ABSTRACT

We present the results of a 30 ks *XMM–Newton* observation of the supergiant fast X-ray transient (SFXT) SAX J1818.6−1703 – the first in-depth soft X-ray study of this source around periastron. *INTEGRAL* observations shortly before and after the *XMM–Newton* observation show the source to be in an atypically active state. Over the course of the *XMM–Newton* observation, the source shows a dynamic range of ∼100 with a luminosity greater than 1×10^{35} erg s^{-1} for the majority of the observation. After an ∼6 ks period of low-luminosity ($\sim 10^{34}$ erg s^{-1}) emission, SAX J1818.6−1703 enters a phase of fast flaring activity, with flares ∼250 s long, separated by ∼2 ks. The source then enters a larger flare event of higher luminosity and ∼8 ks duration. Spectral analysis revealed evidence for a significant change in spectral shape during the observation with a photon index varying from $\Gamma \sim 2.5$ during the initial low-luminosity emission phase, to $\Gamma \sim 1.9$ through the fast flaring activity, and a significant change to $\Gamma \sim 0.3$ during the main flare. The intrinsic absorbing column density throughout the observation ($n_H \sim 5 \times 10^{23}$ cm^{-2}) is among the highest measured from an SFXT, and together with the *XMM–Newton* and *INTEGRAL* luminosities, consistent with the neutron star encountering an unusually dense wind environment around periastron. Although other mechanisms cannot be ruled out, we note that the onset of the brighter flares occurs at 3×10^{35} erg s^{-1}, a luminosity consistent with the threshold for the switch from a radiative-dominated to Compton cooling regime in the quasi-spherical settling accretion model.

Key words: stars: winds, outflows – X-rays: binaries – X-rays: individual: SAX J1818.6−1703.

1 INTRODUCTION

Supergiant fast X-ray transients (SFXTs) are a subclass of high mass X-ray binaries (HMXBs) recognized over the course of the *INTEGRAL* mission (Sguera et al. 2005, 2006; Negueruela et al. 2006). These sources display a large X-ray dynamic range, with intermediate SFXTs, such as IGR J16465−4514 showing a dynamic range of 100 (Clark et al. 2010) while extreme examples, such as IGR J17544−2619, possess an observed dynamic range of 10^6 from quiescence (in't Zand 2005) to maximum flare luminosity (Romano et al. 2015). There are currently 14 spectroscopically confirmed SFXTs lying along the Galactic plane and approximately the same number of candidate systems exist, though they lack spectroscopic confirmation of a supergiant companion star.

A number of geometric effects have been proposed in order to explain the rapid transient nature of SFXTs, including: clumping in the spherically symmetric outflow of the supergiant companion (in't Zand 2005), an enhancement of the equatorial density of the supergiant wind inclined with respect to the orbit of the neutron star (Sidoli et al. 2007) and variations in orbital period and eccentricity to distinguish between transient and persistent supergiant systems (Negueruela et al. 2008). However, Grebenev & Sunyaev (2007) have argued that observed outburst profiles could not be explained solely by the presence of an individual density inhomogeneity.

More complicated models invoked to explain such a large dynamic range in these systems make use of transitions in accretion mechanisms. Bozzo, Falanga & Stella (2008a) suggested transitions

between gating mechanisms, such as centrifugal and magnetic barriers, initiated by density variations in the stellar wind could cause the observed flux ranges.

Recently, Shakura et al. (2012) have proposed a model of quasi-spherical accretion on to slowly rotating neutron stars, in which accretion on to the neutron star is mediated through a quasi-static shell of plasma above the magnetosphere. In this model, bright flares are caused by a transition from a less efficient radiative cooling mechanism to a more efficient Compton cooling regime. The transition to a more effective cooling regime allows the plasma reservoir to drain on to the neutron star through the magnetosphere precipitating a rapid increase in luminosity. Originally applied to the slowly rotating pulsars Vela X$-$1, GX 301$-$2 and 4U 1907$+$09 (Shakura et al. 2012), it has since been used to explain the fast flaring behaviour seen in SFXTs (Drave et al. 2013, 2014; Paizis & Sidoli 2014; Shakura et al. 2014).

SAX J1818.6$-$1703 was discovered by the *BeppoSAX* observatory on 1998 March 11 in a short X-ray outburst lasting a few hours (in 't Zand et al. 1998). Renewed short X-ray activity was subsequently detected by the IBIS/ISGRI telescope on *INTEGRAL* on 2003 September 9 as two intense short outbursts reaching $\sim$380 mCrab in the 18–45 keV energy band (Grebenev & Sunyaev 2005). The observed activity of SAX J1818.6$-$1703 by Grebenev & Sunyaev (2005) showed complex time varying behaviour lasting approximately 1 d, with the main flare event lasting 2.7 h. IBIS/ISGRI spectra taken from this observation were fitted well with a thermal bremsstrahlung model, showing signs of spectral evolution through the flaring event. The nature of the system was unknown at the time of this observation, though the authors did rule out changes in accretion through a standard accretion disc as the cause of the behaviour. Other short X-ray outbursts from SAX J1818.6$-$1703 have been also observed with *RXTE* (Smith et al. 2012).

