Keywords: UAV, LiDAR, Photogrammetry, Tropical Forest, Carbon, Biodiversity

Key Points

- UAV-borne laser scanners (UAV-LS) can generate 3D data on forest structure necessary for mapping patterns in biomass and biodiversity
- UAV-LS is costly to produce. Digital Aerial Photogrammetry (DAP) is a cheap alternative, but its utility over tropical forests is unclear
- DAP cannot reliably measure tree height, yet if ground height is known, it can imitate UAV-LS measurements of canopy and vertical structure

Abstract

Tropical forests are complex multi-layered systems, with the height and three-dimensional (3D) structure of trees influencing the carbon and biodiversity they contain. Fine-resolution 3D data on forest structure can be collected reliably with Light Detection and Ranging (LiDAR) sensors mounted on aircraft or Unoccupied Aerial Vehicles (UAVs), however they remain expensive to collect and process. Structure-from-Motion (SfM) Digital Aerial Photogrammetry (SfM-DAP), which relies on photographs taken of the same area from multiple angles, is a lower-cost alternative to LiDAR for generating 3D data on forest structure. Here, we evaluate how SfM-DAP compares to LiDAR data acquired concurrently using a fixed-wing UAV, over two contrasting tropical forests in Gabon and Peru. We show that SfM-DAP data cannot be used in isolation to measure key aspects of forest structure, including canopy height (%Bias: 40 - 50%), fractional cover, and gap fraction, due to difficulties measuring ground elevation, even under low tree cover. However, we find even in complex forests, SfM-DAP is an effective means of measuring top-of-canopy structure, including surface heterogeneity, and is capable of producing similar measurements of vertical structure as LiDAR. Thus, in areas where ground height is known, SfM-DAP is an effective method for measuring important aspects of forest structure, including canopy height, and gaps, however without ground data, SfM-DAP is of more limited utility. Our results support the growing evidence base pointing to photogrammetry as a viable complement, or alternative, to LiDAR, capable of providing much needed information to support the mapping and monitoring of biomass and biodiversity.

Plain Language Summary

Tropical forests support a diverse array of plant and animal species, and are highly productive, playing a vital role in the global carbon cycle. Quantifying the height and density of these forests can help us better understand the amount of carbon and biodiversity they store. Generating such data over large areas is possible using Light Detecting and Ranging (LiDAR) scanners mounted on an aircraft or on Unoccupied Aerial Vehicles (UAVs), although these data are expensive to collect and process. An alternative method is photogrammetry, which involves collecting several overlapping photographs of the same area from different viewpoints, from which we can generate a 3D reconstruction of the surface. This approach is much cheaper, potentially allowing us to map forests with greater frequency. However, we find this method cannot be used to measure key elements like tree height, due

to difficulties seeing, and thus estimating ground elevation. The forest canopy surface can be measured fairly well while measurements of vertical structure are broadly similar to LiDAR data. If ground height is known, then photogrammetry is a viable means of collecting important data on forest structure necessary for mapping carbon and biodiversity.

I Introduction

Accurate and detailed measurements of forest structure are essential to improving our knowledge of a range of important ecosystem services and functions, including carbon storage, productivity, habitat quality and biodiversity. The recent proliferation of space- and air-borne platforms incorporating light detection and ranging (LiDAR) sensors will provide new insights into these variables due to their ability to map key aspects forest structure across large areas (10s km²), and at fine resolutions (≤ 1 m). Forest structure can be characterised in different ways when measured from above using LiDAR, with common measurements including the horizontal distribution of vegetation across an area, such as its height, heterogeneity, fractional cover, and gap fraction, as well as the vertical distribution and density of plant material below the canopy surface. Retrieving this information is important for several reasons: first, measurements of tree height and fractional cover are essential components in models that estimate aboveground biomass (AGB) (Asner & Mascaro, 2014; Jucker et al., 2018a; Knapp et al., 2020). Measurements of 3D vertical forest structure are also important for estimating AGB (Meyer et al., 2013; Dubayah et al., 2020), and for understanding habitat characteristics and biodiversity patterns on the basis that structurally complex forests provide space for species with different specialisations and niches (Lopatin et al., 2016; Burns et al., 2020; Marselis et al., 2020; Schneider et al., 2020; Valbuena et al., 2020). These data are most commonly acquired using aircraft, however, high acquisition costs mean that data collection, particularly in more remote tropical forests, is typically done in an ad hoc manner, and rarely repeated (Xu et al., 2017). New space-borne LiDAR missions such as NASA's Global Ecosystem Dynamics Investigation LiDAR (GEDI) are helping fill these key observation gaps by providing global measurements of forest structure, including new estimates of AGB, however coverage is sparse and collected at a coarse resolution compared to airborne platforms (separated 25m footprints, compared to cm diameter footprints), and the data collection is time-limited (Dubayah et al., 2020).

