24

25 **ABSTRACT** We studied the winter activity of *Aedes albopictus* (Skuse) from  
26 November 2008 to April 2009 in Bat Trang village of Hanoi, Vietnam. We selected 12  
27 houses and collected: (i) adults with BG sentinel traps, (Fontes et al.) pupae from  
28 household water containers, and eggs (iii) with ovitraps. *Aedes albopictus* adults,  
29 pupae and eggs were not collected from early January to early February. Though the  
30 egg hatching probability tended to be initially high at longer day-length, the maximum  
31 probability gradually shifted to shorter day-length, as the observation period elapsed.  
32 When females were reared under long day-length and their eggs were immersed 1 or 5  
33 weeks after oviposition, >50% of eggs hatched within 20 days. However, when  
34 females were reared under short-day length and their eggs were immersed after 1 week,  
35 hatching was suppressed for 60 days. When females were reared under short  
36 day-length, the median hatching day occurred earlier in eggs kept dry for 5 and 10  
37 weeks after oviposition than in those dried for only 1 week. This indicates that the  
38 extended dry periods accelerate egg hatching. Our results showed that hatchability  
39 gradually changed with day-length, suggesting that selection for overwintering is not as  
40 strong relative to *Ae. albopictus* living in the temperate zone, where winter conditions  
41 are less favorable than in tropical and subtropical areas.

42

43 **KEY WORDS** bet-hedging, photoperiod, sub-tropics, hatchability

44

45 Many major insect vectors of human pathogens have become “domesticated,” breeding  
46 in close proximity to humans and seeking human blood-meals (Powell and Tabachnick  
47 2013). The Asian tiger mosquito, *Aedes albopictus* (Skuse), is a major “domesticated”  
48 vector of Dengue and Chikungunya viruses (Reiter et al. 2006). *Aedes albopictus*  
49 colonizes artificial containers, such as used tires and bamboo stalks (Medlock et al.  
50 2012, Bonizzoni et al. 2013), and this species is now cosmopolitan throughout tropical  
51 and temperate zones.

52 The occurrence of *Ae. albopictus* across temperate (Mori et al. 1981) and tropical  
53 (Suwonkerd et al. 1996) latitudes likely implies a diverse set of strategies to deal with  
54 changing environments (Levins 1968). For example, *Ae. albopictus* females from  
55 temperate latitudes, where winter temperatures limit insect development and activity,  
56 lay diapausing eggs when pupae and/or adults are exposed to short day-length at 25°C  
57 (Mori and Wada 1978, Mori et al. 1981). Moreover, *Ae. albopictus* diapausing eggs  
58 have an increased stress resistance that might enhance survival during long-distance  
59 transport, and could partially explain the remarkable success of this species as a  
60 successful an invasive species (Denlinger and Armbruster 2014). In contrast, *Ae.*  
61 *albopictus* populations from subtropical environments lay eggs during the winter, with a  
62 small proportion of eggs hatching without undergoing any diapause (Higa et al. 2007).  
63 Thus, the study of *Ae. albopictus* overwintering in the transition area between  
64 subtropical and temperate environments is critical to understand how life history  
65 strategies could have shaped its invasion of new habitats worldwide (Lounibos 2002).

66 Hanoi is located in northern Vietnam, where minimum winter temperatures  
67 sometimes fall below 10°C (Weatherbase 2013). Temperatures below 10°C imply that  
68 *Ae. albopictus* here could often be below its developmental zero point (Chen and Huang  
69 1988). *Aedes albopictus* is believed to have been originally restricted to Southeast  
70 Asian forests (Smith 1956). Wing morphometrics suggest that Hanoi *Ae. albopictus*  
71 populations are more closely related to those of Japan and Korea than to southern  
72 Vietnam (Morales et al. 2013). Given this, we asked whether *Ae. albopictus* in Hanoi  
73 enters diapause during winter. Specifically, we investigated the field activity of *Ae.*  
74 *albopictus* immatures and adults during the winter and also examined the effect of  
75 photoperiod on egg diapause in the laboratory.