The identification of a B0.5Iab supergiant within the error circle of the refined *Chandra* position of SAX J1818.6$-$1703 identified the system as an SFXT at a distance of 2.1 kpc (Negueruela & Smith 2006; Torrejón et al. 2010).

The source was undetected in a 13 ks observation on 2006 October 8 with *XMM–Newton* by Bozzo et al. (2008b). The authors placed a 3σ upper limit on the unabsorbed 0.5–10 keV X-ray flux of 1.1×10^{-13} erg s^{-1} cm^{-2} ($L_X = 5.8 \times 10^{31}$ ergs s^{-1} at a distance of 2.1 kpc) using data from the EPIC-pn camera. The source was also not detected in a 45 ks observation on 2010 March 21 with *XMM* (Bozzo et al. 2012c), though due to high flaring background, the effective observation time for EPIC-pn was only 4 ks. This observation placed a 3σ upper limit on the unabsorbed 0.5–10 keV flux of 3×10^{-13} erg s^{-1} cm^{-2}, consistent with the previous observations.

An in-depth study of available *INTEGRAL*/IBIS data by Bird et al. (2008) revealed a 30$\pm$0.1 d orbital period. A period of 30$\pm$0.2 d was independently found by Zurita-Heras & Chaty (2008) and the eccentricity of the orbit was constrained to between 0.3 and 0.4. Using both the orbital period and the ephemeris (MJD 54540.659) from Bird et al. (2008), the previous *XMM* observations were found to have been taken at orbital phases of $\phi = 0.51$ and 0.53 (close to apastron) for the 13 and 45 ks observations, respectively. Using the same *INTEGRAL* data set and performing a recurrence analysis of outbursts from SAX J1818.6$-$1703, Bird et al. (2008) found that the system has a high level of recurrence, showing detectable emission in more than 60 per cent of periastron passages. This high recurrence rate when coupled with the large outbursts as seen by Grebenev & Sunyaev (2005) show the behaviour of SAX J1818.6$-$1703 is atypical of that found in other SFXTs.

A catalogue of *Swift*/BAT bright flares from the SAX J1818.6$-$1703 has been reported by Romano et al. (2014), while a systematic re-analysis of the *INTEGRAL* archival data has been reported by Paizis & Sidoli (2014), who found that the distribution of X-ray flare luminosities follow a power law.

We present phase targeted temporal and spectral analysis of this source, observed with *XMM–Newton* starting on 2013 March 21 and lasting 30 ks. Spectral analysis of this source shows evidence for variation in both absorbing column density and photon index correlated with flaring behaviour.

2 DATA ANALYSIS

2.1 *XMM* data analysis

A single *XMM–Newton*/EPIC (Jansen et al. 2001; Strüder et al. 2001; Turner et al. 2001) observation of SAX J1818.6$-$1703 around the periastron orbital phase of the system was performed beginning at UTC 12:37:22 and ending at UTC 21:24:54 on 2013 March 21, covering the orbital phase region $\phi = 0.121$–0.134 using the ephemeris of Bird et al. (2008) (ObsID: 0693900101). The EPIC-pn camera was operated in small window mode, while the EPIC-MOS cameras were operated in full frame mode. This configuration was chosen to account for the rapid transient nature of this source and reduce pileup in the event of the source experiencing a bright ($\sim$10^{-10} erg s^{-1} cm^{-2}) outburst.

Data from both EPIC-pn and EPIC-MOS detectors were analysed using the standard *XMM–Newton* Science Analysis System (SAS v12.0.1; Gabriel et al. 2004) and the most recent instrument calibration files. The standard EPPROC and EMPROC tasks were used to produce cleaned event files for EPIC-pn and EPIC-MOS cameras, respectively. The data sets were filtered for flaring particle background and checked for photon pileup using the EPATPLOT tool as described in the *XMM–Newton* SAS data analysis threads.[1] The observation was found not to suffer from photon pileup. We created single-event products (PATTERN $= 0$) in the range of 10–12 keV for EPIC-pn and above 10 keV for EPIC-MOS cameras covering the full field of view for each camera and using cutoffs of 0.35 and 0.4 counts s^{-1} for EPIC-pn and EPIC-MOS, respectively, as outlined in the SAS threads. Filtered event files were produced from the resulting good time intervals defined by this filtering.

Optimal extraction regions for all light curve and spectrum generating procedures were generated using the SAS tool EREGIONANALYSE, which yielded extraction regions of 26, 51 and 58 arcsec for EPIC-pn, EPIC-MOS1 and EPIC-MOS2, respectively.

Broad-band 0.2–10 keV light curves from EPIC-pn and EPIC-MOS were extracted with 100 s resolution initially, as shown in Fig. 2. The properties of the EPIC-pn light curve are discussed in Section 3.2.

