Global change has resulted in chronic shifts in fire regimes. Variability in the sensitivity of tree communities to multi-decadal changes in fire regimes is critical to anticipating shifts in ecosystem structure and function yet remains poorly understood. Here, we address the overall effects of fire on tree communities and the factors controlling their sensitivity in 29 sites that experienced multi-decadal alterations in fire frequencies in savanna and forest ecosystems across tropical and temperate regions. Fire had a strong overall effect on tree communities, with an average fire frequency (1 fire every 3 years) reducing stem density by 48% and basal area by 53% after 50 years, relative to unburned plots. The largest changes occurred in savanna ecosystems and in sites with strong wet seasons or strong dry seasons, pointing to fire characteristics and species composition as important. Analyses of functional traits highlighted the impact of fire-driven changes in soil nutrients because frequent burning favored trees with low biomass nitrogen and phosphorus content and with more efficient nitrogen acquisition through ectomycorrhizal symbioses. Taken together, the response of trees to altered fire frequencies depends both on climatic and vegetation determinants of fire behavior and tree growth, and the coupling between fire-driven nutrient losses and plant traits.

Ecosystem resilience to changing fire regimes[1–3] will be a key determinant of how terrestrial ecosystems respond to global change[3,4]. Fire is a pervasive disturbance, burning ~5% of global land area each year and releasing carbon stored in plant biomass equivalent to 20% of anthropogenic fossil fuel emissions[5]. Historically, much of this carbon is re-sequestered through time as plants recover and regrow, then lost again in the next fire. However, in many systems, changes in climate and land use have shifted fire frequencies, potentially changing the ability of plants, especially trees, to regrow between fires[1,6–8].

Although trees can die or be top-killed in fires, prior studies have presented mixed results for the effect of burning frequency on tree biomass[9–13], highlighting the need to understand the factors leading to different fire effects. Climate extremes can moderate fire effects on trees by influencing both tree growth and mortality as well as fire intensity: sites with strong wet seasons have trees lacking physiological adaptations to burning[14], and sites with strong dry seasons can have intense fires and droughts[15]. Furthermore, trees in different ecosystems respond to changes in fire frequency differently, partly due to fuel load and composition but also their physiology[16].

31 For example, traits conferring physiological protection from heating during fire and/or the

32 capacity to colonize and regrow rapidly could decrease tree biomass losses under frequent

33 burning[13,17,18]. Tests of these hypotheses using observational data are limited by the collinearity

34 between fire regime and environmental variables at individual sites[19,20]; instead, tests require

35 experimental manipulations across broad geographic ranges that are long-term, ideally multi-

36 decadal, because fire-driven mortality and top-kill can take decades to impact the tree

37 community[10,13,21].

38   In addition to external factors, changes within the tree community can modify the effect

39 of repeated fires through the increasing abundance of species more tolerant of the direct and

40 indirect effects of fire. Fire effects may be buffered by the colonization and growth of species

41 with structural traits that avoid heat-induced mortality, but also of those with different nutrient

42 use and acquisition traits that help plants optimize for fire-driven changes in nutrient

43 availability[22,23]. Such shifts in nutrient use and acquisition strategies have ecosystem-level

44 implications, as changes in these traits significantly influence soil nutrient cycling[24,25]. For

45 example, plants that form symbioses with ectomycorrhizal fungi, arbuscular mycorrhizal fungi,

46 or nitrogen-fixing bacteria may be better equipped to access nutrients[26] that can be depleted

47 under frequent burning[22]. The distinction between strategies is key because ectomycorrhizal

48 plants tend to slow nutrient cycling and productivity, while arbuscular and nitrogen-fixing

49 species accelerate it[24–26]. Tissue stoichiometry is also relevant, with species containing lower

50 nutrient concentrations better equipped to tolerate low nutrient supply but in turn contributing to

51 slower nutrient turnover and lower nutrient availability[24,25]. Thus, how fire filters for species

52 with different nutrient use and acquisition strategies can influence long-term site productivity.

53   Here, we evaluate how changes in fire frequency alter tree communities, and how

54 climate, vegetation composition, and soils influence the variability in the sensitivity of trees to

55 changing fire regimes. Furthermore, we quantify how fire changes the distribution of functional

56 traits in the tree community to evaluate nutrient use traits that are indicative of tree responses to

57 fire-driven changes in nutrients. We combined published data with new surveys on tree

58 populations from 29 sites and 374 plots in four continents. At 27 of the sites (324 plots), surface

59 fire frequency was experimentally manipulated for 16-64 years (mean of 30 years), and at two

60 sites (50 plots), natural variation in crown fire frequency presented a natural experiment. We

61 focused on tree responses because of their importance for carbon storage, ecosystem productivity

62 and nutrient cycling[23,27,28]. The sites cover locations in North America (coniferous, deciduous,

63 and mixed forests and broadleaf savanna), South America (tropical savanna and temperate

64 shrubland), Africa (broadleaf savanna), and Australia (wet and dry eucalyptus forests) all of

65 which are ecosystems that experience frequent burning (Figure S1, Table S1, *Supplemental*

66 *Information, SI*). For our main analysis, we define ecosystems broadly based on dominant fuel

67 type (grass vs. litter) and tree functional composition (angiosperm broadleaf vs. gymnosperm

68 needleleaf trees) but test the robustness of our conclusions to other classifications. Each surface

69 fire site contains replicate plots including an unburned treatment and different prescribed burning

70 frequencies (Figure S2), where fire frequencies ranged from approximately one fire every decade

71 to one fire every year (Table S1). We evaluated the effects of fire alone and in combination with

72 environmental covariates using model selection (*SI*) to test the importance of climate, soil, and

73 species composition in modifying the effect of fire.

74   There were clear overall effects of fire treatments on tree population size. Stem density

75 (stems per hectare) and basal area were lower in frequently burned plots relative to infrequently

76 or unburned plots (Figure 1a for effects in each site and 1b for the response ratio across sites). A

77 comparison between the most extreme fire frequency treatments using response ratios illustrated

78 that density and total basal area were 44±25% and 54±25% lower, respectively, in the most

79 frequently burned plots compared with unburned plots. The differences between fire treatment

80 effects were larger when fire frequencies contrasted more (e.g., effect of unburned vs. high fire

81 frequency was 55% greater than the effect of intermediate vs. high fire frequency for both stem

82 density and basal area; Figure 1b,2b, Table S2, errors are 95% confidence intervals). Duration of

83 exposure to altered frequencies was also significant, as sites with longer durations of altered fire

84 frequencies had larger differences between fire treatments, with the slope between duration and

85 community size growing more negative with more frequent burning (density: $F_{1,280}=8.4$,

86 p=0.004, basal area: $F_{1,289}=23.3$, p<0.001; Figure 1c,2c). For example, relative to unburned plots,

87 plots with a three-year fire-return interval had 26% lower stem density and 27% lower basal area

88 after 30 years; the differences increased to 48% lower stem density and 53% lower basal area

89 after 50 years (Figure 1c,2c, Table S3, see Figure S3 for non-transformed results). In annually

90 burned plots, the most extreme fire frequency, burned plots had 63% lower stem density and

91 72% lower basal area than unburned plots after 50 years (Figure 1c,2c, Table S3). Thus, both

92   duration of experiment and prescribed frequency help to reconcile the variable effects of fire

93   across studies. Accounting for these factors illustrates that the effects of changing fire

94   frequencies may take a several decades to become substantial, but the impact of the changes will

95   continue to increase for many decades.

96   Fire type was also important, with frequent crown fires affecting tree populations to a

97   greater degree than frequent surface fires. Comparison of 50 plots in needleleaf forests that

98   experienced natural variability in the frequency of stand-replacing crown fires (i.e., wildfires)

99   illustrated that stands with shorter fire-return intervals had significantly lower tree densities,

100   especially when plots with the shortest return intervals were considered ($F_{1,26.5}$=5.2, p=0.03 and

101   $F_{1,21}$=10.3, p=0.004, Figure S4). Experimental manipulation of surface fire frequency (i.e.,

102   prescribed fires) in needleleaf forests in the USA showed that stem densities were lower in more

103   frequently burned plots, but less so than differences caused by frequent crown fires ($F_{1,47.1}$=17.2,

104   p=0.001, Figure S4). The large effect of short-interval crown fires on tree communities,

105   supported by studies from other regions[29,30], highlights the importance of higher fire intensities

106   having more severe effects.

107   Although fire frequency had a large overall effect on trees, there was substantial

108   variability in the sensitivity across sites. Part of the variability was attributable to fire history

109   prior to the establishment of the experiment. In forest sites that burned regularly in the decades

110   prior to the onset of the experiment, fire exclusion resulted in basal area being 50% (±17%)

111   higher than treatments that maintained historical burning frequencies (p=0.002, Figure S5, Table

112   S1 for site fire histories). In contrast, the reintroduction of prescribed fire into forests that had not

113   burned for several decades prior to the onset of the experiment had relatively minimal effects

114   (p=0.13, Figure S5). These results likely differ from those commonly observed with wildfires,

115   which can have larger effects in forests with a history of fire exclusion due to high fuel

116   accumulation[31,32] because prescribed surface fires are less intense. In savannas, where the fire

117   experiments were all initiated in landscapes that burned regularly in the decades preceding the

118   experiment, fire exclusion resulted in basal area increasing by 41% (±20%), but increasing fire

119   frequency resulted in basal area declining by 48% (±16%), relative to an intermediate interval

120   that maintained the pre-experiment frequency (statistics from log response ratios ±95%

121   confidence intervals, p<0.001 for both, Figure S5, *SI*). Taken together, the largest effects of

122   altered fire frequencies were due to fire exclusion in landscapes, especially savannas, that had

123   burned regularly for the past few decades.

124   Model selection illustrated that climate, vegetation type, and continent played significant

125   roles in explaining the variability in the sensitivity of trees to fire. Fire effects were largest in

126   areas that received more rainfall in the wet season, less rainfall in the dry season, and had lower

127   mean annual temperatures ($F_{1,292.2}$=55.2, p<0.001, $F_{1,284.7}$=9.8, p=0.002, and $F_{1,283.2}$=18.1,

128   p<0.001, respectively) (Figure 3a-c, Table S4, see Table S5 for stem density). For example, plots

129   that experienced more frequent burning (2 fires every 3 years, one standard deviation above

130   mean frequency) had 67% lower tree basal area than unburned plots in sites with high wet season

131   precipitation. In sites with average wet season precipitation, the difference between the same

132   treatments was only 22% (Figure 3a,S6, Table S4, see *SI* for details on calculations). Dry season

133   precipitation had the opposite correlation with fire effects: sites with lower precipitation in the

134   dry season experienced twice as large an effect of fire on basal area (46% vs. 22% lower tree

135   basal area in sites with low vs. average dry season precipitation Figure 3c, Table S4). The

136   contrasting response to precipitation in the wet vs. dry season is consistent with our

137   understanding that fires are most intense in areas with stronger wet seasons (leading to more

138   fuel) and more severe dry seasons (lower fuel moisture), thus contributing to potential losses

139   with more frequent burning[33–35]. Rainfall in the dry season likely also influences fire effects by

140   determining the water available for tree growth when fire is excluded. Neither soil texture nor

141   soil carbon explained the sensitivity to changing fire frequencies across sites (Table S4). Thus,

142   climate was a key determinant of fire effects, with more moderately seasonal sites being the least

143   sensitive to changing fire regimes.