76

77

## Materials and Methods

78 **Meteorological Data.** Daily temperature and rainfall records for Hanoi, from  
79 November 2008 to April 2009 were obtained from the national Center for Hydro  
80 Meteorological Forecasting, Vietnam.

81        **Monitoring of *Ae. albopictus*.** From November 2008 to April 2009 we sampled  
82 *Ae. albopictus* in Bat Trang, a suburb of Hanoi. We monitored 12 houses, which were  
83 sampled biweekly. During each sampling session: (1) All the water-filled containers in  
84 each house were examined for the presence/absence of larvae and pupae. “Container  
85 index” was defined as (the number of positive container  $\times$  100) / the number of total  
86 containers. Small containers such as flower vases were emptied into a cup containing  
87 clean water to collect the immature mosquitoes. Jars and concrete tanks were collected  
88 with the quantitative sampling method that estimates the number of immatures (Knox et  
89 al. 2007). Though Bat Trang is famous for ceramics, we defined pottery left outside  
90 over 2 weeks as discarded. Pupae were collected with pipettes and reared to adults,  
91 which were identified using standard mosquito identification keys (Stojanovich and  
92 Scott 1966). (2) One BG sentinel trap (BioGents, Regensburg, Germany) was placed  
93 in a storeroom of each house for 22h (from 1000 to 0800) to collect adults. (3) An  
94 ovitrap was placed within a 3 m radius of each house. The trap consisted of a plastic  
95 bucket (20 cm diameter, 17cm height) filled with 3 l of water for 1 week. The number  
96 of eggs from eight paper strips (30 cm  $\times$  7 cm) placed inside each ovitrap was counted  
97 under a dissecting microscope.

98        **Experiment 1: Egg Hatching from *Ae. albopictus* Grown under Different**  
99 **Photoperiods.** *Aedes albopictus* larvae were collected from Bat Trang in August 2009  
100 and kept at room temperature. Second-instar larvae were divided into six incubators at  
101 25°C (treatments) with different photoperiods: (1) 9h light: 15h dark, (2) 10h light: 14h  
102 dark, (3) 11h light: 13h dark, (4) 12h light: 12h dark, (5) 13h light: 11h dark, (6) 14h  
103 light: 10h dark to examine the threshold photoperiod of diapause. All adults used in  
104 this experiment were confirmed as *Ae. albopictus* before oviposition started. Eggs  
105 were collected from females reared in each incubator. Eggs were also dried for two  
106 days, and kept in each incubator for five days prior to the hatching experiment. For  
107 the experiment, we prepared 8 cups that contained 20 eggs each per treatment, eggs  
108 were submerged in deionized water, and repeated twice. During the 100 d observation  
109 period for egg hatching, water was changed every day and eggs were kept at 25°C.  
110 Unhatched eggs were dissected under a microscope to examine embryonation.

111        **Experiment 2: Egg Hatching from *Ae. albopictus* Grown at Different**  
112 **Photoperiods, with Different Post-oviposition Age and Hatching Photoperiod.**  
113 Eggs from *Ae. albopictus* raised at 25°C in the following two photoperiods: (1) 10 h  
114 light: 14h dark (i.e., short-day) and (2) 14h light: 10h dark (i.e., long-day) conditions  
115 were removed and dried. They were submerged in plain water 1, 5, and 10 weeks after  
116 oviposition, and hatched under the two photoperiods defined previously, i.e., short-day

117 and long-day. The resulting treatments, i.e., the combination of *Ae. albopictus*  
118 development photoperiod until oviposition and post-oviposition age, were conducted  
119 using 20 eggs per cup. Hatching was observed for 100 d in all the treatments, each  
120 treatment comprising 12 cups. After 100 d immersion, unhatched eggs were then  
121 dissected under a microscope to examine embryonation. As in the previous  
122 experiment, all adults used in the experiment were confirmed as *Ae. albopictus* prior to  
123 oviposition.

124 **Statistical Analysis.** To study the critical photoperiod of *Ae. albopictus*, we fitted  
125 a negative binomial generalized linear model (Venables and Ripley 2002) to the number  
126 of eggs that hatched in 25 day intervals during the 100 d of experiment 1, as a function of  
127 both day-length and the day when unhatched eggs were counted. We chose a negative  
128 binomial model to account for the over-dispersion in the number of hatched eggs (Mangel  
129 2006). The model and parameter estimates are presented in Table S1.