All spectra reported below were extracted using standard procedures from the *XMM–Newton* analysis threads and the appropriate response for each spectrum was generated using the SAS tools RMFGEN and ARFGEN. The spectra were fit in the 0.5–15 keV band using XSPEC version 12.7.1 (Arnaud 1996) and uncertainties are quoted at the 90 per cent confidence level. In this work, the interstellar element abundances for photoelectric absorbing model components are set by the abundances of Wilms, Allen & McCray (2000). Spectral properties are discussed in Section 3.3.

2.2 *INTEGRAL* data analysis

INTEGRAL/IBIS (Ubertini et al. 2003; Winkler et al. 2003) observed SAX J1818.6−1703 between UTC 00:19:37 on 2013 March 12 and UTC 18:15:52 2013 March 13 as part of Revolution 1271. During this revolution, the source was observed for a total of 10 ks. SAX J1818.6−1703 was also observed by *INTEGRAL*/IBIS between UTC 11:10:03 and UTC 20:44:48 on 2013 March 20 and between UTC 09:00:11 and UTC 20:13:27 on 2013 March 22. These *INTEGRAL* observations cover the phases $\phi = 0.804$–0.862, $\phi = 0.086$–0.099 and $\phi = 0.150$–0.165, respectively, using the ephemeris of Bird et al. (2008). This archival data were processed and analysed using the *INTEGRAL* Offline Science Analysis (Goldwurm et al. 2003) software version 10.1. Images were created in the 18–60 keV energy range for each science window (ScW; an individual pointing of *INTEGRAL* lasting approximately 2 ks) and each observation of the source. Light curves in the 18–60 keV band on ScW and 250 s time-scales and spectra in the 18–500 keV band were also generated following standard procedures. A list of all observations discussed in this work can be found in Table 1. We are aware that the low-energy threshold of IBIS/ISGRI on-board *INTE-*

GRAL has increased since launch and consequently the *INTEGRAL* Science Data Centre recommend ignoring data below 22 keV for all revolutions after Revolution 1090. We generated images in the 18–60 keV and 22–60 keV bands for both observations in Revolution 1274. We find that there is no significant difference in the detections of the source between the energy bands. In order to compare our results with previous hard X-ray studies using *INTEGRAL*, we adopt the 18–60 keV energy band for subsequent analysis.

3 RESULTS

3.1 *INTEGRAL* results

SAX J1818.6−1703 was not detected in the earlier observation of the source during Revolution 1271, which was prior to the periastron passage. Fig. 1 shows the *INTEGRAL*/IBIS 18–60 keV significance maps for the observations in Revolution 1274 that bracket the *XMM* observation of SAX J1818.6−1703. The left-hand panel shows the significance map for the observation taken one day prior to the *XMM* observation; SAX J1818.6−1703 is detected at the 10σ level. The
Figure 1. Left-hand panel: 18–60 keV *INTEGRAL*/IBIS significance map from the observation of SAX J1818.6−1703 between UTC 11:10:03 and UTC 20:44:48 on 2013 March 20. The best X-ray positions of SAX J1818.6−1703 and other sources in the field of view are marked with black circles. Right-hand panel: as the left-hand panel for the observation between UTC 09:00:11 and UTC 20:13:27 on 2013 March 22.
Figure 2. 0.2–10 keV EPIC-pn 100 s resolution light curve of the *XMM* observation of SAX J1818.6−1703. In this case, $t_0 = $ MJD 56372.530 and is the first time stamp of the EPIC-pn light curve. This observation covered the orbital phase region $\phi = 0.121$–0.134.

right-hand panel shows the significance map for the observation taken one day after the *XMM* observation. In this map, there is a marginal detection of the source at 6σ; however, due to the short exposure time, there is a high level of systematic noise in the map. To look for signatures of fast variability, the 250 s bin light curve of these two observations was analysed. There is evidence of activity and variability through this observation period.

3.2 *XMM* temporal analysis

Fig. 2 shows the background subtracted 0.2–10 keV EPIC-pn light curve with 100 s time bins and filtered for low fractional exposure (FRACEXP < 0.5). Times in this light curve are given with $t_0 = $ MJD 56372.530 being the first time stamp of the EPIC-pn light curve. For t < 6000 s, the source shows a low level of X-ray emission with an average flux for this region of the light curve is 0.16 ± 0.009 counts s^{-1} and a minimum count rate of 0.01 ± 0.04 counts s^{-1}. Following this, the source then shows an increase in activity up until t∼7500 s when the source enters a period lasting ∼7.5 ks where 3 small flares occur, reaching up to counts of 2–3 counts s^{-1}. Following the onset of this flaring activity, a large (up to ∼8 counts s^{-1}) flare occurs, lasting approximately 7.5 ks after which the source exhibits small-scale flaring activity until the end of the observation. Over the course of the observation, the source exhibits a dynamic range of ∼100 in count rate.