In recent years, Unoccupied Aerial Vehicles (UAVs) (Joyce *et al.*, 2021) equipped with small, lightweight LiDAR sensors have become a viable alternative to LiDAR data collection via aircraft (Brede *et al.*, 2019; Kellner *et al.*, 2019; Yin & Wang, 2019). The

unique combination of low flight altitudes (10s - 100 m) - which normally removes the need to notify national civil aviation authorities before operation - slower flight speeds, and a wider field of view mean that UAV-borne LIDAR is capable of producing 3D point clouds with sufficient density $(100s - 1000 \text{ pts/m}^2 \text{ vs. } 10s \text{ pts/m}^2 \text{ for aircraft})$ to allow individual tree crowns, and branches to be resolved (Brede et al., 2017, 2019; Kellner et al., 2019; Puliti et al., 2020a). Improvements in flight times (up to 1h) mean UAVs can now cover relatively large areas (1 - 10s km), and so provide an important bridge between fine-scale ground measurements, e.g. from Terrestrial Laser Scanning (Disney et al., 2018; Burt et al., 2021), and sparse and/or coarse resolution satellite data, the resolution of which is often too coarse (20 - 50 m +) to reliably capture small-scale patterns and changes associated with growth and mortality (Espírito-Santo et al., 2014; Assmann et al., 2020). However, there remain potentially significant barriers to the widespread adoption of the technology, namely the capital cost of equipment, which includes the sensor itself, GPS-IMU hardware to accurately measure UAV position, as well as a UAV platform capable of carrying a relatively heavy payload (>3 kg), which itself may require special flights permissions, and/or trained, certified pilots to operate (Brede et al., 2017; Beland et al., 2019; Kellner et al., 2019). Platform and sensor may be subject to import/export control regulations, while widespread restrictions on transportation of powerful batteries on commercial airlines creates logistical issues if the system is being applied outside the country of origin.

To that end, alternative methods based on digital aerial photogrammetry (hereafter DAP) have been posited as a potential lower-cost source of fine-resolution 3D information on forest structure (Iglhaut *et al.*, 2019; Puliti *et al.*, 2020b) . The approach, which uses multiple images collected from different positions to construct a 3D model of the visible surface - a technique termed Structure from Motion (SfM) - can generate point cloud data similar to that obtained from LiDAR, but using hardware a tiny fraction of the cost and weight. Its application has increased markedly over the past decade (Goodbody *et al.*, 2019), due in part to the utility of consumer-grade imaging platforms and sensors, and the associated low cost of acquiring data, but also due to increases in computing capacity, and the availability of commercial and open-source software for processing what can often run to hundreds to thousands of images (Bayley & Mogg, 2020). This, combined with the ability to generate fine resolution orthomosaic images covering a whole study area, means that image-based methods are a potentially attractive alternative to more costly LiDAR data collection.

However, as with LiDAR data, there are challenges to image-based methods that potentially limit its widespread usage, particularly over dense tropical forests. The first is that

optical images, without the penetration of the laser beams of LiDAR, mostly only collect information from the canopy surface, with information on lower strata or the ground only provided in rare canopy gaps. This creates known errors when estimating important variables such as tree height, due to difficulties in extracting the ground elevation (Rosca et al., 2018; Swinfield et al., 2019; Vaglio Laurin et al., 2019). A common solution is to use LiDAR derived ground elevations, with SfM-DAP used for repeat, or retrospective monitoring of canopy structure (St-Onge et al., 2008; Gobakken et al., 2015; Ali-Sisto & Packalen, 2017; Goodbody et al., 2019; Krause et al., 2019), although this negates many of the original attractions of using SfM-DAP over LiDAR. Secondly, tropical forests present a challenge for image and feature matching algorithms which rely on visual similarities between overlapping images to reconstruct the 3D surface model. For example, trees and dense vegetation, due to their complex shape and structure may appear very different between overlapping images, which coupled with potential movement (e.g. due to wind) and areas of occlusion (i.e. obscured/shadowed areas), can potentially lead to incomplete reconstruction and/or noisy point clouds (Cunliffe et al., 2021). Differences in lighting conditions, e.g. due to changing cloud cover, or the time of day the data was acquired, may also affect the consistency of image based point clouds, which is potentially problematic when conducting missions across large areas, or conducting repeat measurements over several days.

Although the benefits and challenges of structure-from-motion photogrammetry are well understood (Goodbody *et al.*, 2019; Iglhaut *et al.*, 2019) - having been widely applied for surveying over temperate forests - there remains limited data on how well it performs in tropical forests, and under what conditions it can begin to resemble information obtained by LiDAR. For example, it is unclear how the retrieval of tree height, and other metrics vary depending on local forest structure, such as canopy cover or vegetation density (Wallace *et al.*, 2016; Mlambo *et al.*, 2017), and whether these errors are systematic, or primarily random in nature. Understanding the nature of these errors is important, as if they can be taken into account it may be that SfM-DAP is sufficient for many use cases where LiDAR (or no data collection at all) might have been the alternative. Further, as with LiDAR, the increasing use of UAVs provides new opportunities for SfM-DAP, given their ability to image the forest from a greater number of viewpoints, and potentially image beneath the canopy itself, reducing or removing the aforementioned challenges.

To that end, in this paper we compare various forest structural metrics relevant to AGB estimation, and to our understanding of wider ecosystem function such as biodiversity and productivity. These datasets were generated using extensive LiDAR and SfM-DAP data

collected concurrently using a UAV over two contrasting areas of tropical forest in Gabon and Peru. The scale of our datasets, which cover a larger area than previous comparisons, provides a novel basis for assessing the capacity of SfM-DAP, and where it can be successfully applied - information that is crucial in order to facilitate rapid, low-cost measurement and monitoring of tropical forests.