130 A Kruskal-Wallis rank sum test was used to compare the hatching day of eggs with  
131 different post-oviposition ages in the four different light treatments resulting from the  
132 combination of growing photoperiod and hatching photoperiod of Experiment 2. For  
133 Experiment 2, we also developed an egg hatching hazard model. *Aedes albopictus* egg  
134 hatching ( $eh_x$ ) was estimated daily using the equation  $eh_x = Eh_x/eh_0$ , where  $Eh_x$  indicates  
135 the cumulative number of eggs that remained without hatching up to day X, and  $eh_0$  the  
136 initial number of eggs in each treatment, i.e., 120. Since  $eh_x$  can be seen as analogous  
137 to a survival schedule, daily egg hatching was analyzed using a Cox proportional hazard  
138 model. The Cox hazard model considered the additive effects of light treatment and  
139 the number of weeks eggs were dormant (i.e., post-oviposition age) as covariates  
140 driving the hatching hazards. In the Cox hazard model egg hatching was modeled  
141 using a baseline hazard function  $h_0$ , so that the hazard function  
142  $h(t)=h_0\exp(f(covariates(t)))$  measured the proportional increase in egg hatching. When  
143 implementing the Cox hazard model, we only counted the eggs that were still viable  
144 (alive) at day 100 when the experiment finished. We compared whether unhatched  
145 eggs across the range of post-oviposition times and light treatments had similar dead to  
146 alive odds ratios at the end of the experiment (day 100), using a binomial generalized  
147 linear model (Faraway 2006).

148

149

## Results

150 **Field Survey of *Ae. albopictus*.** Mean temperature dropped below 17°C from late  
151 December to early March, with the lowest in late January (Fig. 1A). Precipitation  
152 decreased suddenly from mid-November (Fig. 1B). Though precipitation was above

153 80mm per day in early November, there was little rain from mid-November to  
154 mid-March. Discarded containers were the most abundant container in most  
155 households (Table 1). One household (No. 12) had the highest number of flower vases,  
156 Bonsai, and discarded containers. The mean number of containers with water was 3.0  
157 to 10.6 from November to February and it was above 10 from March to April (Fig. 2A).  
158 There was no correlation between mean number of containers with water and the  
159 precipitation from the previous survey date to the current survey ( $P>0.05$ ). The  
160 container index was highest in early November and then decreased gradually, reaching a  
161 minimum in late February (Fig. 2B). The container index gradually increased from  
162 March onward. Density of pupae per container was low from November to February  
163 and increased from March onward (Fig. 2C).

164 We collected 3,244 *Culex pipiens quinquefasciatus* Say, 102 *Ae. albopictus*, 38  
165 *Armigeres subalbatus* (Coquillett), 21 *Cx. vishuni* Theobald, 14 *Anopheles sinensis*  
166 Wiedemann, 11 *Cx. tritaeniorhynchus* Giles, and 6 *An. tessellatus* Theobald from  
167 November to April by BG sentinel trap. The number of *Ae. albopictus* adults per trap  
168 decreased from November, reaching a minimum in January, and increased from  
169 February onward (Fig. 3). Ovitrap were positive at a rate of over 0.5 until  
170 mid-December, then less than 0.4 from late December to early March (Fig. 4A). The  
171 number of eggs decreased from November onward, nearly reaching zero from late  
172 December to early March, except for late February (Fig. 4B). Both positive rate and  
173 the mean number of eggs increased after late March, though there were fewer eggs in  
174 spring than in autumn.

175 **Laboratory Diapause Experiment.** The egg hatching probability tended to be  
176 high at longer day-length for the 25 d observation period (Fig. 5). However, as the  
177 observation period was extended, the day-length at the maximum hatching probability  
178 was reduced. The hatching probability was highest at an 11 hour day during 75 days  
179 of the observation period in the Experiment 1.