The EPIC-MOS1 and EPIC-MOS2 light curves show similar levels of variability and flaring activity, though due to the lower sensitivity of these instruments and hence lower count rates with respect to the EPIC-pn instrument, we focus our temporal analysis on the EPIC-pn light curves for the remainder of this work.

A filtered light curve with 1 s binning was tested for the presence of periodicities in an attempt to locate the as yet unknown neutron star spin period of SAX J1818.6−1703. A Lomb–Scargle periodogram (Lomb 1976; Scargle 1982) was produced using the fast implementation of Press & Rybicki (1989). Significance levels, above which one would consider the detection of a periodic signal to be true, were calculated using Monte Carlo simulations. The method of Hill et al. (2005) was used in order to gain appropriate confidence levels with 100 000 iterations utilized. Using this
Figure 3. Hardness ratio of the 0.5–5 keV and 5–10 keV EPIC-pn light curves of SAX J1818.6−1703 with 400 s binning. As with Fig. 2, $t_0 = $ MJD 56372.530 and is the first time stamp of the EPIC-pn light curve.

Table 2. Times associated with the regions used for spectral and hardness ratio analysis. T_{start} and T_{stop} are given in seconds since beginning of the observation.

Spectrum	T_{start}	T_{stop}	MJD$_{start}$	MJD$_{stop}$
A	0	6000	56372.530	56372.599
B	8400	8800	56372.627	56372.632
C	10 200	10 500	56372.648	56372.652
D	12 600	13 300	56372.676	56372.684
E	15 800	20 500	56372.713	56372.767
F	20 500	23 800	56372.767	56372.806
G	25 500	25 800	56372.825	56372.829
H	27 100	27 500	56372.844	56372.848

method when applied to the light curve of the whole observation, we did not find any significant peaks in the Lomb–Scargle power in the range of 2 s–4.2 h. Searches for periodic signals in temporally selected windows corresponding to low and brighter intensities (t < 8500, 8500< t < 15 000, 15 000 < t < 25 000, t > 25 000) were also carried out in the range of 2–2500 s and yielded no significant signals.
An epoch folding method using the Q^2 statistic as defined by Leahy et al. (1983) was also utilized to identify periodic signals. As for the Lomb–Scargle periodogram, 100 000 iterations of a Monte Carlo process were undertaken and confidence levels determined. This method yielded no significant peaks in the range of 2s–4.2 h.
3.3 *XMM* spectral analysis

We performed a preliminary, model independent check for spectral variability by calculating the hardness ratio, defined as

$$HR = \frac{H - S}{H + S}, \tag{1}$$

where H is the counts in the hard X-ray band (5–10 keV in this work) and S is the counts in the soft X-ray band (0.2–5 keV). The calculated hardness ratio between these two bands is shown in Fig. 3 with 400 s binning. Given the evident evolution in hardness ratio, we extracted spectra from temporal regions showing similar flux behaviour and constant hardness ratio. The time intervals associated with these extraction regions are listed in Table 2 and correspond to the regions specified by dot–dashed lines in Fig. 4. Region A corresponds to the low flux, early period of the observation. Regions B, C, D, G and H correspond to small flares that occur after the initial low-flux interval but either side of the main flare period. Data from these flares were

Table 3. Hardness ratios and best-fitting parameters for a power-law model [*cons*phabs*cflux(powerlaw)*] fit to spectra extracted from the regions outlined in Fig. 4 and Table 2. Absorbing column density, n_H is in units of 10^{22} cm^{-2}, the 0.5–10 keV unabsorbed flux is in units of $\times 10^{-10}$ erg cm^{-2} s^{-1}.

Parameter	A	E	F	B+C+D+G+H
Hardness ratio	0.30 ± 0.06	0.66 ± 0.01	0.68 ± 0.02	0.54 ± 0.02
n_H	56^{+12}_{-10}	43^{+2}_{-2}	51^{+3}_{-3}	53^{+4}_{-4}
Γ	$2.4^{+0.6}_{-0.5}$	$0.36^{+0.1}_{-0.1}$	$0.57^{+0.1}_{-0.1}$	1.86 ± 0.2
Unabsorbed flux	$0.27^{+0.38}_{-0.13}$	$1.49^{+0.07}_{-0.07}$	$1.66^{+0.16}_{-0.16}$	$1.82^{+0.50}_{-0.37}$
$\chi^2_{\rm red}$ (dof)	1.07 (68)	1.34 (302)	1.39 (242)	1.02 (163)

3.4 *INTEGRAL* and combined spectral analysis

With the aim of better constraining the spectral model of the source, an average *INTEGRAL*/IBIS spectrum was extracted from the ScWs with the greatest significance detections of the source in the first observation in Revolution 1274. This spectrum was fitted in the 18–60 keV range with a power-law model, yielded a photon index of $\Gamma = 3.15^{+1.15}_{-0.99}$ with $\chi^2_{\rm red} = 0.80$ (2 dof) and a model flux of 2.879×10^{-10} erg s^{-1}.