Figure 1 – Location and extent of the two study areas in a) Peru (image centred on: -11.00, -69.72) and b) Gabon (image centre: -0.1480, 12.266), with base satellite imagery from Planet Labs (RapidEye and PlanetScope respectively). For the Gabon site, the image extent is consistent with LiDAR data coverage and are presented on the same scale as the map of the Peru site. The photographs adjacent to each map give an insight to the forest structure at each site.

2 Methods

2.1 Study region

The two study areas are located in remote areas of Peru and Gabon, selected primarily due to their contrasting vegetation structures. The Peruvian site is centred on a small community (Communidad Nativa Bélgica) located approximately 40 km west of Iñapari in the Madre de Dios region. The area has a mean annual rainfall of ~1800 – 2200 mm, with a distinct dry season between June and October. The area of interest covers approximately 20 km² and comprises a mosaic of agricultural land, pasture, secondary, and mature forest (Figure 1). The vegetation is dominated by species in the genus *Socratea*, *Matisia* and *Pseudolmedia*, with tree densities ranging from ~500 – 600 stems/ha (counting stems >10 cm diameter at 1.3m). The site in Gabon is located in an active logging concession operated by Rougier Gabon, and covers 10 km² with the vegetation consisting almost exclusively of mature forest, with more open patches located close to the track network (Figure 1). Tree density is markedly lower, in the range of 200 – 300 stems/ha, with tree species composition typically dominated by slower growing species, with denser wood, including those in the genus *Coula*, *Coelocaryon*, and *Pentaclethra*. The area has a similar mean annual rainfall of 1900– 2100 mm with a short dry season from January – February, and another between June and September.

2.2 Data acquisition

Data were collected in July 2019 (Peru) and January 2020 (Gabon) using a DELAIR (DT26X fixed-wing UAV equipped with a RIEGL miniVUX-1DL discrete-return LiDAR sensor (RIEGL Laser Measurement Systems GmbH, Horn, Austria), and a 36 MP RGB camera. The LiDAR sensor operates in the near-infrared (905 nm), has a field of view $\pm 23^{\circ}$ off-nadir, and has laser beam divergence of 1.6 mrad with up to five returns from each pulse digitised. The payload also includes an Applanix APX-15 IMU and L1/L2 GNSS receiver for PPK correction of the flight trajectory (Figure 2). The RGB camera has a horizontal and vertical field of view of $\pm 20^{\circ}$, and $\pm 17^{\circ}$ off-nadir respectively, with an acquisition rate of 1 image/second. A temporary GNSS base station (LEICA) was established at each site and initially left to collect data for 24 hours to derive an accurate and precise position. The receiver is set to record in sync (1 measurement/s) with the UAV, and was set to run for an hour before and after each day's missions to allow PPK correction. A minimum of three Ground Control Points (GCPs) - square targets $1 - 2 \text{ m}^2$ composed of alternating black and white material arranged in a checkerboard pattern – were placed across the road/ track

network to allow further correction of the flight trajectory and support co-registration during the processing of each mission. Additional marker points, such as buildings and other invariant objects (e.g. solar panels, road marker posts) were used to refine and check the accuracy of the final datasets. These were geo-located using a secondary 'rover' GNSS receiver referenced back to the base station (Figure 2).

Figure 2 – a) The UAV prepared for launch in Gabon, using conventional take-off and landing (CTOL) procedure aided by a catapult. (b) An example mission over the same study area with flight lines and an approximate image footprint. (c) A static GNSS receiver, the data from which is used to correct the flight trajectories, with additional refinements and corrections possible via ground control points (d + e), located across the study area, the location of which are measured using a 'rover' GNSS receiver.

All flights were conducted in perpendicular lines and at a nominal altitude of 100 - 130 m above the ground surface with an average flight speed of 17 m/s (60 km/h). For the LiDAR,

this results in a swath width of 100 m, with an average flight line spacing of 25 m (based on a target 70 - 80 % side overlap), and a maximum laser beam footprint at ground level of 20 - 30 cm, reducing to 10 - 15 cm at 50 m. For the RGB data, the altitude and field of view mean each image covers an area ~80 x 70 m in size, with a side and front overlap of 70 and 75% respectively meaning each area was imaged ~8 - 10x with a ground sampling distance (GSD) of 3 cm per pixel. The flight parameters were chosen to maximise information content in both the LiDAR and SfM-DAP datasets; however for the latter, it should be noted that the degree of image overlap and the resultant GSD, whilst sufficient (see next section), should be considered the minimum when working over dense vegetation (Assmann *et al.*, 2019; Iglhaut *et al.*, 2019).

The data used in this study comprises a total of 15 missions conducted over the course of 7 days in Peru and 3 days in Gabon. All data were principally collected in the morning between 8 am and 11 am in an attempt to obtain consistent light conditions between missions, and to avoid solar hotspots and the typically high temperatures (>30° C) after solar noon. However, given the size of the study area and the large distances travelled by the UAV from the operator (1 - 7 km), combined with the relatively long flight times (45 – 75 minutes), recording and controlling for light conditions was not possible meaning there are undoubtedly some differences within and between missions. It is important to note that special permissions were sought and obtained for flying Beyond Visual Line of Sight (BVLOS), which may or may not be possible in certain contexts, particularly if flying close to population centres.