144   The effect of fire on tree basal area also differed across ecosystems, with frequent

145   burning having a larger effect on tree basal area in savannas relative to broadleaf and needleleaf

146   forests ($F_{2,279}$=14.5, p<0.001, model incorporating climate effects; Figure 3d, Table S4). Relative

147   to the unburned plots, basal area in frequently burned plots was 6% lower in needleleaf forests

148   and 22% lower in broadleaf forests (Figure 3d, burn frequency of two fires every three years, *SI*).

149   In savannas, frequently burned plots had 70% lower basal area relative to the unburned plots

150   (Figure 3d, Table S4). Interestingly, stem density responses to fire frequency were qualitatively

151   different between savannas and forests (Table S5). Stem densities increased with more frequent

152 burning in forests while basal area decreased, potentially due to higher light availability and tree

153 recruitment in the forests. To assess the sensitivity of these findings to our classification of

154 ecosystem type, we also tried using a subdivided classification by partitioning broadleaf forests

155 into oak and eucalypt types and needleleaf forests into those that transitioned between oak and

156 pine dominated (Table S1). When included in the final model, the subdivided vegetation

157 classification still had a significant main effect ($F_{4,19.4}=12.4$, $p<0.0001$), and a significant

158 interaction with fire frequency ($F_{4,276.8}=7.8$, $p<0.001$, Figure S8), with basal area in savannas

159 responding the most to changes in fire frequency (Figure S8).

160 Fire-driven changes in basal area and stem density are important for ecosystem function,

161 but fire can also impact ecosystems by changing the functional composition of trees. To address

162 this, we analyzed functional composition in only the experiments from North America (77 tree

163 species, 16 sites, 181 plots) because trait data were available there to (*i*) categorize species by

164 nutrient-acquisition strategies, and (*ii*) assign wood, leaf, and root traits related to growth,

165 survival, and nutrient-use strategies.

166 We found that structural traits were important for explaining cross-site variability in the

167 sensitivity of tree communities to fire. Across sites, frequent burning impacted basal area more

168 where tree species had thinner bark and denser wood (bark: $F_{1,154.3}=5.7$, $p=0.018$; wood density:

169 $F_{1,154.1}=12.9$, $p<0.001$, Table S6, Figure 4a,b). However, within sites, we found mixed evidence

170 that fire filtered for species with different structural trait values. Mean wood density of the tree

171 community tended to be lower in frequently burned plots, potentially because of increasing

172 dominance of gymnosperm trees, which tend to have lower wood density. In contrast, we did not

173 observe any effect of fire on the mean bark investment of the tree community (Table S6),

174 demonstrating that bark investment at the community scale does not appear to change in

175 response to fire. Nevertheless, bark investment helped to predict basal area loss patterns across

176 broad biogeographic scales.

177 We found evidence for compensatory responses in the nutrient use and acquisition

178 strategies of the tree communities under different fire frequencies. On average, plots burned

179 frequently for longer periods of time were dominated by tree species with low nitrogen (N)

180 concentrations in green and senesced leaves and roots, and which resorbed a greater proportion

181 of N before leaf senescence ($p<0.001$ for all variables, Figure 4d, Table S7). This is consistent

182   with the hypothesis that fire-driven soil N losses[22] filters for species with adaptations to low N

183   conditions. Tissue phosphorus (P) concentrations also declined with frequent burning in leaves

184   and litter but not in roots (Figure S10, Table S7). Given that P is less prone to being lost than

185   N[22,36,37], this result was surprising and raises questions about how fire may change the P

186   economy of trees in an opposite way to changes in soil P availability. Taken together, fire filters

187   for species with more conservative nutrient-use strategies in both their leaves and fine roots

188   across several North American savannas and forests.

189   Fire also affected the relative abundance of nutrient-acquisition strategies, evaluated by

190   trees' abilities to form symbioses[38]. Trees that formed symbioses with ectomycorrhizal (ECM)

191   and arbuscular mycorrhizal (AM) fungi were the most abundant nutrient-acquisition strategies

192   across our plots; ericoid and nitrogen-fixing trees were absent from most sites (Figure 4c;

193   categorization based on tree species' taxonomy[38]). ECM trees, which associate with fungal

194   symbionts capable of acquiring N from organic matter[39], tended to be more successful in

195   frequently burned plots. The relative abundance of ECM trees increased from 85% in unburned

196   plots to nearly 100% in annually burned plots (Figures 4c, Table S8). ECM trees were also more

197   common in warmer climates and on soils with low carbon concentrations (Figure S11, Table S8).

198   ECM trees typically have lower concentrations of N and P in leaves, litter, and roots than AM

199   trees[38] (Figure S12, Table S9), suggesting the turnover in symbiont composition may be driving

200   the shift in stoichiometry of the tree community. Since repeated fire tends to decrease inorganic

201   N and N mineralization[23], it makes sense that frequent fire causes the tree community to shift

202   towards species capable of obtaining N from soil organic matter.

203   The tendency for frequently burned plots to have tree communities dominated by ECM

204   species with low N and P content in leaves, roots, and litter indicates that frequent burning favors

205   conservative nutrient use and acquisition strategies. This trend is likely a result of fire-driven soil

206   nutrient losses, which should favor species better equipped to cope with low nutrient

207   environments; however, other factors such as phylogenetic conservatism of traits may be at

208   play[38]. These trait shifts may themselves reinforce an important fire-nutrient feedback if N losses

209   cause a decline in productivity that limits the ability of trees to regrow in between fire events,

210   further decreasing ecosystem N. Our results only unpack one part of this feedback loop (fire

211 effects on traits), and further study is needed to connect changes in strategies with the observed
212 differences in nutrient availability and plant growth.

213   Our analysis also highlights several areas for future work. For one, an improved
214 representation of fire experiments in different ecosystem types across continents in our dataset
215 (e.g., tropical forests in Africa and savannas in Australia) would help further unpack the
216 variability across ecosystems and continents. Second, longitudinal data on how fire effects
217 emerge through time could assist with better understanding how the turnover in tree species
218 composition influences changes in total tree cover within experiments[10,18,40]. Third, considering
219 other plant groups (e.g., herbaceous plants) will help obtain a more comprehensive picture of
220 how shifting fire regimes change the structure of the entire plant community. Finally, the extent
221 of fire effects on plant strategies across temperate ecosystems highlights the need for more
222 studies of plant strategies to consider fire. For example, the effect of fire on fungal symbiosis
223 strategies should be integrated into theories seeking to explain their biogeographic distribution,
224 which generally rely on climatic factors alone[41].

225   Our observation that changing fire frequencies shift both tree basal area and density as
226 well as trait composition is important because it identifies two means by which fire can indirectly
227 alter carbon and nutrient storage in other ecosystem pools, such as soil organic matter. For one,
228 the observed multi-decadal decline in tree populations mirrors multi-decadal shifts in soil carbon
229 and nitrogen[22,23] both in timescale and across ecosystems. The greater rates of change in tree
230 population sizes in savannas and broadleaf forests are consistent with the higher losses of soil
231 carbon and nitrogen reported in those ecosystems relative to needleleaf forests[22,42]. Furthermore,
232 a shift towards conservative nutrient use and acquisition traits is consistent lower N turnover[23,42].
233 Consequently, our findings support hypotheses that fire-driven changes in tree biomass inputs
234 and the turnover of plant traits may both contribute to changes soil carbon and nutrient pools[42–45].

235   In conclusion, widespread changes in fire regimes are likely to shift both the population
236 size and functional composition of tree communities, with both factors affecting the storage and
237 cycling of carbon and nutrients. The effects are not homogenous however, with certain
238 ecosystems being especially sensitive, such as savannas experiencing rapid encroachment of tree
239 cover when fire is excluded. Climatic factors were also key, as regions with extreme
240 precipitation amounts in the wet and dry seasons (high and low, respectively) changed more than

241 areas with moderate precipitation. The effects of fire were not limited to tree population sizes,

242 but also extended to the functional composition of the community. The convergent response of

243 frequent burning promoting conservative nutrient use strategies indicates that fire not only

244 impacts nutrient cycling over decadal timescales, but also suggests that fire likely influences the

245 evolution of these plant strategies. Consequently, climatically sensitive shifts in fire frequency,

246 even when relatively low intensity, will alter the structure and functioning of ecosystems through

247 multiple direct and indirect pathways.

248

249 **Data availability statement:** All data will be made available online following publication or

250 freely available from the authors upon request.

251 **Author contribution statement:** AFAP and RBJ conceived of and designed the overall study.

252 TR, CA, and CT helped with data acquisition and provided feedback on statistical analyses.

253 DGB, AC, WC, CC, JDH, SHE, WAH, JK, TL, WKM, STO, BP, KGP, PBR, CR, MASS, BCS,

254 TS, GRS, KS, CS, MGT, and JMV provided data and/or assisted with interpreting the field data

255 from experiments. All authors contributed to the writing on the manuscript.

256 **Code availability:** Full code will be made available upon request to the corresponding author.

257 However, most of the analyses are conducted using code described in the statistical software

258 packages cited within our manuscript.

290   **basal area.** Partial residual plots of the mixed-effects model illustrating the interactive effects
291   between covariates (site as a random intercept). Panels centered on cross-sectional values from
292   one standard deviations around the median (-1, 0, 1). MAT: mean annual temperature. Partial
293   residual predictions account for the values of all other covariates in the model (i.e., accounting
294   for collinear effects). Comparisons of rainfall scenarios relative to the mean in the text used wet-
295   season precipitation of +1 standard deviation above the mean (525 vs. 375 mm yr^{-1}) and dry
296   season precipitation of -1 standard deviation below the mean (25 vs. 133 mm yr^{-1}). The duration
297   of experiment held at its mean of 28 years. All model fits are p<0.05; statistics are in Table S4.