180 When females were reared under long day-length (Long-Long, Long-Short) and  
181 their eggs immersed 1 and 5 weeks post-oviposition, >50% of eggs hatched within 20 d  
182 (Fig. 6A, B). Hatchability of eggs from females reared under long-day conditions and  
183 immersed 10 weeks post-oviposition was between 0.6 and 0.7 after 100 d. When  
184 females were reared under short-day (Short-Long, Short-Short) and their eggs immersed  
185 after 1 week, hatching were suppressed for about 60 days (Fig. 6C, D). When eggs of  
186 short-day females were immersed 5 or 10 weeks post-oviposition, hatchability was  
187 higher than that of 1-week post-oviposition eggs. The Cox Proportional Hazards  
188 model showed that both time post-oviposition and light treatment had an effect on egg

189 hatching (Table 2). When we examined unhatched eggs for embryonation at the end of  
190 the 100 d observation period, both time post-oviposition and light treatment had an  
191 effect on embryonation status (Table 3).

192 The median day of hatching was also significantly different when females were  
193 reared under long-day (Long-Long,  $\chi^2=91.00$ , d. f. =1,  $P <0.001$ ; Long-Short,  $\chi^2=133.21$ ,  
194 d. f. =1,  $P <0.001$ ) (Fig. 7A, B). When females were reared under short-day,  
195 the median day of hatching was earlier in eggs dry for 5 and 10 weeks than those dry 1  
196 week (Short-Long,  $\chi^2=165.67$ , d. f. =1,  $P <0.001$ ; Short-Short,  $\chi^2=318.02$ , d. f. =1,  
197  $P <0.001$ ) (Fig. 7C, D). This indicates that extended time until immersion accelerates  
198 hatching of eggs in diapause.

## 200 Discussion

201 Our results indicate that reproduction of *Aedes albopictus* was markedly suppressed  
202 during winter in Hanoi, although there was some oviposition. The primary reason for  
203 low winter reproduction is that flight activity is reduced, as seen *Ae. aegypti*  
204 (Christophers 1960), as the average air temperature is 17°C and the minimum average  
205 temperature is 12°C in January (Weatherbase 2013). Unlike *Ae. aegypti* which prefers  
206 concrete tanks underground, *Ae. albopictus* prefers containers put outside (e.g. garbage  
207 and flowerpots) (Tsunoda et al. 2014), exposing them to colder temperatures. Data  
208 indicate that *Ae. aegypti* is sluggish below 17°C and flies with difficulty at 12-14°C  
209 (Christophers 1960). Thus, flight activity would seem problematic for *Ae. albopictus*  
210 in January.

211 A second consideration is egg diapause in winter. Geographic variation of the  
212 photoperiodic response is known for North American and East Asian populations of *Ae.*  
213 *albopictus*, and populations collected from Taiwan and Hong Kong do not exhibit  
214 diapause (Hawley et al. 1987, Philippi and Seger 1989). However, though Hanoi is  
215 located at a lower latitude than Taiwan and Hong Kong, our data show that hatchability  
216 of *Ae. albopictus* eggs collected here were affected by day-length, as eggs laid under  
217 short-day delayed hatching. Since the hatching rate of *Ae. albopictus* eggs is low  
218 during winter in Okinawa Island despite a high embryonation rate, they are considered  
219 in “light dormancy” (Higa et al. 2007). Our results suggest the same situation in  
220 Hanoi.

221 Bet-hedging is defined as a strategy, where unpredictably variable environments  
222 favor genotypes with lower variance in fitness at the cost of lower mean fitness (Cohen  
223 1966, Philippi and Seger 1989, Hopper 1999, Ripa et al. 2010). When species do not  
224 have reliable cues for the start of unfavorable environmental conditions, natural

225 selection will favor either genotypes with an obligate diapause commencing before  
226 conditions become unfavorable, or genotypes that produce both diapausing and  
227 non-diapausing phenotypes with or without modification of diapause frequency by  
228 environmental cues (Seger and Brockmann 1987, Hopper 1999). Diapause theory  
229 suggests that in environments with unpredictable lengths of favorable seasons, the  
230 proportion of individuals diapausing should increase during the favorable season as the  
231 likelihood of completing another generation declines. This leads to that a gradual  
232 increase in the proportion diapausing as the season advances, suggesting risk-spreading  
233 as long as the variation in diapause frequency is not genetic (Seger and Brockmann  
234 1987, Hopper 1999).