2.3 Data processing

The flight trajectories were reconstructed using the GNSS/ IMU measurements and adjusted using the differentially corrected base station data within the Applanix POSPac Software. The corrected flight paths and laser data were combined using the RIEGL software package, RiPROCESS to generate the initial laser 3D point cloud. Residual errors in the flight trajectory, e.g. due to discrepancies in GPS tracking and elevation, were corrected using small buildings to guide additional adjustments to the relative position and orientation of individual flight lines/scans. The trajectories were further refined using the GCPs resulting in a final LiDAR-derived point cloud with a geometric accuracy of 1.8 cm. The images were processed using the Pix4DMapper software (Pix4D, Lausanne, Switzerland; v. 4.4.12) and were sharpened prior to analysis. The process is largely automated and broadly follows the guidance set out by the software provider based on the vegetation type, flight plan, and sensor

rig used. A more detailed description of the theoretical principles and techniques can be found elsewhere (Westoby *et al.*, 2012; Iglhaut *et al.*, 2019), however in short, the processing chain first identifies points or sets of pixels with a distinctive and similar texture from sets of overlapping images. We used a custom matching procedure which leveraged the accurate geolocation of the images to ensure pairs were selected based on triangulation of proximal images, as well as capture time. An iterative bundle adjustment then refines the initial camera parameters, using the corrected positions and orientations of each image as a starting point, to derive an initial point cloud consisting of key-points matched in different images. The GCPs were then manually identified and marked in all available images to aid the optimisation before a multi-stereo algorithm generated a densified point cloud containing estimated 3D point positions. All elevation data were calculated according to the ellipsoidal height (m), with the Peru processed in WGS84 UTM 19S and Gabon in the UTM 33S coordinate system respectively. Each flight was processed separately with all datasets merged before being exported. All subsequent processing of the points clouds was done using elements of the lidR package (V3.1.0; Roussel *et al.*, 2020).

Point clouds were filtered to remove outliers using a two-step approach; first, discontinuities in height profiles were used to identify and remove isolated clusters of points clearly separated, i.e. > 5 m difference in height, from the remainder of the point cloud, a feature that was more apparent in the image-based point clouds. The mean Euclidean distance between each remaining point and its 10 nearest neighbours was then calculated and if this value exceeded 2 m, the point was considered an outlier and removed. Filtering was conducted in 0.25 ha (50 x 50 m) segments to limit topography affecting the height profiles. Point clouds were thinned using 10 cm voxels to account for differences in sampling intensity between areas, which will more likely affect the LiDAR data. The final voxelised LiDAR point clouds have a mean density of 220 pts m² in Peru, and 240 pts m² in Gabon, while for the DAP datasets, it is 210 and 140 pts m² for Peru and Gabon respectively (Figure 2: Figure 3). We exclude areas with densities <10 pts m² within a 10 x 10 m² moving window, which includes areas towards edge of the dataset, and gaps between flight lines where data quality was deemed to be low, leaving a total area coverage of 1100 ha in Peru and 655 ha in Gabon.

2.4 Forest Structural Metrics

We selected a range of metrics considered important for area-based AGB estimation, and for measuring various aspects ecosystem structure and function. All datasets are gridded and presented in the main text at 20 m (0.04 ha) resolution, with the agreement of different data

sets assessed according to the Concordance Correlation Coefficient (CCC), the Mean Error or Bias, and the Root Mean Square Error (RMSE), expressed in both absolute terms and relative to the LiDAR derived values.

The first variable we compare is mean *Top-of-Canopy Height* (TCH), and its spatial heterogeneity or *Rugosity*, both of which are key variables in the area-based estimation of AGB (Asner & Mascaro, 2014; Bouvier *et al.*, 2015; Jucker *et al.*, 2017; Knapp *et al.*, 2020). Ground returns were identified by extracting the lowest returns within a 1 m grid, and then applying a cloth simulation filter (Zhang *et al.*, 2016) to separate ground from non-ground points. These were aggregated to create an average ground elevation for comparison. First returns were extracted (canopy surface elevation) and compared with the coincident ground elevations to generate an estimate of TCH, which along with canopy surface elevations, were averaged during the aggregation. The variation in surface height, sometimes referred to as rugosity, were calculated as the standard deviation of heights in each grid, although alternatives measures of spread have also been suggested and applied (e.g. Coefficient of Variation (CV) and Gini Coefficient) (Bouvier *et al.*, 2015; Knapp *et al.*, 2020). For these direct comparisons, no interpolation, or averaging was used with areas of no data excluded from all subsequent comparisons between methods and sensors.