298
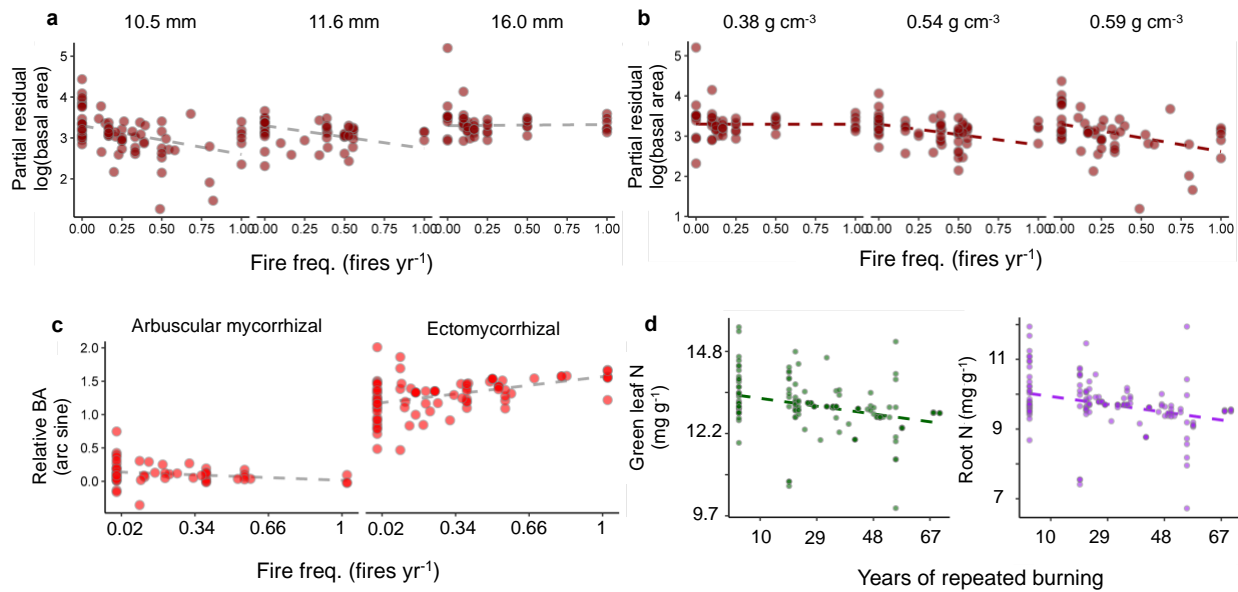

Figure 4

Figure 4: Frequent burning drives turnover in the functional composition of tree communities. Partial regression plots from mixed-effects models with community weighted means of (**a**) bark investment scaled to a 10 cm stem size and (**b**) wood density (WD) as modifying variables. Bark and wood density were included in the same model and were negatively correlated σ = -0.86. Statistics are in Table S6. Basal area is log_e transformed. **c-d**) community weighted means of nutrient acquisition (**c**) and nutrient use (**d**) strategies. **c**) relative basal area (arc sine transformed) of arbuscular vs. ectomycorrhizal trees as a function of fire frequency. **d**) green leaf and live root N as a function of study duration. Statistics are in Tables S7-S9. Data on litter N and resorption are in the Tables and phosphorus content data are in Figure S8.

Supplemental Information

Experimental design and site descriptions

The majority of sites sampled are in ecosystems that experience surface fires (from fire manipulation experiments, n=27). Our main analyses are based on the surface fire experiments, but we compare these data with a network of plots across n=2 sites with natural variability in the frequency of stand-replacing crown fires to evaluate the effect of fire regime. We describe the sites briefly in Table S1, and present detailed descriptions of site history in Dataset 1. Most of the data were obtained from existing studies, but we complemented these data with unpublished surveys in the Sequoia and Kings Canyon sites. We identified these sites first by using a list of sites from a previous meta-analysis of multi-decadal changes in fire frequencies[22]. Not all of the sites in the other study contained vegetation surveys and in some cases the authors of the other studies did not share data. We then complemented these studies with other long-term fire manipulation experiments using a literature search and conference presentations. Finally, data from some of the sites were collected specifically for this study.

The surface fire experiments mostly are experimental prescribed burn plots. The managers generally try to burn in a broad seasonal window (e.g., a spring fire in North America may occur anytime from March-May) to optimize burn timing for the local fire conditions most suitable to their planned fire intensities. Treatments were not applied in a uniform fashion across sites, which is one motivation for using mixed-effects models (see description of our statistical approach below).

The sites contained different land use histories before the establishment of the experiment, which was not always documented in detail, but we describe key factors in Tables S1 and Dataset 1. We describe how we evaluated the potential role of land use history in *Testing role of fire and land use history* below.

Because these experimental sites utilized different survey methods, the classification of a plant as a tree differed. In some cases, such as savannas with relatively small woody plants, all woody plants over a basal diameter of 5 cm were measured (which includes shrubs). In other

340   cases, stems only above 10 cm diameter at breast height were measured. Consequently, the

341   definition of 'tree' is based on the local knowledge of what is the relevant size threshold for a

342   particular ecosystem, and in some cases, it includes all woody plants. Generally, surveys of tree

343   communities were conducted using the standard methods of belt transects, permanent plots, or

344   random sampling along a grid.

345   The stand-replacing crown fires are from one extensive ecosystem type that accounts for

346   a large amount of forest fire area in North American temperate regions. Specifically, we used

347   data from 50 plots in lodgepole pine forest in the Western United States[17] (n=50) spanning

348   different elevations and plots along a continuum of fire return intervals[17]. Because this ecosystem

349   experiences stand-replacing fires, time-since-fire is critical for determining tree abundance

350   because it determines the stage of regrowth. We dealt with this by sampling plots that differed in

351   their fire return interval over the past several hundred years but shared the same time since last

352   fire because of a large fire that burned forests with different times since the previous fire. Given

353   the previous study found elevation to be significant, we included elevation categories in the

354   model (<2400 m and >2400 m, respectively).

355

356   Choice of plots within 27 sites with surface fires

357   Within each site, we only used one sampling time period for our analysis. Eight sites

358   contained time series data: Cedar Creek, Lombard, Sequoia, Kings Canyon, and the four Kruger

359   sites. For Lombard, we used the surveys from 2002, for Cedar Creek we used 2010, for Kruger

360   we used 1996-98 and for Sequoia and Kings Canyon it varied according to the replicate plots

361   because their most recent surveys occurred in different years. For Cedar Creek, more recent

362   surveys exist, but the outbreak of oak wilt has resulted in large amounts of tree mortality not due

363   to fire (Reich *personal communication*). For Highland Rim, we used two different sets of data:

364   the first dataset contains plot-level data (thereby allowing us to determine a variance around the

365   mean) but no tree species identities; the second dataset contains no plot-level data but has

366   treatment-level averages within each tree species, which allowed us to analyze composition

367   changes. We utilized the plot-level data for analyses of basal area and stem density. For Morton

368   and Okmulgee, there are not always true replicates in each fire treatment. Morton contains two

369 true replicates for the unburned, but no true replicates for the burned plots. Okmulgee contains
370 no true replicates.

371   In sites that manipulated burn seasons in addition to frequency, we used a single burn
372 season treatment in the analysis in an attempt to match seasons of burns within a particular
373 ecosystem type within a particular region. Specifically, we excluded certain treatments because
374 we wanted consistency in the season of burning across frequency levels within a site. For
375 example, a site that had three levels of fire frequency, may have two levels of season of burn in
376 only one treatment (e.g., unburned, triennial winter burns, triennial summer burns, and annual
377 summer burns). We kept only the season of burns that spanned all the fire frequency treatments
378 within a site to avoid confounding frequency and intensity within a site. In North America, we
379 standardized fire season to burning conducted in the winter to early spring because not all sites
380 contained fire treatments with summer burns. For Hitchiti, we used the December-March burns,
381 dropping the June burns. For Kisatchie we used March, dropping July and May. For Kruger, we
382 used August, dropping all the other seasons. For Lombard, we used March-May, dropping the
383 June-Aug. Lamto and La Pampa only contained data on the number of tree stems. Consequently,
384 these were incorporated into the stem abundance analysis only.

385

Soil chemistry data

387   We collected and analyzed soil data using several methods. First, we determined the
388 dominant soil type using either author descriptions or reported soil texture analysis. Second, we
389 used the highest resolution soil data as possible (e.g., soil samples from each replicate plot within
390 a fire treatment), but some sites only contained site-level soil properties. Consequently, we
391 analyzed overall effects of fire on all sites without any covariates, followed by a model that uses
392 model selection to account for collinearities among variables when testing for factors that modify
393 fire effects. To extend data on soils across plots, we sampled soils (top 0-5 cm of the mineral
394 horizon) in 24 plots across four sites: Kings Canyon, Sequoia, Limestone Flats, and Chimney
395 Springs. Each site contained three replicate plots of an unburned treatment and a high fire
396 frequency treatment. We collected n=5 pseudo-replicates within the true replicate plot, analyzed
397 the soils for carbon, nitrogen, and texture, and averaged within each plot. For chemical analyses,
398 soils were sieved to <2 mm, dried to constant weight, and ground on a ball mill. Subsets were

399   then analyzed using combustion on an Elemental Analyzer at Stanford University; duplicates

400   were run every 10 samples (analytical accuracy was >90%). Texture was analyzed using the

401   hydrometer method (adopted from the Kellogg Biological Station, Long-Term Ecological

402   Research center website, https://lter.kbs.msu.edu/protocols) on sieved soils.

403

Climate data

405   To obtain long-term climate averages at each site, we used WorldClim[46]. WorldClim

406   integrates data from 1970-2000 across 9,000-60,000 weather stations and spatially extrapolates

407   the values by integrating other covariates from topography maps and satellite data (described in

408   detail in ref. [46]). The timespan of the climate data overlaps the duration of the experiments

409   reasonably well (mean study initiation = 1983; mean survey year = 2006). Managers timed

410   burning to coincide with consistent weather conditions over the course of the experiment,

411   therefore we did not obtain high resolution inter-annual variability in climate. We focused on

412   several climate variables based on ecologically relevant *a priori* hypotheses: (i) precipitation

413   partitioned into the driest and wettest quarters of the year because precipitation influences fuel

414   accumulation (primarily in the wettest quarter) and fire conditions (primarily in the driest

415   quarter) and (ii) mean annual temperature because of its large effect on a variety of

416   biogeochemical processes. Precipitation in wet and dry quarters are not as correlated with one

417   another but are highly correlated with mean annual precipitation and temperature (Table S10).

418

Calculation of fire effects in different environmental conditions

420   Several methods exist to calculate variable importance, with no clear optimal method [47].

421   We chose to use the regression coefficients in the model to understand the sensitivity of basal

422   area and stem density to changes in relative values of each variable. Importantly, the models

423   were fit to re-scaled data by subtracting each value by the mean and dividing by the standard

424   deviation of the variable. Consequently, the product between the mean value of a variable and its

425   coefficient is always zero. Thus, we can compare the relative impact of variables by comparing

426   the magnitude of the fitted coefficients because they reflect the potential change in basal area for

427   a one standard deviation change in a variable value.

428   To perform meaningful comparisons, we use the standard deviations of variables to

429   illustrate the sensitivity of basal area to a change in the value. For example, using the model to

430   estimate the effect of increasing fire by 1 standard deviation from the mean (mean = 0.34, mean

431   + 1σ = 0.67) tells us the sensitivity of basal area to fire, with all other variables held at their

432   means. Interactions can be tested by moving two variables away from their means: for example,

433   changing the fire value in conjunction with precipitation in the wet quarter. Because the model is

434   fit to re-scaled data, the intercept of the model is not representative of the unburned fire

435   treatment, which is calculated by re-scaling the fire frequency data $(0-\mu)/\sigma$, which gives a value

436   of -1.081, making the unburned calculation of 25.6 m^2 ha^{-1} when all other variables are held at

437   their means.

438   Here are the different levels of comparisons we used in the results and the corresponding

439   figures.

440   *Wet season precipitation* (Figure 3a): wet season precipitation varied one standard deviation

441   above the mean vs. at the mean (525 vs. 375 mm yr^{-1}, respectively). Fire frequency varied from

442   unburned to one standard deviation above the mean (2 fires every 3 years).