Simultaneous fits of the *INTEGRAL* spectrum with the *XMM* MOS and pn spectra were performed in the 0.5–50 keV range. Fits of an absorbed power-law model described in Section 3.3 yielded good fits and best-fitting parameters consistent with those presented in Table 3 for the *XMM* data only. The statistics of the *INTEGRAL* spectrum are such that they do not constrain the hard X-ray spectral shape well and consequently the much better statistics in the *XMM* energy range cause it to dominate when fitting over the full spectral range. As a result, combining *XMM* and *INTEGRAL* spectra does not allow us to better constrain the spectral model achieved with *XMM* data alone.

4 DISCUSSION

We present the results of a 30 ks *XMM–Newton* observation of the SFXT, SAX J1818.6−1703. This is the first in-depth soft X-ray investigation of the source located around the peak in the *INTEGRAL*/IBIS phase folded light curve (fig. 3 of Bird et al. 2008), likely located near periastron. We also present the results of contemporaneous archival *INTEGRAL*/IBIS observations spanning 115 ks with 25 ks on-source exposure.

4.1 *INTEGRAL* context

Previous studies of this source with *INTEGRAL* have revealed a long (30 d), eccentric (e ∼ 0.3–0.4) orbit and shown detections in more than 60 per cent of neutron star periastron passages.

SAX J1818.6−1703 was not detected by *INTEGRAL* in an observation carried out between 2013 March 12 and 2013 March 13 during Revolution 1271, at a time that corresponds to an orbital phase of 0.804–0.862. During this region of a long eccentric orbit, the stellar wind, through which the neutron star passes, is not expected to be sufficiently dense or structured so as to produce detectable emission from accretion.

A bright flare from SAX J1818.6−1703 detected by *Swift*/BAT on 2013 March 17 (corresponding to phase, $\phi = 0.970$) was reported by Romano et al. (2014). During this flare the source reached a peak flux of 146 mCrab (15–50 keV), clearly showing that the source exhibited enhanced X-ray emission a few days prior to the *XMM* observation reported here.
The source was also detected by *INTEGRAL* during Revolution 1274 at a significance of ∼13σ. A more detailed analysis of this revolution shows that the source was first observed between UTC 11:10:03 and UTC 20:44:48 on 2013 March 20, corresponding to orbital phases $\phi = 0.086$–0.099, with a total source exposure of 7.5 ks. During this observation, the source was detected with an average count rate of 2.17 ± 0.22 counts s^{-1} (18–60 keV) or ∼10 mCrab. The source was subsequently observed between UTC 09:00:11 and UTC 20:13:27 on 2013 March 22, corresponding to orbital phases $\phi = 0.150 - 0.165$, again with a total source exposure of 7.5 ks. The average count rate in this observation was 1.27 ± 0.22 counts s^{-1} (18–60 keV). In order to compare these fluxes to previous periastron passages, we performed the recurrence analysis of Bird et al. (2008) using an *INTEGRAL*/IBIS light curve of SAX J1818.6−1703 from the first 1000 revolutions of *INTEGRAL*. We calculated the mean flux detected by *INTEGRAL* during a 4-day period centred on periastron and from this, we find that during the first observation of Revolution 1274, the source is brighter than 80 per cent of periastron passages observed by *INTEGRAL*. The flux detected between UTC 09:00:11 and UTC 20:13:27 on 2013 March 22 is consistent with fluxes observed by *INTEGRAL* during the majority of periastron passages. However, it is different from the distribution of apastron flux measurements and still represents a significant detection of the source. When considering both the *Swift*/BAT bright flare on 2013 March 17 and the *INTEGRAL* observations during Revolution 1274, it is clear that SAX J1818.6−1703 was in an atypically active state during the periastron passage covered by the *INTEGRAl* and *XMM* observations presented in this work.

4.2 Source distance

Knowledge of the source distance is critical in order to calculate associated luminosities and hence disentangle the accretion processes generating the observed dynamic X-ray behaviour. A number of source distances have been suggested for SAX J1818.6−1703, though the distance is still one of the best constrained for an SFXT. Using near infrared spectroscopy, Torrejón et al. (2010) inferred a distance of 2.1 ± 0.1 kpc. More recently, Coleiro & Chaty (2013) inferred a distance of 2.7 ± 0.28 using a similar method. For the subsequent discussion, we adopt the better constrained distance estimate of 2.1 ± 0.1 kpc from Torrejón et al. (2010). The range of possible distances to the source is such that the luminosities calculated assuming a distance of 2.1 kpc could be a factor of 1.3 larger if the source is located at 2.7 kpc.
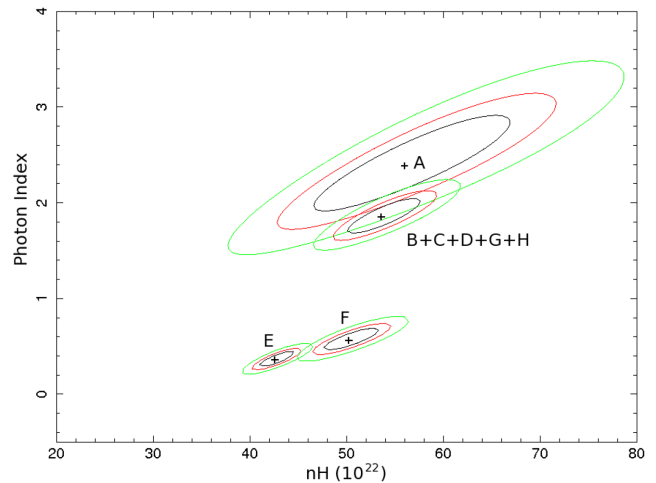