235 Egg-hatching in *Aedes* mosquitoes is regarded as bet-hedging, since emergence is  
236 often staggered even if environmental conditions are favorable and development is  
237 prepared (Evans and Dennehy 2005). Since a bet-hedging strategy implies an  
238 evolutionary tradeoff between risk aversion and early reproduction, many organisms  
239 may be affected by competing selective pressures for both immediate and delayed  
240 hatch (Khatchikian et al. 2010). Selection for risk-spreading might explain variation  
241 in frequency of diapauses in species with facultative diapause (Walker 1980, Bradford  
242 and Roff 1993, Groeters 1994, Fontes et al. 1995). Assuming a model that considers  
243 genetic variation in the duration of egg dormancy in populations occupying larval  
244 habitats that occasionally become entirely unsuitable, the model shows that a more  
245 catastrophic environment will favor the late-hatching allele, presenting the possibility  
246 for a decline in the intrinsic rate of increase (Denlinger and Armbruster) with an  
247 increase in environmental uncertainty (Livdahl 1979). In *Aedes triseriatus*, both low  
248 precipitation and high variability in precipitation directly increase the delaying pattern,  
249 which is an adaptive bet-hedging strategy that allows the species to manage desiccation  
250 risks (Khatchikian et al. 2010).

251 As precipitation is low during winter in Hanoi, it is reasonable to conclude that  
252 delaying egg hatching under short-day would develop as risk aversion for low and  
253 unpredictable precipitation in winter. Since season and precipitation are closely  
254 related in Hanoi, the delaying pattern would be influenced by day-length. The  
255 sharpness of the photoperiodic response will be greater the larger the standard  
256 deviation from the mean maturation date of a particular generation, which may explain  
257 why mosquitoes, which usually have short generation times, have diapausing fractions  
258 which increase only gradually as the season advances (Cohen 1970). Insects that  
259 were under greater pressure from natural selection for timing of the induction of the  
260 overwintering exhibit a steeper curve through the critical photoperiod (Lees 1968).

261 The strains of *Ae. albopictus* from northern Asia and North America showed higher  
262 overwintering survival rates than the strains from tropical Asia, Hawaii, and Brazil in  
263 field experiments (Hawley et al. 1989). Our results show that hatchability gradually  
264 changed with day-length, suggesting that natural selection for overwintering is not as  
265 strong as in temperate zone *Ae. albopictus*.

266 Our study also showed that *Ae. albopictus* eggs hatched at higher rates as the period  
267 before or after immersion in water was prolonged, suggesting that hatching is  
268 dependent on the energy content of the eggs themselves. Diapausing insects with low  
269 energy reserves have higher mortality during diapause than those with enough energy  
270 reserves (Hahn and Denlinger 2007). Metabolism is proportional to temperature in  
271 diapausing insects (Irwin and Lee 2003). The low temperatures during winter greatly  
272 favor conservation of energy reserves to maintain high survival (Irwin and Lee 2000).  
273 Though diapause is not uncommon phenomenon among tropical insects, metabolic  
274 depression is still important in diapausing insects living here (Denlinger 1986).  
275 When winter temperatures are mild, as in Hanoi, it may be hard for eggs to maintain  
276 low metabolic levels, even if they enter diapause.

Short-Short	0.186	-1.679	0.240	-7.009	2.39E-12*

404 \*Statistically significant, P<0.05.

405

406

407 **Table S1** Negative Binomial generalized linear model parameter estimates employed to  
 408 generate the surface of Fig. 5.

