.

1 **Figure legends**

2

3 *Figure 1.* Effect of sugar beet residue and amendments on soil mineral-N (0-30 cm depth)  
4 following incorporation in October 1999. Errors are SED.

5

6 *Figure 2* Nitrous oxide emission (N<sub>2</sub>O) following incorporation of sugar beet residue and  
7 amendments in January 2000. Data reflects single replicates for each treatment

8

9 *Figure 3* Relationships between Grain Yield 1<sup>st</sup> harvest and properties of the amendment  
10 materials, a) acid cellulose, b) Lignin. Trendline shown for October incorporated  
11 amendments (closed symbols) where regression significant ( $p > 0.05$ ). Open symbols  
12 January Incorporated Amendments

13

14 *Figure 4* Relationship between cellulose content of amendment materials with grain yield  
15 of spring barley (4a) and nitrogen uptake (4b) at 2nd harvest. Closed and open symbols  
16 data from October incorporation and January incorporation respectively. Square symbols  
17 with fertiliser, Circles without. Dotted line represents trendline for October incorporated  
18 treatments only with 60kg/ha fertiliser applied in the spring. Solid line – no spring  
19 fertiliser