4.3 Observed luminosity

In order to critically evaluate the accretion processes taking place over the course of the *XMM–Newton* observation, the pn count rates

Figure 7. Confidence contours for the best-fitting spectral parameters to regions A, B+C+D+G+H, E and F using an absorbed power-law model [*cons*phabs*cflux(powerlaw)*] with the 68 per cent, 90 per cent and 99 per cent statistical confidence regions shown.
Figure 8. The *XMM–Newton* light curve shown in Fig. 4 with count rate converted into luminosity using an absorbed power law with photon index $\Gamma = 1.9$, absorbing column density, $n_H = 5 \times 10^{23}$ cm^{-2} and a source distance of 2.1 ± 0.1 kpc. The red dashed line corresponds to the critical luminosity for transition between the radiatively cooled to Compton-cooled regimes in Shakura et al. (2013).

Figure 6. Top panel: power-law fit and residuals to EMOS (Black and Red) and EPN (Green) spectra from region A. Middle panel: power-law fit and residuals to EMOS (black and red) and EPN (green) spectra from region B+C+D+G+H. Bottom panel: power-law fit and residuals to EMOS (black and red) and EPN (green) spectra from region E.

shown in Fig. 4 were converted to X-ray luminosities. To convert from count rate to luminosity, we assumed an absorbed power-law spectral model with photon index $\Gamma = 1.9$, an absorbing column density of $n_H = 5 \times 10^{23}$ cm^{-2} and a source distance of 2.1 ± 0.1 kpc. These spectral parameters are consistent with the fits to regions A and B+C+D+G+H. Although these are not consistent with regions E and F, we apply the same model to these sections of

the light curve so as not to introduce discontinuities in the luminosity light curve scale factor. The resulting luminosity light curve is shown in Fig. 8.

During the first 6 ks of the *XMM* observation, the source exhibits low-level persistent emission with luminosities of $\sim 10^{34}$ erg s^{-1}. This corresponds to low-level accretion of material from the stellar wind, however the light curve shows no flaring behaviour during this interval. We investigate this further by estimating the 0.5–10 keV luminosity for the *INTEGRAL* observation of the source between UTC 11:10:03 and UTC 20:44:48 on 2013 March 20. Using an *INTEGRAL*/IBIS source count rate of 2.17 counts s^{-1} and the cut-off power law of Sidoli et al. (2009) and the absorbing column density measured in this work of 5×10^{23} cm^{-2}, we calculate an

XMM count rate of 4.45 counts s^{-1} (0.5–10 keV). Assuming the same absorbed power law used to produce Fig. 8, this corresponds to a luminosity of 3.3×10^{35} erg s^{-1}. This suggests that the initial 6 ks of the *XMM* observation is a low-flux interval between periods of higher activity.

One possible explanation for initial low flux observed by *XMM–Newton* could be the obscuration of the emitting region by circumstellar material. However, the spectral analysis of Section 3.3 rules out this scenario as the values of absorbing column density for this region are consistent with the regions showing flaring activity.

Excluding the obscuration of the source by a dense clump, other possibilities are often discussed in the literature to explain these 'dips' or 'off-states' sometimes observed in supergiant HMXB pulsars. These include a transition to a less effective accretion regime likely triggered by a mild variability in the wind properties. If this is the case, the initial dip could be explained by either a transition to the subsonic propeller regime where the low luminosity is produced by means of matter penetrating the magnetosphere by the Kelvin–Helmholtz instability (Doroshenko, Santangelo & Suleimanov 2011) or by a cooling regime switch (Shakura, Postnov & Hjalmarsdotter 2013). In this latter scenario, an accretion regime transition from a Compton cooling-dominated regime (implying a higher accretion rate through the magnetosphere) to a radiative dominated regime (producing a lower X-ray luminosity) is produced in the equatorial plane of the neutron star magnetosphere, due to a switch from a fan beam to a pencil beam geometry (Shakura et al. 2013).