443   *Dry season precipitation* (Figure 3c): dry-season precipitation was one standard deviation below

444   the mean vs. at the mean (25 vs. 133 mm yr^{-1}, respectively). Fire frequency varied from

445   unburned to one standard deviation above the mean (2 fires every 3 years).

446   *Vegetation type* (Figure 3d): fire frequency effects were made using two levels of comparisons.

447   Unburned plots vs. burning at the mean frequency (1 fire every 3 years) and unburned plots vs.

448   burning at one standard deviation above the mean frequency (2 fires every 3 years).

449

450   **Testing overall fire effects**

451   We first tested the overall effects of the fire treatments across sites with log response

452   ratios using techniques employed meta-analyses[48,49]. First, we calculated the log response ratio

453   between the different fire frequency categories (low, medium, and high) for basal area and stem

454   density averaged within each category, with the lowest fire frequency in the comparison always

455   in the denominator. Next, we determined the variance based on the number of true replicates

456 within each treatment in a site and the standard deviations within the fire frequency category.
457 These values across sites were then used to determine the effects of fire treatments on tree basal
458 area and stem density.

459   We first evaluated the overall effect of fire frequency and duration that frequency was
460 altered on tree basal area and stem density without considering any potential modifying role of
461 covariates. To accomplish this we analyzed (i) a mixed-effects model containing fire frequency,
462 fire period, and their interaction, and (ii) log response ratios of stem density and basal area
463 relativized within each site. We excluded the 50 crown fire plots for this initial analysis. We fit
464 the mixed-effects models with site as a random intercept. The statistical design is nested because
465 each site has several replicate plots receiving different fire treatments. As a result of this design,
466 the responses to fire at the plot level are likely more related within sites than between sites,
467 necessitating a random intercept. Although our design is not balanced (sites differ in their
468 number of replicate plots), models are generally robust to unbalanced designs unless sample
469 sizes are low and/or a random slope is being estimated [47], neither of which are applicable here.
470 Models were constructed based on our *a priori* hypotheses of how fire would influence tree
471 population sizes and the potential to interact with covariates. In all cases of mixed-effects
472 models, we tested for model significance using Satterwaith's approximation for degrees of
473 freedom and a Type III ANOVA [50]. In the event of an insignificant main effect but significant
474 interaction, we tested whether the main effect could be dropped from the model using a change
475 in Aikake Information Criterion (AIC) with a threshold of two.

476

Comparison between surface vs. crown fire regimes

478   To analyze the effect of crown vs. surface fire types, we analyzed stem density data from
479 50 plots (paired within 25 locations) in the Western USA in a separate model. All plots had the
480 same time since fire of 12 years. For this analysis, we used a mixed-effects model to test the
481 relationship between fire return interval and stem density for all locations across the entire return
482 interval span with location as a random intercept. As a further test of fire return interval effects,
483 we selected the short fire return interval (<100 years) in each paired plot and analyzed the
484 relationship with a linear model.

486 **Testing the role of fire and land use history**

487   We partitioned studies into three categories based on their disturbance history. Using

488 knowledge of fire history for several decades prior to the fire experiments, we determined if the

489 fire treatments within a site reflected (i) an increase in fire frequency above a historical mean, (ii)

490 fire exclusion after decades of repeated burning prior to the experiment, and (iii) reintroduced

491 fire after decades of pre-experiment fire exclusion (Table S1); the historical mean was defined

492 based on fire activity data for several decades prior to initialization of the experiment (Dataset 1).

493   The fire experiments in the savannas were all initiated in sites that had regularly burned

494 for several decades before the establishment of the experiment. The intermediate fire frequency

495 treatments were reflective of the historical mean, but the most frequently burned plots in those

496 sites were burned at a frequency higher than the historical mean. Consequently, we could use the

497 intermediate frequency plots to evaluate the relative changes due to fire exclusion (unburned vs.

498 intermediate) or tree cover declines because of more frequent burning (frequent vs.

499 intermediate). In one savanna site, Marondera, all trees were removed before the onset of the

500 experiment, and consequently we are not able to assume that the difference between the

501 intermediate and high frequency treatment is due to declines in trees since the onset of the

502 experiment, rather, it is likely due to a restriction on recovery. Consequently, we omit Marondera

503 from these calculations.

504   The fire experiments in the forests varied in their historical fire frequency and the

505 occurrence of other disturbances. Several sites were in some stage of recovery from previous

506 land use (e.g., selective logging, agriculture, etc.), but we focused on the variability in fire

507 history to categorize the sites into fire response categories. We partitioned forests into those that

508 had remained unburned for several decades before the onset of the fire treatments (i.e.,

509 reintroduction burns) vs. sites that burned regularly before the experiment. We assume that in the

510 case of the reintroduction burns, changes in tree cover arises from losses due to more frequent

511 burning.

512   In the sites that burned regularly prior to the establishment of the experiment, the

513 differences between the unburned plots and those burned at the historical mean was assumed to

514 arise from gains under fire exclusion, and not necessarily increased losses due to frequent
515 burning (although that can clearly occur).

516 We analyze the effect sizes of fire in the comparisons of the unburned vs. intermediate
517 vs. frequent treatments using the same meta-analysis method described above.

518

Model selection to determine parsimonious variable combinations

520 For the plots with surface fires, we performed model selection by incorporating
521 covariates of climate, soil, and plant composition into mixed-effects models to test for pairwise
522 interactions and possible collinearities (see discussion below of collinearities). Finally, we
523 constructed a full model containing fire, climate, soil, and composition variables based on our
524 hypotheses that these factors will interact with fire frequency as well as information gained from
525 the pairwise tests. There were several insignificant effects in the final model, which we tested for
526 removal using model selection with a threshold AIC of two. All variables were re-scaled by
527 subtracting the mean and dividing by their standard deviation.

528 Our selection process in the tables illustrates the sensitivity of the final model to the
529 inclusion of additional interactive effects that are not in the final model as well as main effects of
530 the climate, geography, and soil variables. We do not present the exhaustive comparisons
531 because they are not guided by our *a priori* hypotheses of factors modifying fire effects. Soil
532 type was not reported for one location with stem density measurements in South America, so we
533 just use soil carbon content in the model selection analysis.

534

Evaluating assumptions of aggregating ecosystem types

536 The vegetation composition at each site differs substantially, ranging from diverse
537 tropical savannas with dozens of tree species (e.g., Kruger sites) to monodominant coniferous
538 forests (e.g., Limestone Flats and Chimney Springs). Classifying the sites into broad categories
539 was done methodologically, by balancing the need to maintain parsimony (and thus statistical
540 power) with accurately capturing how plant composition may modify fire effects. Consequently,
541 we performed two levels of classification: (i) a coarse categorization separating savannas vs.

542 forests, and within forests treating broadleaf and needleleaf forests separately, which we refer to

543 as a vegetation type; and (ii) accounting for variability within forest types by partitioning

544 broadleaf forests into Myrtaceae (eucalypt) vs. Fagaceae (oak) dominated, and needleleaf forests

545 into forests that are near completely dominated by needleleaf trees vs. a mixed forest containing

546 both needleleaf and broadleaf trees, which we refer to as a sub-vegetation type.

547

548 **Collinearity among climate variables:**

549 Climate variables can be highly collinear, which can inflate the risk of error in statistical

550 inference. To evaluate collinearity, we first determined the Pearson correlation coefficients

551 between the main climate variables (precipitation in wet quarter, precipitation in dry quarter,

552 mean annual temperature, mean annual precipitation, and aridity). We excluded variable

553 combinations with a correlation >0.70. Most climate variables relating to water availability were

554 not correlated with mean annual temperature. For water availability, we used precipitation in the

555 driest quarter and the wettest quarter because their correlation coefficient was relatively low and

556 they are ecologically more relevant than annual means because they determine the potential

557 productivity in the wet season when most growth occurs but also potential water stress and fire

558 conditions in the dry season (Table S10). In contrast, mean annual precipitation and aridity were

559 tightly correlated with one another, as well as with the precipitation values in the separate

560 quarters. Consequently, we used precipitation in the different quarters (because they are more

561 relevant for fire dynamics and water limitation of tree growth) and mean annual temperature.

562

563 **Species classifications and functional traits**

564 Bark thickness data were collected from a dataset in the Fire and Fuels Extension of the

565 Forest Vegetation Simulator. https://www.fs.fed.us/fmsc/ftp/fvs/docs/gtr/FFEaddendum.pdf .

566 Although broad syntheses of bark investment exist for many tree species in North America, not

567 all species contained data from empirical measurements, and thus we used the data from the Fire

568 and Fuels Extension. Bark thickness was assumed to scale linearly with stem diameter, which is

569 generally valid for smaller stems, but it is known bark saturates with increasing stem diameter [51].

570 The ability of bark investment to predict fire effects will likely improve with better consideration

571   of the non-linear relationship between bark and stem diameter. We evaluate the relative bark

572   investment, and not absolute bark thickness, which is based on bark investment as well as stem

573   size.

574   Wood density was compiled from the literature using a global wood density database [52],

575   supplemented with additional data [53,54]. We assigned a genus-level average for 19 species lacking

576   data.

577   Plant tissue stoichiometry and mycorrhizal type were determined using both trait data as

578   well as phylogenetic trait estimates calibrated to trait data used in a previous global analysis of

579   plant mycorrhizal traits [38]. Full data selection criteria are presented in [38], but we describe them

580   briefly below.

581   The plant phylogeny contained >49,000 plant species [55]. Plant species were added to this

582   phylogeny as needed using the *congeneric.merge* method [56]. This method uses congeners to add

583   species missing genetic data to the phylogeny, conservatively replacing genera with polytomies

584   where more than one member of the genus is present in the analysis. Our North American dataset

585   used for this trait analysis contained 78 species.

586   We next generated a species-level phylogenetically estimated trait value for each species

587   and trait by fitting models to all data for a particular trait as a function of phylogenetic distance,

588   leaving out each species one at a time using the *phyEstimate* function within the picante package

589   for R statistical software[57]. This way, each species trait estimate is based on its own phylogenetic

590   position and a phylogenetic model of evolution (Brownian motion) parameterized without that

591   specific species trait observation. For species without trait data, we estimated trait values based on

592   a model fit to all available trait data. We did not assign trait values to individuals not identified to

593   species or for species in genera lacking any stoichiometry data.

594

Testing the interactions between species composition and fire

596   To test for fire effects on the relative abundance of symbiotic strategies, we calculated the

597   relative basal area of the different strategies (ectomycorrhizal, arbuscular mycorrhizal and the

598   less abundant ericoid mycorrhizal, non-mycorrhizal, and nitrogen-fixing tree species). Given the

599 low occurrences of ericoid, non-mycorrhizal, and nitrogen-fixing species, we analyzed the

600 relative abundance of arbuscular mycorrhizal and ectomycorrhizal species only. We then fit

601 mixed-effects models with relative basal area as the dependent variable and fire, climate, broad

602 vegetation type (broadleaf, needleleaf, savanna), and soil conditions as the independent

603 variables, each modified by a symbiont term. Relative basal area was arcsine transformed. This

604 analysis was conducted in the North American plots.