The second set of variables are related to tree canopy cover, and its inverse, canopy gap fraction, for which multiple definitions and measures exist. Canopy cover, or the number and size of canopy gaps are a keystone, and widely used descriptor of ecosystem structure. This information is important when assessing the ability of different datasets to correctly detect non-stand replacing disturbances, such as low intensity logging, or monitor smaller changes related to tree growth and mortality (Asner et al., 2013; White et al., 2018; Goodbody et al., 2020; Dalagnol et al., 2021). The first metric we compare is Tree Fractional Cover, defined as the proportion of the ground surface covered by the vertical projection of the tree canopy, based on a 1 m CHM and a fixed height threshold of 10 m. This has been used as a predictor of basal area for use in AGB estimation (Coomes et al., 2017; Jucker et al., 2018b; Fischer et al., 2019), and as a proxy for disturbance impacts on tree structure (Almeida et al., 2019). An alternative measure is Canopy Closure (sensu. Jennings et al., 1999), defined as the proportion of the sky hemisphere obscured by vegetation from a single point on the ground and measured here as the proportion of the total points in each grid cell above the same 10 m canopy height threshold. Given data were collected from multiple viewpoints, this metric is better suited to fractional cover when comparing LiDAR and DAP, and the extent to which the sub-canopy or ground surface is likely to be visible.

In this context, we also created datasets describing gap fraction, which includes information on gap size given that smaller, isolated canopy gaps are unlikely to allow sufficient illumination of the sub-canopy. We used the methods contained in the ForestGapR package (Silva et al., 2019), with the same fixed canopy height threshold of 10 m used to separate tree canopies from gaps (Fixed Gap Fraction) (Dalagnol et al., 2021), but with an additional minimum size threshold of 10 m^2 , and a maximum of 2 ha to exclude small isolated gaps and naturally open areas respectively. Small linear gaps (~10 m²), e.g. between tree crowns, were removed as they often connected large canopy gap openings meaning their calculated size is misleading, and led to true gaps exceeding maximum size threshold. We also applied a variable height threshold (sensu White et al., 2018; Dalagnol et al., 2021) classifying an area as a gap if its canopy height is less than 50% of the corresponding maximum height within a 50 x 50 m (0.25 ha) window (Variable Gap Fraction). This measure is better for capturing small discontinuities or temporal changes in tree canopy cover (Dalagnol et al., 2021), particularly where disturbance impacts are minimal, or have been obscured via regrowth in the sub-canopy. In both cases, a smoothed digital surface model (DSM) was generated at 1 m resolution to avoid no-data areas in the image-based point clouds being incorrectly labelled as a gap, based on the 'pitfree' method from Khosravipour et al., (2014). For this, ground returns were interpolated using the 20 nearest neighbouring points, located within a 50 m radius to create a 1 m Digital Terrain Model (DTM) which was subtracted from the DSM to create a smoothed top-of-canopy height model (CHM).

The final set of variables describe vertical forest structure and the ability of different methods to capture the variation and number of canopy layers. Each metric is applied to the vertical point cloud profiles separated in to 1 m height bins (Figure 3). The first of these is the *Vertical Complexity Index (VCI)* or *Entropy*, which measures the diversity and the evenness of points within a vertical profile based on the Shannon Diversity Index ('entropy' function; lidR), with higher values (0 - 1) reflecting a more uniform distribution of points. The next set of metrics are the *Relative Height (RH)* percentiles, which refer to the heights within a vertical profile at which a given percentage of points are located below that value. We extracted the 5th – 95th percentiles, and from these calculated the *Canopy Ratio* (Schneider *et al.*, 2020), which is measured as: (RH95 – RH25) / RH95 and describes both the ratio between vegetation depth and height, and the skew in point densities. High values typically result from a more complex forest structure (i.e. caused by multiple canopy layers), and are considered a good indicator of habitat quality for plants and animals (Schneider *et al.*, 2000).

2017, 2020; Burns *et al.*, 2020). These, and other metrics that use RH data also form a key part of models for estimating AGB (Meyer *et al*, 2013; Dubayah *et al*, 2020).

3 Results

3.1 LiDAR-based measurement of forest structure

Forest structure varied markedly across, and between the two study regions, with top-ofcanopy heights (TCH) in Gabon reaching 35 - 50 m in areas with a fractional cover > 50%, compared to 25 - 40 m in Peru (Figure 3; Figure 4). Despite their relatively low stature, the Peruvian forests are more structurally complex, with vertical profiles capturing the known sub-canopy layer 10 - 15 m in height (Figure 1; Figure 3), and metrics describing vertical structure also indicating a greater density and more even spread of vegetation (Figure 3f-h). These patterns contrast sharply in Gabon where there is typically a single dominant tree layer varying little in height (Figure 3a-c). The relatively low variation in tree height means fewer areas are identified as gaps, as detected using the variable height method, with 7% of the forest area in Gabon identified as such (log transformed mean size: 91 m²), compared to 20% in Peru (113 m²) (Figure 4; Figure 6). Canopy gaps measured using a fixed height threshold (10 m) were rare, comprising <5% of the forest area at either site, and by definition were correlated with tree fractional cover meaning these are not considered further.

Figure 3 – Comparison of key metrics describing forest structure across the study areas in Gabon and Peru as measured by the LiDAR sensor. Measurements of surface rugosity (b), and Relative Height (g) are expressed relative to the corresponding mean top of canopy height. Outliers are not included

Figure 4 - A comparison of canopy height models (CHM) across a 9 ha patch of forest obtained via LiDAR, and the DAP based points clouds, with tree heights estimated using both the LiDAR derived DTM, and using the estimated ground elevations from the DAP data directly. Red polygons indicate gaps detected via the Variable Gap method, i.e. areas where canopy height is <50% of the maximum height within a 50 x 50 m moving window. Transects delineated in the LiDAR CHM show the location of 3D vertical profiles in Figure 5.