409

Parameter	Estimate	S. E.	z value	Pr(> z )
Intercept ( $\mu$ )	-21.87	4.96	-4.408	<0.0001*
Time ( $\alpha$ )	0.304	0.030	10.02	<0.0001*
Light ( $\beta$ )	2.70	0.81	3.326	<0.0008*
Time <sup>2</sup> ( $\gamma$ )	-0.0008	0.0001	-6.267	<0.0001*
Light <sup>2</sup> ( $\delta$ )	-0.0675	0.0339	-1.988	<0.046*
Time*Light ( $\theta$ )	-0.0161	0.0019	-8.398	<0.0001*
Dispersion ( $\kappa$ )	3.50	0.78		

410 \*Statistically significant (P<0.05)

411 Model fitted had the following structure:

412 
$$E_{hi}(\text{Time}, \text{Light}) = \omega$$

$$\omega = \exp(\mu + \alpha * \text{Time} + \beta * \text{Light} + \gamma * \text{Time}^2 + \delta * \text{Light}^2 + \theta * \text{Time} * \text{Light} + \text{error})$$

413 Where  $E_{hi}$  is the number of hatched eggs at a given time interval (Time) and kept under  
 414 different day lengths (Light), and has a mean equal to  $\omega$ , and a variance equal to  $\omega + \omega^2/$   
 415  $\kappa$ , where  $\kappa$  is the dispersion parameter of the negative binomial distribution. The Akaike  
 416 Information Criterion (AIC) of this model was 423, and was minimum when compared  
 417 with simpler, and more complex, versions of the model presented in the above equation  
 418 (differences were greater than 10 AIC units, also supporting that the model was not  
 419 over-parameterized). Finally, to generate the hatching probability the recorded number of  
 420 eggs and the surface fitted by the model were divided by 240, the number of eggs in each  
 421 treatment at the beginning of the experiment.

422

## Figure legend

423

424

425 Fig. 1. Meteorological data from November 1, 2008, to April 30, 2009, in Hanoi.

426 (A) Daily mean temperature. (B) Daily precipitation.

427

428 Fig. 2. (A) Mean number of containers with water in a household of Bat Trang from

429 early November 2008 to late April 2009. (B) Container index of *Aedes*

430 mosquitoes in Bat Trang from early November 2008 to late April 2009. Number

431 in parenthesis is total number of containers holding water. (C) Mean number of

432 *Ae. albopictus* pupae per container of Bat Trang from late November 2008 to late

433 April 2009. Bars indicate SE.

434

435 Fig. 3. Mean number of *Ae. albopictus* adults collected by BG Sentinel trap in Bat

436 Trang from early November 2008 to late April 2009. Bars indicate SE.

437

438 Fig. 4. (A) Ovitrap positive rate of ovitrap in Bat Trang from late November 2008 to

439 late April 2009. Numbers under x-axis are the collection date. (B) Density of

440 *Aedes albopictus* eggs collected from ovitraps in Bat Trang from late November

441 2008 to late April 2009. Bars indicate SE.

442

443 Fig. 5. Critical photoperiod for *Aedes albopictus* egg hatching. The x axis is the egg

444 day-length during Experiment 1, the y axis the day cumulative hatching was

445 recorded, colors indicate egg predicted hatching probability for different times and

446 day lengths (a color graded scale is at the right of the main plot). Circles represent

447 the observed data, and circle size is proportional to the observed hatching

448 probability, and a reference scale is provided to the right of the main plot. For

449 reference, the black dot in the bottom-left corner of the plot corresponds to a

450 hatching probability of 0.1. Parameters employed for the probability surface

451 construction are presented online only in Table S1.

452

453 Fig. 6. *Aedes albopictus* egg hatching trajectories under different light treatments and

454 post-oviposition times (A) Long-Long light treatment (lt), (B) Long-Short lt (C)

455 Short-Long lt and (D) Short-Short lt. For the post-oviposition times, refer to the

456 inset legend in panel D.

457

458 Fig. 7. Median day of *Aedes albopictus* egg hatching after immersion in water under

459 different day-length. (A) Long-Long, (B) Long-Short, (C) Short-Long, (D)  
460 Short-Short. 'Long' means 14 h light and 10 h dark condition. 'Short' means 10  
461 h light and 14 h dark condition. Combination of day-length (e.g. Long-Long)  
462 indicates the day-length condition of eggs before and during the observation.