605   To test how functional traits correlated with the effects of fire frequency and duration of

606 experiment, we calculated community trait means in plot j by averaging the traits of each species

607 i by their relative basal area (BA) in a plot. Bark thickness (Bark) for example:

608
$$\mu_j = \sum_{i=1}^{S} BA_i Bark_i$$

609 We calculated community weighted means (CWM) for wood density, bark thickness, live and

610 senesced leaf nitrogen (N) and phosphorus (P) and live root N and P.

611   We also calculated retranslocation of N and P from a live leaf before senescence using

612 the data from live and senesced leaf N and P (i.e., not directly measured). Calculations using N

613 as an example:

614
$$Retranslocation = \frac{N_{green} - N_{senesced}}{N_{green}}$$

615   Bark thickness was calculated as a scaling coefficient relative to stem diameter (β)

616
$$Absolute\ bark\ thickness = \beta * stem\ diameter + \alpha$$

617 To test the potential for traits to predict the response of trees to fire, we fit linear mixed-effects

618 models with the CWM modifying fire effects but allowing for main effects of fire. For example,

619 $(plot\ basal\ area) \sim FirePeriod + FireFreq + FireFreq{:}WD_{CWM} + FirePeriod{:}WD_{CWM}$
620 $+ FireFreq{:}BT_{CWD} + FirePeriod{:}BT_{CWM} + (1|Site)$
621

622   To test how fire influenced the trait composition of the community we fit mixed-effects

623 models to test the effect of both fire as well as environmental factors in explaining the

624 community weighted mean trait values.

625   We do not include an independent effect of either wood density or bark thickness because

626   we are primarily concerned with how they may modify fire effects.

627   We also tested for whether the symbiotic strategies differed in their traits. To do so, we

628   assigned symbiotic strategies and the dominant ecosystem in which they occurred to different

629   species. We then analyzed linear models incorporating symbiotic strategy and ecosystem type as

630   additive effects.

631

632

633 Table S1: List of sites with key meta-data. Cont=continent (AU=Australia, NA=North America,
634 SA=South America, AF=Africa). Vegetation type presented in broad categories (NL=needleleaf,
635 BL=broadleaf) and the families of the dominant tree species. Sites with a pine-dominated ecosystem that
636 can change from pine to oak depending on fire regime are noted. Number of plots is the total within the
637 entire site. Duration is the number of years over which fire frequencies have differed across plots.
638 Frequency is in # fires yr^{-1}. Prior conditions describe the ecosystem type at the beginning of the
639 experiment, whether the site experienced regular burning prior to the experiment and if not, how long it
640 had remained unburned (reintroduction burns). The asterisks indicate that the sites included data
641 previously unpublished in the peer-reviewed literature (n=7).

Site	Cont	Vegetation type	# plots	Duration	Freq.	Ref	Prior conditions

648

649 Table S3: Results from mixed-effects model fit to log basal area and stem density (ANOVA for
650 significance of terms, and then fitted model coefficients) testing the effect of fire frequency (FireFreq),
651 the length of time plots were exposed to different frequencies (Duration) and their interaction
652 (FireFreq:Duration). The means and standard deviations used to re-scale the data were: Basal area: fire
653 frequency, mean=0.34, standard deviation=0.32; duration of experiment, mean=28, standard
654 deviation=19. Stem density: fire frequency, mean=0.35, standard deviation=0.33; duration of experiment,
655 mean=29, standard deviation=19. Units for frequency are fires per-year and duration are years. The main
656 effect of fire frequency was dropped from the top model based on the AIC being lower. df=degrees of
657 freedom.

Basal area	df		F value	p value	del AIC
FireFreq					-FireFreq=9.4
Duration	1	290.5	94.3	<0.0001	
FireFreq:Duration	1	288.6	23.3	<0.0001	
Stem density	df		F value	p value	
FireFreq					-FireFreq=3.8
Duration	1	281.6	47.3	<0.0001

658

659

660

661

662

663 Table S4: Results from mixed-effects model fit to log basal area a) ANOVA for significance of terms, b)
664 fitted model coefficients, and c) change in the model AIC with altered additions and removals. All
665 analyses performed on mean centered and standard deviation scaled data for continuous variables with
666 site as a random intercept. ANOVA uses Satterthwaite's method to estimate degrees of freedom. Colon
667 denotes interactions. Variable abbreviations are: FireFreq= fire frequency (fires yr^{-1}), Veg=vegetation
668 type (needleleaf forest, broadleaf forest, savanna), MAT=mean annual temperature (°C),
669 PWQ=precipitation in wet quarter (mm), PDQ=precipitation in dry quarter (mm), Duration=length of
670 time plots have experienced the repeated burning regime (years). For the fitted model coefficients, the
671 intercept gives the value for broadleaf forest (so to calculate the basal area in a savanna, you would
672 exponentiate the sum of the coefficient of "VegSavanna" and the intercept). See Figures 3, S7 for the
673 effects. Independent effects of PWQ, PDQ, and Continent were not included in the model because the
674 models did not pass the criterion that an improved model needed to have a >2 AIC difference. C)
675 Sensitivity of model to changes in terms illustrates what happens when the model only includes
676 interactions and the effect of adding or removing independent effects, as well as the interactions between
677 fire and soil. df=degrees of freedom.

697 Table S6: Results from mixed-effects models testing for the interaction between traits and fire frequency
698 treatments. This is split into two levels: (i) testing whether the relationship between fire frequency and
699 tree basal area across plots were influenced by the community weighted mean trait value in that plot, and
700 (ii) testing whether fire frequency changed the community weighted mean trait value within plots.
701 Whether the site was a savanna, broadleaf forest, or needleleaf forest was included in the model because
702 of the large difference in wood traits between needleleaf forests and the other ecosystems. df=degrees of
703 freedom.

Supplemental figures

743   **Figure S1:**
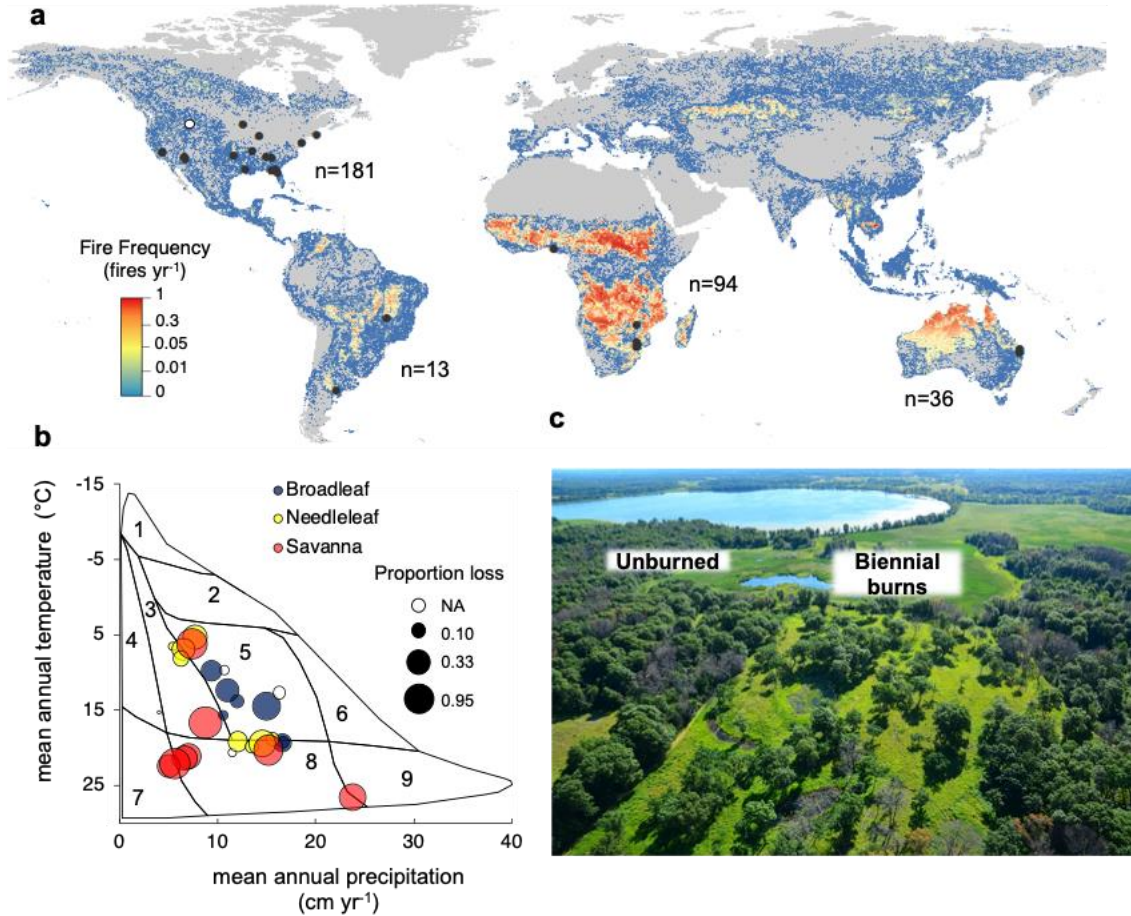

744

745   **Figure S1:** Distribution of sites**.** a) map displaying the distribution of sites (dots) with the surface fire
746   sites filled with black and the crown fire sites filled with white. The coloration indicates the average fire
747   frequency within a gridcell using [1]. The sample size of plots is written adjacent to the continent. b)
748   distribution of sites in climate space overlying Whittaker's biome distribution [77]. (1=tundra, 2=boreal
749   forest, 3=woodland/shrubland, 4=temperate grassland/desert, 5=temperate forest, 6=temperate rainforest,
750   7=subtropical desert, 8=tropical forest and savanna, 9=tropical rainforest). Dots colored according to
751   broad vegetation type category. Plots span a mean annual temperate range from 5.2-27.3° C and a mean
752   annual precipitation range from 408-2378 mm yr^{-1}. c) aerial picture of two different fire treatment plots
753   from Cedar Creek, a temperate oak savanna, where different fire frequencies have created a stark biome
754   boundary between forests in unburned plots and savannas in biennial burn plots (Pellegrini et al. 2019).