Figure 5 – Example 3D LiDAR point cloud profiles, with black lines showing the SfM-DAP DTM, and the grey lines the DAP DSM for the same area.

3.2 Comparison of LiDAR and DAP metrics

Many of the broad patterns in forest structure observed on the ground, and in the LiDAR data, are also apparent in the SfM-DAP derived point clouds (Figure 4; Figure 6). Measurements of surface elevation and its variability/ rugosity showed good correspondence (CCC: 0.99), varying by maximum 1 - 2 m between methods (Figure 4; Figure 7). However, the ability of SfM-DAP to extract information from lower in the canopy, including ground returns (CCC: 0.42), becomes increasingly limited in areas with higher canopy cover (>70%), which comprise the majority of both study areas. Consequently, we find large, but variable differences in TCH (Figure 7), with individual estimates lower by an average of 6 m (RMSE: 11.6 m) in Gabon, and 8 m (RMSE: 10.0 m) in Peru, equivalent to an 18% (SD: 36%) and 40% (26%) underestimation of TCH relative to the LiDAR estimates (Figure 8). For Peru, the relative bias on TCH was consistent up to 80 - 90% cover, after which estimates decrease rapidly, falling to <50% of the LiDAR measurements (Figure 8). An almost identical pattern was observed in Gabon, with errors increasing exponentially as canopy closure exceeds 90%, however over-estimation of TCH was also common (Figure 5), resulting in more comparable, but highly variable estimates in the small number of areas with moderate tree cover (<80%). Areas with higher surface rugosity were associated with progressively more comparable

24

25

33

Figure 6 – The four panels to the left (a,b,e,f), show the vertical point density profiles (1 m height bins) from the LiDAR, and DAP derived point clouds, averaged across each study area, and separated by Canopy Closure (%). The data were extracted within 20 x 20 m grids, with the values in square brackets the percentage of each study area with the corresponding canopy closure. The remaining four panels on the right (c, d, g, h) show the averaged RH profiles for the LiDAR data (c, g), with heights expressed as a proportion of the TCH in each grid cell, and the difference to the DAP data (d,h).

Figure 7– The absolute difference between the LiDAR and SfM-DAP derived estimates of forest structure from across the study areas in Gabon (red) and in Peru (blue). The x-axis limits encompass up to 95% of the data at either study site. Summary statistics include the mean error, or bias, for each dataset, and is shown by the vertical hatched lines. The inset tables present the mean bias in relative terms (to the mean of the LiDAR data), and the RMSE in absolute and relative terms.

These differences in ground elevation, and therefore TCH, have clear implications for other metrics that use this information in their derivation (Figure 7e - 1); indeed, there is a tendency for DAP to overestimate both the variable gap fraction (%Bias: Gabon = 40%; Peru = 37%) and the size of these gaps (200%; 91%), and to underestimate tree fractional cover (-15%; -40%) and canopy closure (-7%; -29%). As with TCH, larger discrepancies were typically in areas with lower surface rugosity, and high canopy closure, due to the associated

35

49 negative bias on tree heights (Figure 8). We find a similar skewed distribution for metrics 50 describing vertical structure, including vertical complexity/ entropy, and RH values (Figure 51 7), however for each, the overall bias was relatively small with estimates typically within 10-52 20 % of the LiDAR derived values (Figures 5 - 7). In general, the RH values for mid- to upper canopy (RH50 – RH95) are similar between methods, although the greater density of 53 54 ground returns in the LiDAR results in greater divergence lower in the canopy profile (Figure 55 6). Crucially, we find that incorporating the LiDAR ground elevations in to the DAP point clouds reduced the overall bias in tree fractional cover, canopy closure and gap fraction 56 57 (Figure 8). However, there are differences that canopy height cannot account for, with DAP 58 predicting gaps where none, or few exist in the LiDAR data. Importantly, we find the RH 59 values, and the Vertical Complexity Index, were broadly unaffected by the inclusion of a 60 more accurate DTM (Figure 8), indicating such information can be extracted independent of 61 LiDAR with a similar degree of precision and accuracy.

Accepted

64 65 horizontal and vertical structure as a function of various descriptors of tree canopy structure, 66 created using the LiDAR point clouds (x-axis). Here, differences are expressed according to 67 the relative error, or % Bias, with the exception of Variable Gap Fraction and Canopy Closure 68 which is the absolute difference (Figure 7). The solid lines refer to the SfM-DAP data used 69 in isolation, while the hatched lines show the trend using the LiDAR DTM corrected SfM-70 DAP data. The relative bias was smoothed using a LOESS (locally weighted scatterplot 71 smoothing) procedure. The error bars encompass half of the SD to better display both the 72 average trend, and the range of estimates for a given context, with the upper and lower 73 bounds also smoothed using LOESS.