Following the method of Doroshenko et al. (2011) and Drave et al. (2013), we apply the framework of Bozzo et al. (2008a) to explain this low activity region seen in the first 6 ks of the *XMM* observation. For supergiant stellar parameters, we adopt a stellar mass and radius of 25 M$_\odot$ and 30 R$_\odot$, respectively, a stellar mass-loss rate $\dot{M}_w = 5 \times 10^{-7}$ M$_\odot$ yr^{-1} and terminal wind velocity of 1000 km s^{-1}. We also assume a magnetic field strength of 10^{12} G for the neutron star, in line with measurements of other field strengths in HMXBs and the SFXT, IGR J17544−2619 (Kreykenbohm et al. 2002; Bhalerao et al. 2015). Using an average luminosity of 1×10^{34} erg s^{-1}, equation (21) of Bozzo et al. (2008a), the range of wind velocities and plasma density ratios used by Drave et al. (2013), the corresponding neutron star spin periods fall between 50 and 90 s. Hence the subsonic propeller regime could be invoked to explain this low activity period if the neutron star is slowly rotating with a magnetic field strength typical of HMXB pulsars.

Given the low luminosities associated with region A, we can also apply the quasi-spherical accretion theory of Shakura et al. (2012). In this framework, for luminosities below $\sim 3 \times 10^{35}$ erg s^{-1}, the source inhabits a region where plasma held above the magnetosphere cools by thermal bremsstrahlung before entering the magnetosphere by the Rayleigh–Taylor instability (Shakura et al. 2013). The low-luminosity interval at the beginning of the *XMM* observation can be explained as lower density plasma entering the magnetosphere during this time.

Recently, hydrodynamic simulations of Vela X-1, taking into account ionization of the stellar wind by the central X-ray source, by Manousakis & Walter (2015) have shown that off-states lasting between 300 and 7.2 ks can be generated by lower density 'bubble' structures forming in the wind around the neutron star. The density of these bubbles is approximately one-tenth that of the time-averaged density of the plasma surrounding the neutron star causing a corresponding luminosity drop of the same factor. Therefore, the presence of one of these low-density bubbles could also explain the first 6 ks of this *XMM* observation

The increase in luminosity following the low-activity region can also be explained within this framework as increases in the amount of material entering the magnetosphere while still in the radiative cooling regime. The main flare event (regions E and F) at approximately 17 500 ks exceeds the critical luminosity value of $\sim 3 \times 10^{35}$ erg s^{-1} (shown as a red dashed line in Fig. 8) for a transition between the radiative and Compton cooling regimes (Shakura et al. 2013). This occurs at approximately the same time as the evolution to a harder photon index in the spectral fits.

After the period of enhanced soft X-ray emission, the source decreases in luminosity and appears to return to the radiatively cooled regime, again with flaring behaviour. Using the second *INTEGRAL* observation of SAX J1818.6−1703 during Revolution 1274, we can infer the soft X-ray behaviour of the source after the *XMM* observation. During the *INTEGRAL* observation, an average source flux of 1.27 counts s^{-1} was detected. Using the same method as for the previous *INTEGRAL* observation between UTC 11:10:03 and UTC 20:44:48 on 2013 March 20, we infer an *XMM* 0.5–10 keV count rate of 2.6 counts s^{-1}. Assuming an absorbed power law with absorbing column density, $n_H = 5 \times 10^{23}$ cm^{-2} and photon index, $\Gamma = 1.9$, this corresponds to a luminosity of 1.9×10^{35} erg s^{-1}. This is consistent with continued flaring behaviour following the *XMM–Newton* observation of SAX J1818.6−1703.

We note that although the distribution of orbital eccentricities of SFXTs is not well known (see Paizis & Sidoli 2014 and references therein), short-period systems are likely to have more circular orbits. The high eccentricity of SAX J1818.6−1703 and resulting wind density variation along the orbit experienced by the compact object is likely to be an additional factor and acting alongside the mechanisms discussed above driving the atypical variability seen in this source.

4.4 Spectral variation

The analysis of the hardness ratio evolution shows that SAX J1818.6−1703 undergoes clear spectral evolution, shown in Fig. 7, during the development of the flaring behaviour. The 'harder-when-brighter' relation often seen in HMXBs is also seen in this observation, as shown in Fig. 5. Spectra A, E and F clearly show this behaviour; however, in the intermediate intensity range, this relationship is less clear. One explanation for this could be that the average source count rate is not representative of source luminosity as the spectral extraction regions contain both flare peaks and lower intensity portions of the light curve. Changes in absorption caused by circumstellar material could also mask or distort the 'harder-when-brighter' relation, but we see no evidence for that here.

A more detailed analysis (Table 3) revealed variations in the photon index. The source shows significant variation in photon index and when comparing this to the EPIC-pn light curve of Fig. 4, it is clear that the source evolves from a soft spectrum at the onset of the flaring episode to a harder spectrum around the main flare event. From Fig. 7, using a power-law fit, it is evident that this is a true variation within this model and not a result of the correlation of the fit parameters as the parameters are seen to be only weakly correlated. However, using a more realistic absorption model could change the observed relationship between the absorption and spectral slope. Although the evolution shown in Fig. 7 is model-dependent, evolution in the hardness ratio shows that higher energy photons are being detected for periods of higher flux. An absorbed power law is one method of characterizing this change which gives reasonable fits to the data.