755

756

757   **Figure S2:**

758
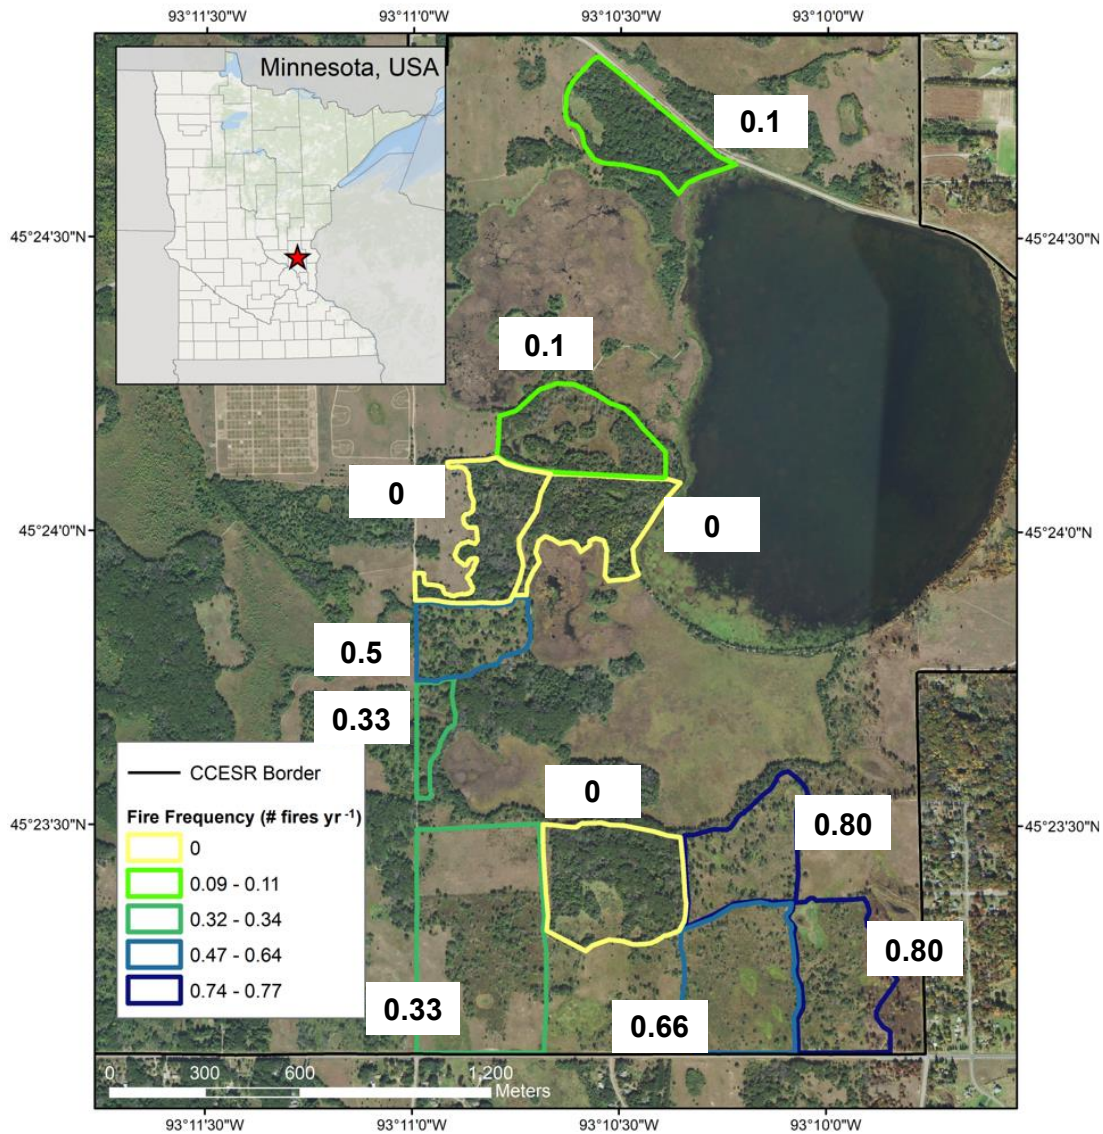

759   **Figure S2:** Example of the experimental layout of a fire manipulation experiment taken from Cedar
760   Creek (a temperate savanna in Minnesota, USA), where fires have been manipulated since 1964. Aerial
761   imagery (taken in 2017) from the National Agriculture Imagery Program from the Farm Service Agency.
762   Plots are outlined with a color corresponding to their fire frequencies expressed in terms of number of
763   fires per year (e.g. 0.33 is one fire every 3 years).

764
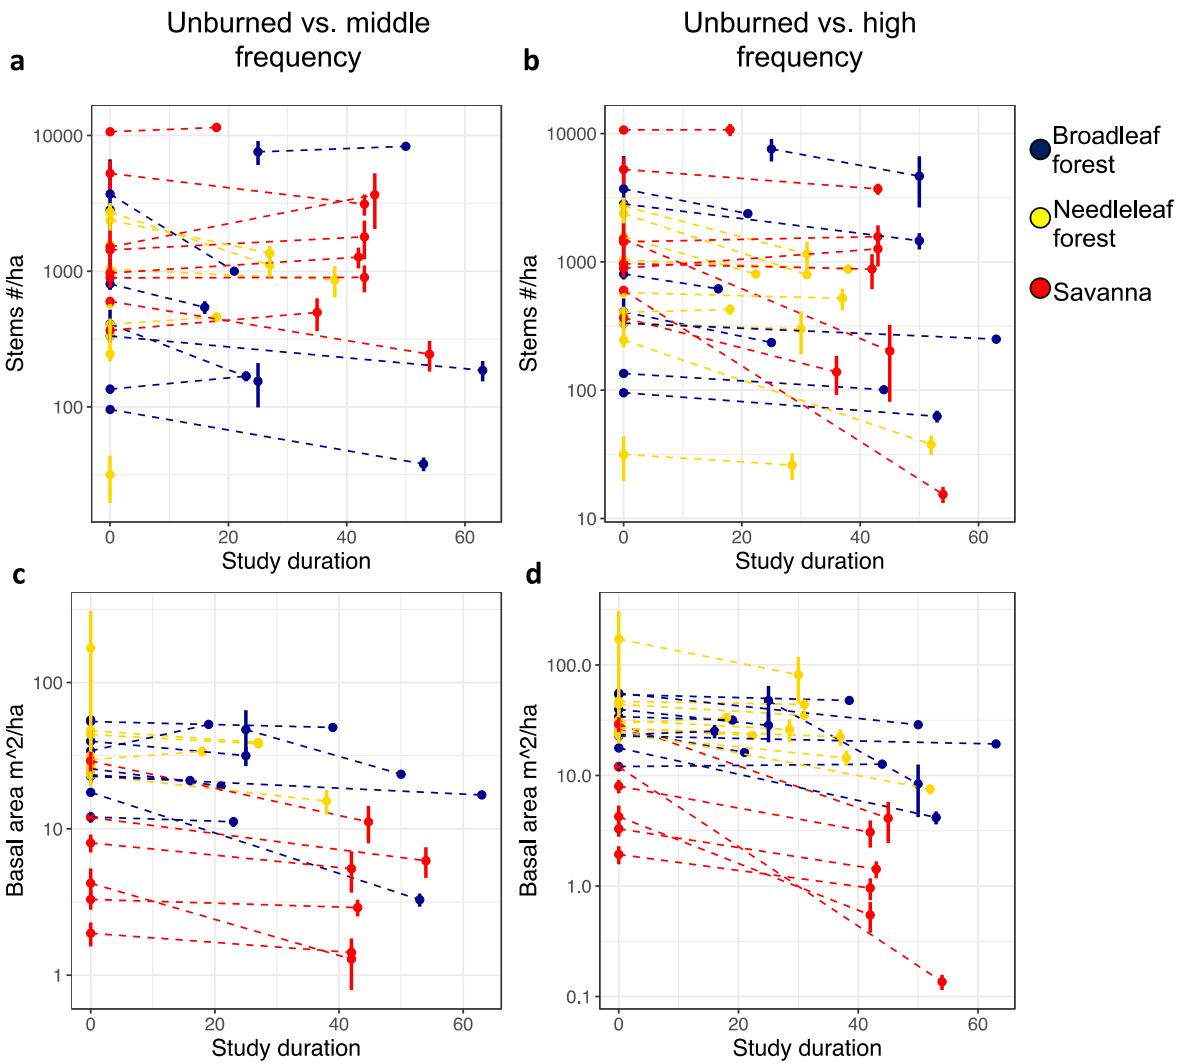

Figure S3:

767   **Figure S3:** Untransformed data on stem density (**a-b**) and basal area (**c-d**) as a function of the duration
768   that plots have been exposed to burning in the experiment (0=unburned plots). Each dot represents a site
769   and the dashed lines connect treatments within sites. Columns represent two sets of fire frequency
770   contrasts comparing unburned vs. the intermediate frequency in **a** and **c**, and unburned vs. the high
771   frequency in **b** and **d** (levels defined based on treatments within sites). Dots and bars based on mean and
772   standard error calculated across the replicate plots within a fire treatment in a site. Note y-axis is on a
773   log10 scale.

774

775

776
Figure S4:

Figure S4: Comparison between fire types (surface in **a,** $F_{1,94.3}=50.6$, $p<0.001$, and crown in **b,** $F_{1,21}=10.3$, $p=0.004$) in needleleaf forests with fire expressed in terms of return period (crown fire plots are all 12 years postfire, data subset to include short-interval burn plots). **c**) illustrates the mean response ratios +/- standard error for the fire types with crown fires split into high (>2,400 m) and low (<2,400) elevation sites (Crown 1 and Crown 2, respectively). Analyses were robust to considering surface fires in only Western US needleleaf forests: $F_{1,47.1}=17.2$, $p=0.001$. Response ratios were split into long and short fire return interval plots (Crown 1 and 2, respectively), with the justification for definition of interval in [17].

790   **Figure S5:**
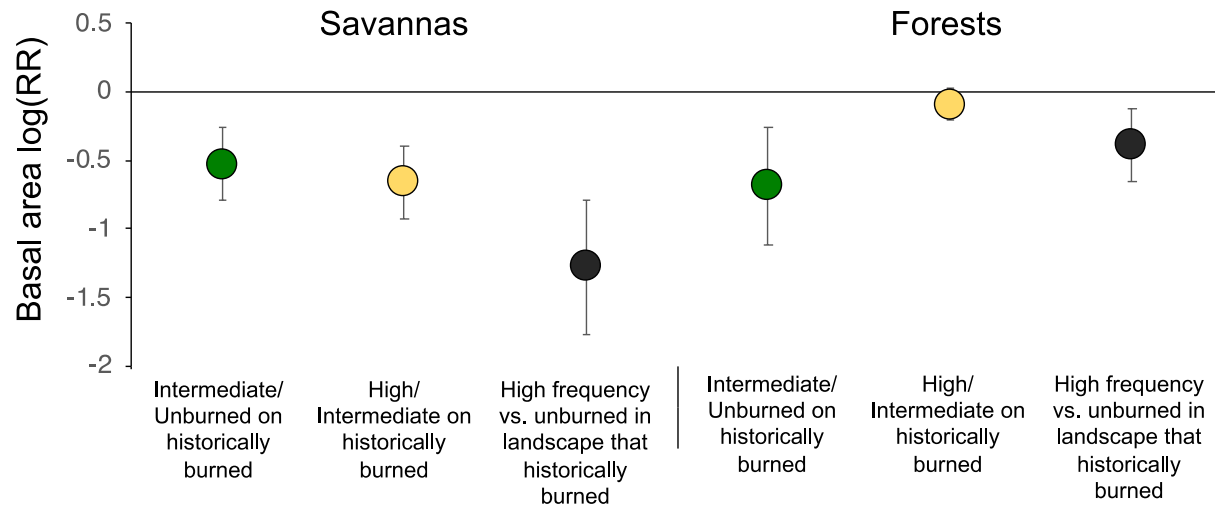

791

792   **Figure S5:** Log response ratios of basal area for sites categorized based on their different fire histories
793   prior to the establishment of the experiment. Suppression is calculated for sites where the experiment was
794   established on historically burned landscapes and is the unburned/historical frequency. Increased
795   frequency is calculated for sites where the experiment increased fire frequency relative to the historical
796   average (for forests this was generally the reintroduction of fire into a historically fire suppressed forest).
797   The extremes compare the highest frequency vs. unburned.