74 **4 Discussion**

75 In this study, we examined to what extent information on 3D forest structure obtained via 76 digital aerial photogrammetry and structure-from-motion techniques (SfM-DAP) can replicate that obtained from a LiDAR sensor. These datasets were obtained simultaneously 77 78 using an Unoccupied Aerial Vehicle (UAV), which due to their ability to fly low and image 79 the same area from multiple oblique viewpoints, have the potential to provide a much 80 improved and novel basis for evaluating the capacity of image-based methods. We compared 81 various metrics of canopy and vertical forest structure demonstrated as important for 82 aboveground biomass (AGB) estimation, and/or for measuring various aspects of ecosystem 83 structure and function, including proxies for habitat quality and biodiversity. These data 84 were collected over two contrasting areas of tropical forest; one in central Gabon, where 85 forests are typically characterised by a single layer of relatively tall trees (TCH: 30 - 50 m), 86 and the second in Peru, where the forests are structurally more complex, with multiple 87 canopy layers (TCH: 25 - 40 m).

88 We show that SfM-DAP derived point clouds cannot be used in isolation to generate 89 accurate estimates of top-of-canopy height (TCH) - a central variable in LiDAR-AGB 90 allometric models (Asner & Mascaro, 2014; Jucker et al., 2018a; Knapp et al., 2020) - due to 91 the difficulties in extracting accurate estimates of ground elevation. Our results broadly echo 92 the conclusions of previous studies, including those working in tropical forests (Swinfield et 93 al., 2019; Vaglio Laurin et al., 2019), leading to suggestions that image-based methods are 1) 94 only permissible in more open forest stands, e.g. those with < 50 - 60% canopy cover 95 (Wallace et al., 2016; Mlambo et al., 2017), or 2) only suitable for conducting measurements 96 in areas with existing digital elevation models (DTMs), such as those obtained via LiDAR 97 (White et al., 2013; Goodbody et al., 2019; Vaglio Laurin et al., 2019). In this paper, we 98 examined both of these assertions due to the scale of our datasets (100s ha), and the varying 99 vegetation types and densities present within the two study areas.

Overall, the size of the underestimation on TCH was highest at the site in Peru, where
estimates were 40% lower than the LiDAR values, compared to 20% in Gabon. The size of
the underestimation in TCH increased markedly in areas where canopy closure exceeded
80%, which account for large proportion of the forest area at both study sites. However, even
in more open areas, there still exists large, and, inconsistent differences (40 – 50% RMSE)
between the SfM-DAP and LiDAR derived estimates of tree height, even in areas with low
to, non-existent tree cover, or in areas with larger canopy gaps. That these differences are

107 inconsistent is important as it prevents bias-correction of the TCH based on a local LiDAR 108 (or other tree height) dataset. In Peru, the presence of a clear sub-canopy, and relatively dense 109 ground vegetation layer seemingly precludes accurate ground detection using SfM-DAP. In 110 Gabon, the estimates were more comparable, particularly in the relatively small number of 111 more open forest patches, albeit with greater tendency for SfM-DAP to overestimate tree 112 height. Observations of the imagery suggests the combination of tall trees, lower surface 113 rugosity, and by extension, the lower gap fraction creates insufficient illumination, and thus darker patches resulting in lower estimates of ground elevation (White et al. 2018). Our 114 115 results, and interpretation diverge from those detailed by Swinfield et al. (2019), who showed 116 that DAP systematically underestimated TCH among recovering secondary forests in 117 Indonesia, and presented a simple linear model to correct these estimates. Adopting a similar approach is complicated by the comparatively weak, and variable correspondence between 118 119 measures of TCH, which when coupled with the non-linear effect of canopy closure, and 120 influence of surface rugosity, suggests that a more complex model would be required to 121 properly account for these uncertainties across these landscapes. Other potential sources of 122 random error/variation in the data include the intensity and angle of solar illumination when 123 the data was acquired (Gobakken et al., 2015; Roşca et al., 2018), which is hard to control for 124 in tropical forests, or when collecting measurements over large areas due to frequent and 125 rapidly changing cloud cover. This complexity is acknowledged in Swinfield et al. (2019), 126 who notes that local refinement and calibration of the model would be required along with 127 the collection of independent height data, likely from LiDAR, which would largely negate the 128 need for a corrective model assuming ground data can be reliably obtained across the area of 129 interest.

130 However, despite the clear, and widespread difficulties in measuring ground elevation, SfM-DAP can be an effective method for retrieving information on top-of canopy 131 132 structure including surface elevation and heterogeneity (St-Onge et al, 2008; Gobakken et al, 133 2015; Roşca et al, 2018; Swinfield et al, 2019). This is important as it suggests that in areas 134 where an accurate DTM is available, for example, from a previous (but non-repeatable) airborne or UAV LiDAR campaign, SfM-DAP can be used to reliably extract information on 135 136 canopy height, heterogeneity and fractional cover, all of which are key predictor variables in 137 commonly applied area-based LiDAR-AGB allometric models (Asner & Mascaro, 2014; 138 Jucker et al., 2018a; Knapp et al., 2020). However, the need for an accurate DTM negates 139 many of the unique benefits of using SfM-DAP over LiDAR. For that reason, Giannetti et al., 140 (2018) developed new models for predicting stem volume in Italy and Norway using DTM-

independent variables alone, producing estimates with similar accuracy to LiDAR data, even
in areas with steep terrain. The creation and testing of models that do not require a DTM
would be an important addition to the literature and should allow data collection in areas
where more expensive LiDAR (or no data collection at all) might have been the alternative.