798   **Figure S6:**
799

800   **Figure S6:** partial residual plot displaying the relationship between $\log_e$ basal area and precipitation in the

801   wettest quarter cross-sectioned based on fire frequency. This plot is based on the same mixed-effects

802   model presented in Figure 3 and Table S4, just re-arranged to emphasize how precipitation-basal area

803   relationship changes with more frequent burning.
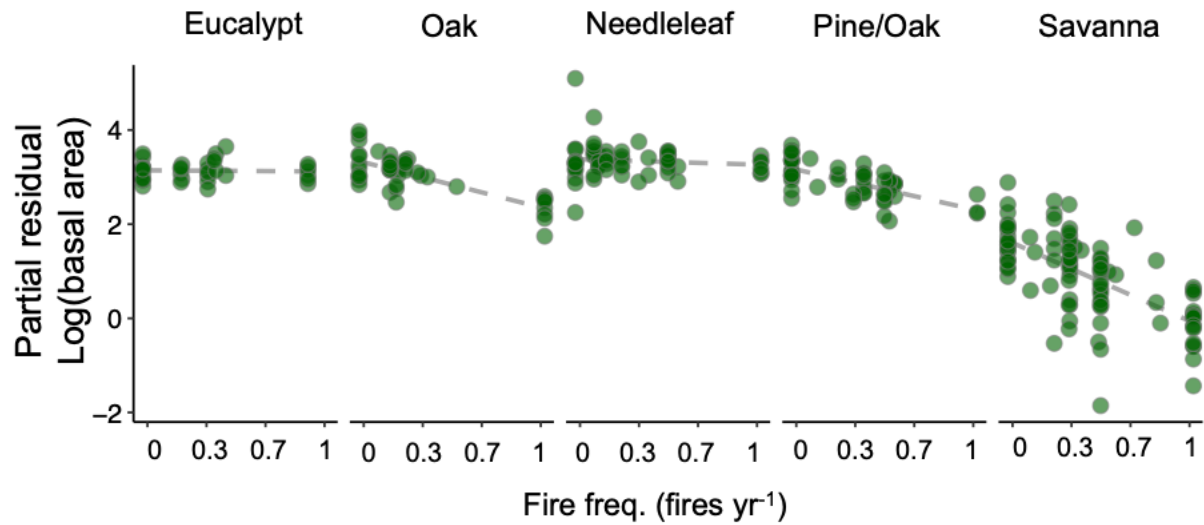

804

805

806   **Figure S7:**
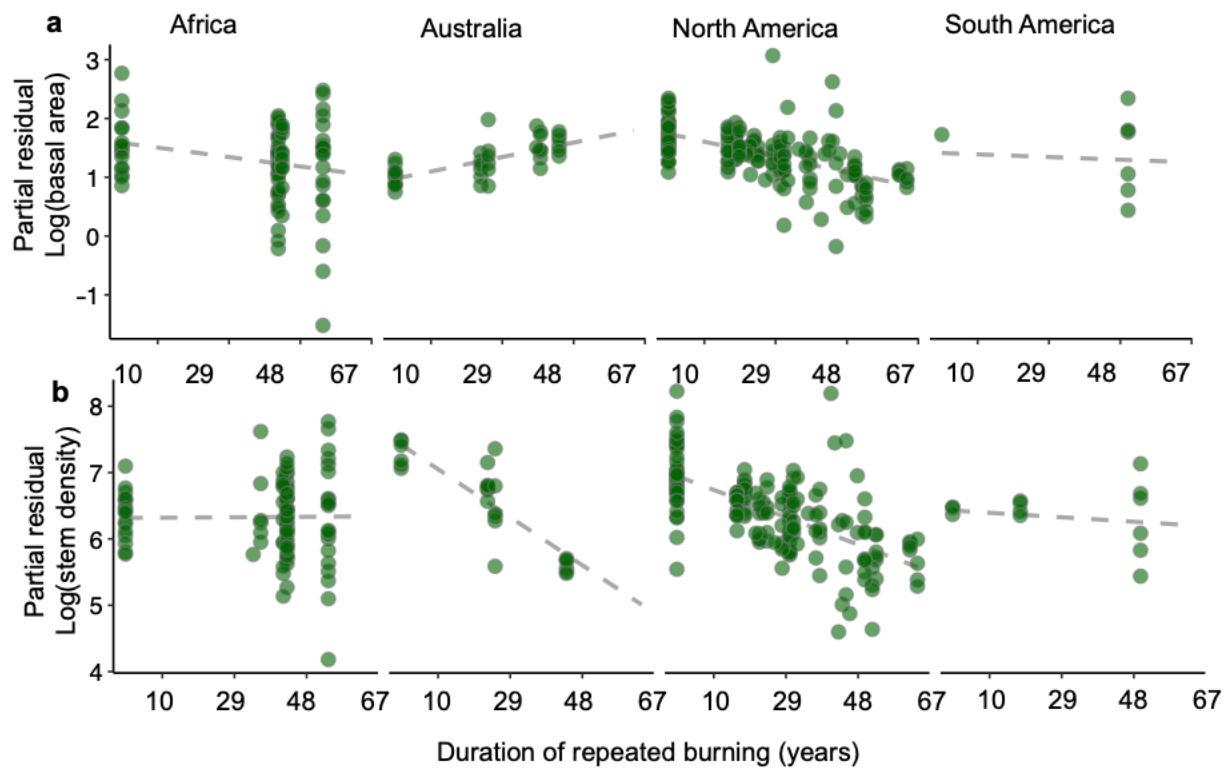

807

808   Figure S7: partial residual plot between the length of time plots were exposed to frequent burning and the

809   log basal area (a) and stem density (b) in the different continents (from the main mixed-effects model

810   with site as a random intercept in Tables S4-S5).

811

812   **Figure S8**

813

814   **Figure S8:** partial residual plot between the length of time plots were exposed to frequent burning and the

815   log basal area in the different sub-vegetation types (from the main mixed-effects model, presented in

816   Table S4 but substituting the broad vegetation effect with the more detailed classification. We found no

817   evidence that accounting for the finer-scale variability in ecosystem classification increased the accuracy

818   of the model or changed our conclusions

819

820
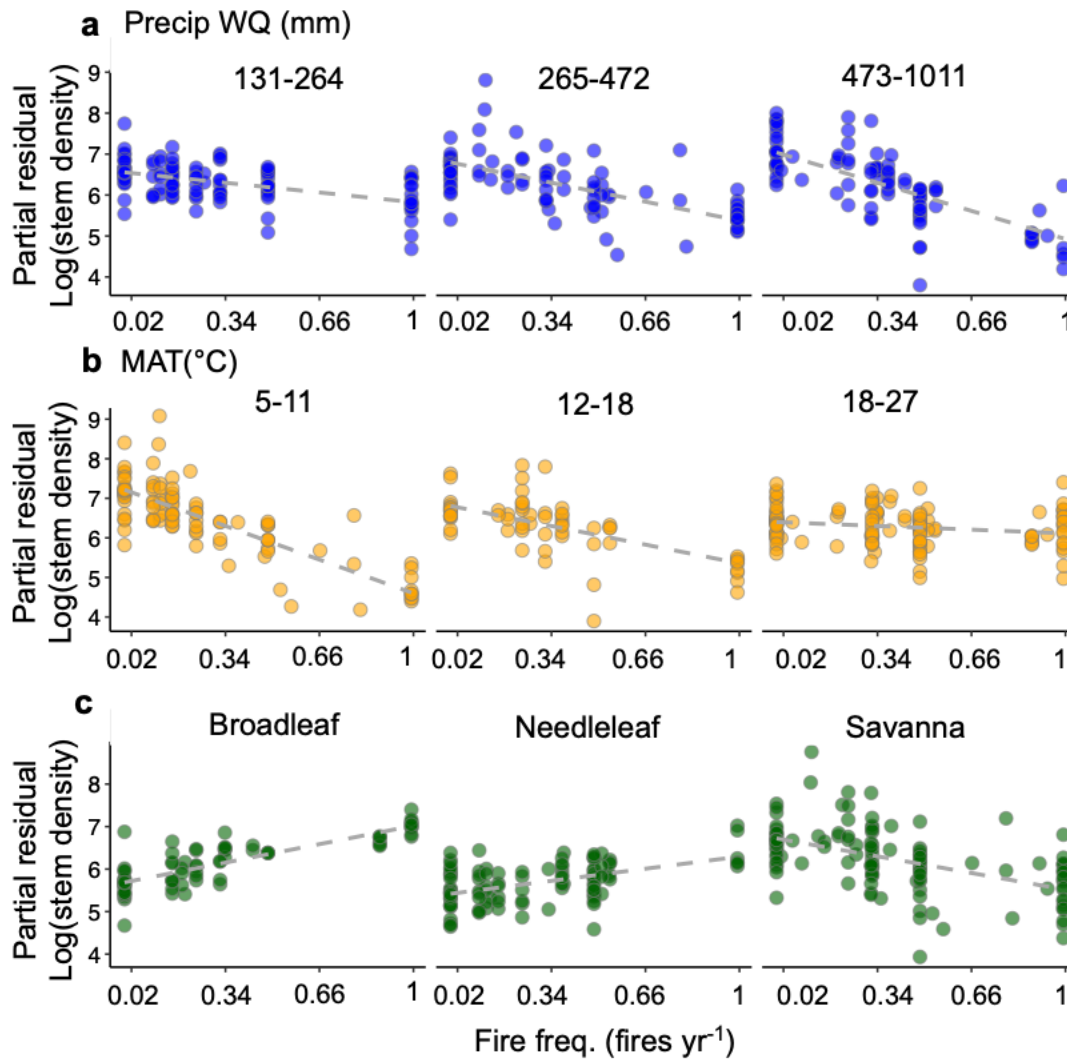

Figure S9: Partial residual plots of the mixed-effects model for stem densities illustrating how fire frequency effects changed according to wet-season precipitation, mean annual temperature, and ecosystem type. Panels structured by standard deviations around the median to visualize the spread (-1, 0,1), PWQ: precipitation in the wet quarter, MAT: mean annual temperature. All model fits are $p<0.05$ and specific results can be found in Table S5. The predictor variables are mean-centered and standard deviations are scaled to facilitate comparisons of variable influence. In needleleaf and broadleaf forests, stem densities actually increased with more frequent burning initially, but declined with increasing experiment duration, potentially because of increased light availability initially stimulating recruitment of small trees (Figure S7, Table S5). Stem density in African sites changed little through time (Figure S7). The trends in density may reflect the ability of many of the tree species to re-sprout in between fire events[78].
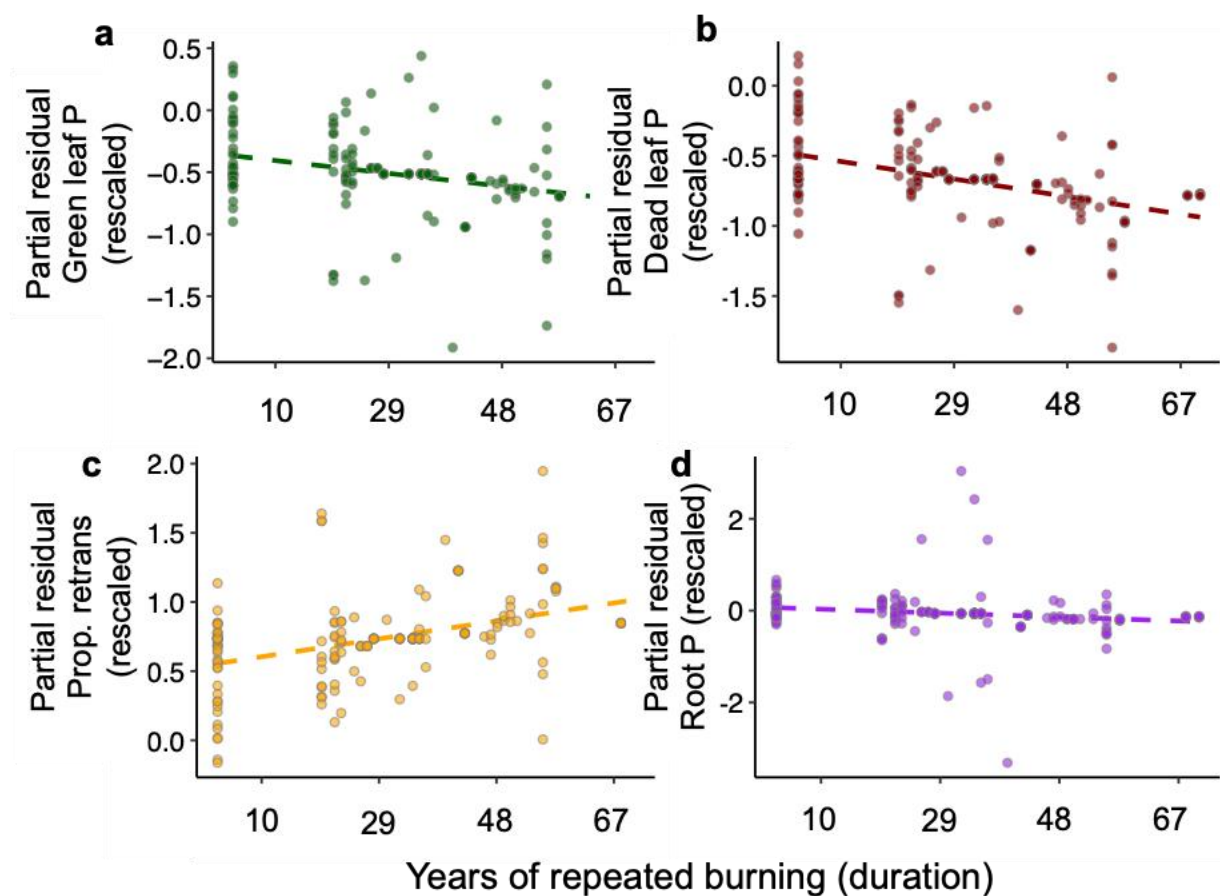

836   **Figure S10:**

837

838   **Figure S10:** Partial residual plots of the phosphorus (P) stoichiometry of community weighted means as a
839   function of years of repeated burning. Taken from mixed-effects models presented in Table S7. The
840   models include a vegetation type effect. Tissue P is rescaled by subtracting the mean and dividing by the
841   standard deviation.

842

843

845
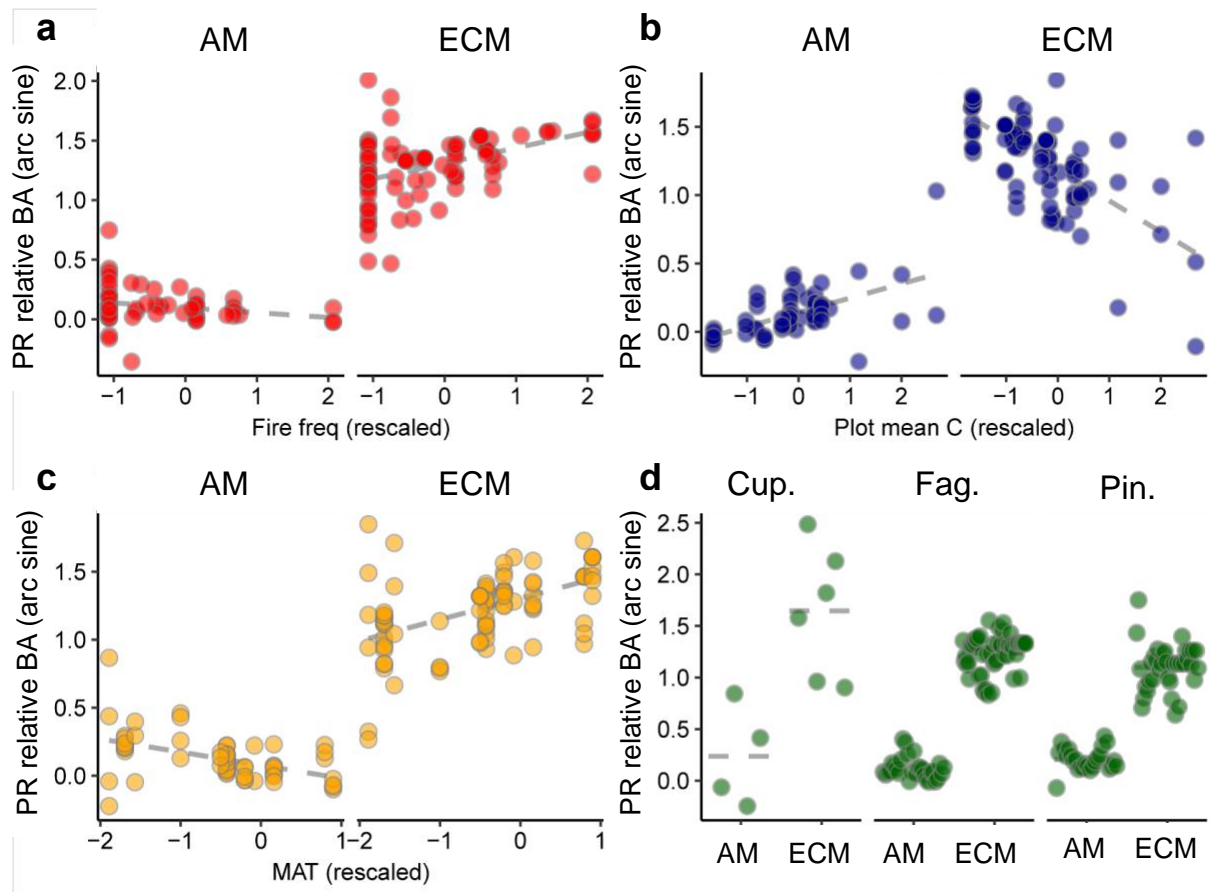

846

847 **Figure S11:** Partial residual (PR) plots of the mixed-effects model between relative basal area different

848 symbiotic groups within a plot (AM=arbuscular mycorrhizal and ECM=ectomycorrhizal on the left- and

849 right-hand side of each panel, respectively). Relative basal area was arcsine transformed. In all panels, the

850 continuous predictor variables were re-scaled by mean centering and dividing by the standard deviation

851 for comparability testing the relationship with fire frequency (a), soil total carbon content (b). mean

852 annual temperature (c). d) illustrates composition across different plant communities grouped based on

853 the family of the dominant tree species (Cup= *Cupressaceae*, Fag=*Fagaceae*, Pin=*Pinaceae*). Dotted lines

854 illustrate median. Statistics are given in Table S8.

855

856

857

858   **Figure S12:**
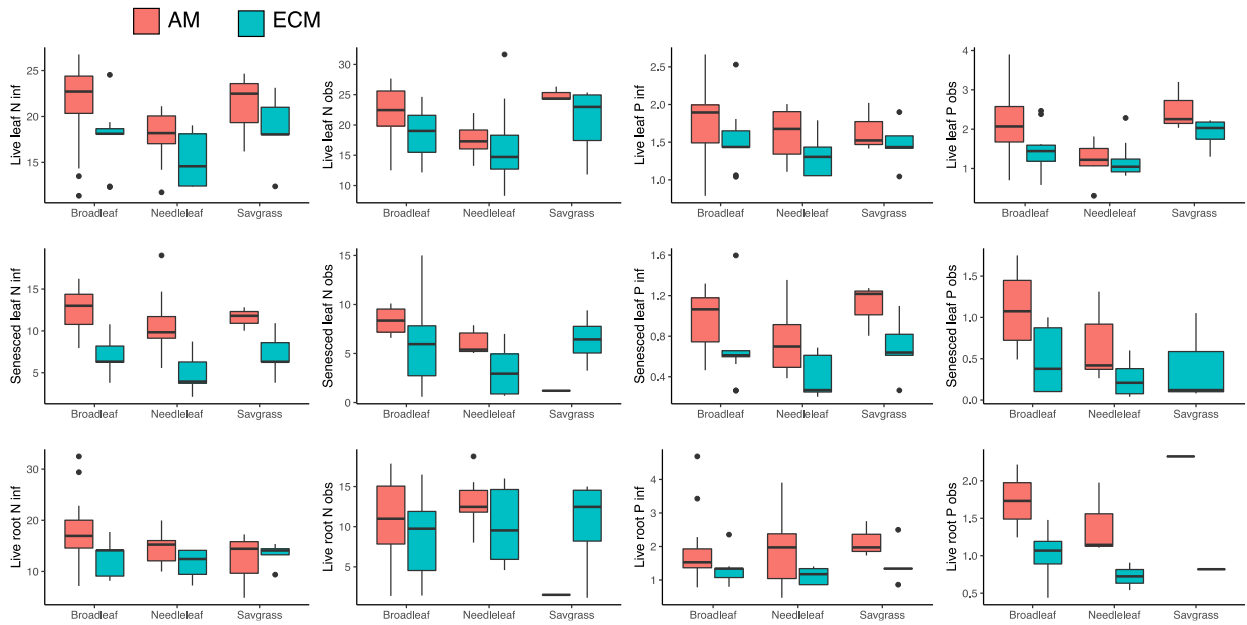

859

860   **Figure S12:** Box and whiskers plot displaying the tissue stoichiometry for tree species averaged within
861   symbiont strategy (AM= arbuscular mycorrhizal; ECM=ectomycorrhizal) and then grouped according to
862   which overall ecosystem type the species generally occurred in (broadleaf forest, needleleaf forest, or a
863   savanna-grassland). For both N and P, we conducted our comparisons using data that were either based on
864   direct observations ("obs" in the y-axis), or inferred via a phylogenetic relatedness statistical filling ("inf"
865   in the y-axis). Statistics are in Table S9.