Despite the close correspondence in surface heights, the results of this study also 145 146 demonstrate some potentially important, albeit minor differences between the surface models 147 (DSM) obtained from LiDAR and SfM-DAP data, particularly in the detection of canopy 148 gaps. Prior to this study, the relative capacity of SfM-DAP data to capture canopy gaps in 149 complex tropical forests had not been investigated and compared to LiDAR data. Again, the 150 results show that incorporating an accurate DTM greatly reduces the bias on measures of 151 canopy gap fraction, resulting in broadly consistent estimates between methods, thus highlighting the capacity of SfM-DAP to capture these data. However, the results also 152 153 suggest a tendency for SfM-DAP to detect openings in areas where the LiDAR data does not, or where the detected gaps are small ($<100 \text{ m}^2$). Although these differences are minor, they 154 155 are potentially important when considering the ability to capture and monitor changes 156 associated with small-scale logging, or mortality (Dalagnol *et al.*, 2021). The results may be 157 improved upon by increasing the front- and side-overlap in the imagery to 80 - 85% (e.g. by 158 increasing altitude, and/or flying slower), which may result in better reconstructions by increasing the ground sampling distance and potential number of matches, particularly in 159 160 areas where the vegetation is more uniform, like in Gabon where the SfM-DAP surface models were more variable relative to LiDAR. That being said, our data could also be 161 162 considered optimal, given the accurate geolocation of the images through PPK correction 163 which may not be possible with lower cost platforms and sensors. The use of ground control 164 points (GCPs) should improve reconstructions, however this also requires survey grade GNSS receivers to differentially adjust the data, and their placement in dense forest areas can 165 166 be challenging. It is therefore possible that the quality of the DSMs produced by SfM-DAP will be lower in some cases. 167

The final set of comparisons were for metrics describing vertical structure. We posited that UAVs may provide new insights into the capacity of DAP to capture the vertical profile due to their ability to fly low (relative to aircraft), and view the forest from multiple oblique angles. Indeed, we find that each measure of vertical structure, most notably the Relative Height percentiles, and associated metrics, were similar, and in some near identical between methods, with values from the DAP point clouds within 5% of the LiDAR derived values. This novel finding most likely reflects that even with UAV-borne LiDAR, a small

175 proportion of total returns are located close to, or at the ground surface $(1 - 10 \text{ pts m}^2)$, which 176 although critical for estimating ground elevation, results in a small difference in RH percentiles compared to SfM-DAP, which principally captures the outer envelope of the 177 178 forest. For many, if not all ecological applications, errors of this size (< 10 %) may be 179 considered acceptable, suggesting that DAP may be used as a direct substitute for LiDAR 180 data, for example, as part of calibration models estimating AGB (Meyer et al., 2013; Qi et al., 181 2019), or perhaps more applicable, for mapping and understanding patterns in plant and animal diversity (Burns et al., 2020; Schneider et al., 2020). Again, there are some caveats 182 183 to this interpretation, namely, that RH metrics and others based on vertical point profiles, are 184 sensitive to the LiDAR sensor (e.g. power, beam divergence), and platform (e.g. flight speed, 185 height) used to collect the data. Similarly in the case of SfM-DAP, methods used to generate image-based point clouds may differ significantly between software, and versions, although 186 187 any sensitivity is hard to predict as the underlying algorithms are proprietary and a black box 188 to the scientific community. These differences may be minor, however it is proposed that 189 metrics derived from SfM-DAP data should only be transferred to existing models in areas 190 where correspondence to the data underpinning the original model is already established, as 191 demonstrated by Tompalski et al., (2019).

192 Overall, our results help to reinforce the ever growing body of literature pointing to SfM-DAP as a viable alternative to LiDAR for the extraction of key metrics of forest structure, 193 194 particularly in areas with existing data on ground elevation. The decision on whether to 195 apply SfM-DAP based methods must consider not only the costs of data acquisition and 196 processing, but also the potential uncertainties in the approach, and the full value of the 197 information provided. Although it is clear from our results that some area-based metrics are 198 likely to be comparable between methods, it is important to note that LiDAR is capable of 199 generating more detailed information on forest structure, including models of crown structure 200 and depth, and the segmentation of individual trees, even in relatively dense forests (Brede et al., 2017). This is significant when considering the relative importance of area-based vs 201 202 individual-based methods of mapping aboveground biomass in dense tropical forests. Current data suggests that area-based methods tend to out-perform more complex attempts to 203 204 segment and model individual trees in tropical forests, largely due to difficulties in separating 205 overlapping tree crowns, and detecting lower vegetation (Coomes et al., 2017). However, the 206 increasing use of UAVs equipped with powerful LiDAR sensors, including the one used here, 207 means we now have the potential produce similar levels of detail to Terrestrial Laser 208 Scanners (TLS), certainly for the upper canopy, which coupled with improvements to tree

- segmentation algorithms (Ferraz *et al.*, 2020; Williams *et al.*, 2020), have the potential to
- allow a more direct, or accurate estimation of canopy and/or tree volume, and thus AGB.
- 211 As such, we assert that LiDAR should remain the preferred source of information on forest
- 212 structure, however, in areas with existing terrain models, we show that SfM-DAP can be used
- to generate much-needed information on forest structure needed to better understand
- 214 vulnerable and understudied forested ecosystems around the globe.