It can be seen from Table 3 that the photon index of the underlying continuum varies from 0.3 to 2.5 on a time-scale of approximately 10 ks. The absolute values of absorbing column density are among the highest ever observed in an SFXT and are comparable with the observed $(6 \pm 1) \times 10^{23}$ cm^{-2} in IGR J16465−4507 (Walter et al. 2006). Previous soft X-ray observations of an outburst of this source around periastron by Sidoli et al. (2009) with *Swift* did not reveal any spectral variability in either photon index or absorbing column density; however, the source was in outburst for the duration of the observation. Those observations did reveal a high absorbing column density of $(5–7) \times 10^{22}$ cm^{-2} and a photon index of $\Gamma = 0.3 \pm 0.2$ for a cut-off power-law fit to *Swift*/XRT and BAT data. This absorption is still an order of magnitude less than that measured in this observation, while the photon index is consistent with that measured here. Such large values of absorbing column density are more in line with those measured in the highly obscured persistent HMXBs discovered by *INTEGRAL* (Walter et al. 2003; Filliatre & Chaty 2004). Given the line of sight absorption to SAX J1818.6−1703 ($n_H = 1.42 \times 10^{22}$ cm^{-2}; Dickey & Lockman 1990), it is clear that this increased absorption is intrinsic to the system.

4.5 Temporal studies

Spin periods of neutron stars in SFXTs are known for less than half of the known sources and range from ∼5 s in AX J1841.0-0536 (Bamba et al. 2001, see also Romano et al. 2011 for further discussion) to ∼1212 s in the case of IGR J16418–4532 (Sidoli et al. 2012). Previous observations of SAX J1818.6−1703 with *XMM–Newton* and *Swift* have failed to find a periodic signal that could be interpreted as a neutron star spin period (e.g. Sidoli et al. 2009; Bozzo et al. 2012c).

Searching for a neutron star spin period in this system using a both a Lomb–Scargle periodogram and an epoch folding method as described in Section 3.2, we detected no significant periodicities in the range of 2 s–4.2 h. This period range is the range over which the data set would allow for a periodic signal to be detected with confidence and covers the spread in known neutron star spin periods in SFXTs (Paizis & Sidoli 2014). Since spin periods in some systems have only been detected in certain accretion states, we selected time windows corresponding to periods of lower and higher intensity from the EPIC-PN light curve ($t < 8500, 8500 < t < 15\,000, 15\,000 < t < 25\,000, t > 25\,000$) and tested for the presence of neutron star spin periods; however, no significant signal was detected.

A possible explanation for the lack of a neutron star spin period detection comes from the nature of the behaviour during this observation. The source exhibits flaring activity, with 5 flares each lasting ∼1 ks and a main flare event, seen to occur approximately 17.5 ks after the start of the observation. The rapidly changing nature of the flux could have masked any periodic modulation due to the rotation of the neutron star.

Another explanation for the non-detection could be that the spin period value lies outside the range probed in this work. This would imply the neutron star is either a faster or slower rotator compared to other neutron stars hosted in SFXTs. Currently, the longest known neutron star spin period in an HMXB is ∼2.8 h found in 2S 0114+650 (Corbet, Finley & Peele 1999). If the neutron star in SAX J1818.6−1703 were to have such a slowly rotating neutron star, it would be located at the extreme end of the spin period distribution for HMXBs (fig. 1 of Enoto et al. 2014; catalogue: Liu, van Paradijs & van den Heuvel 2006).

One further possibility to explain the lack of pulsations would be a geometric effect such as low inclination of the binary plane or the existence of a small angle between rotation and magnetic field axes as suggested by Reynolds et al. (1999) for the HMXB 4U 1700–37.

The non-detection of a spin period allows the possibility that the compact object could be a black hole. However, there are currently no candidate black hole systems amongst SFXTs and only a handful in the entire population of HMXBs e.g. Cyg X−1, LMC X−3 and MWC 656 (Bolton 1975; Cowley et al. 1983; Casares et al. 2014).

There is a hint of 'quasi-periodic' flaring in the light curve, on a time-scale of about 2 ks. This could be explained by a number of models of HMXB accretion (see for example, the discussion in Sidoli et al. 2012 regarding quasi-periodicity in X-ray flaring of the SFXT, IGR J16418–4532). The explanations that seem to better apply to SAX 1818.6−1703 include the quasi-spherical settling accretion model (Shakura et al. 2012), where convective motion at the base of the shell located above the magnetosphere can produce X-ray flares on a quasi-periodic time-scale, or the effects seen in hydrodynamic simulations of the accretion flow in the vicinity of the neutron star (Manousakis & Walter 2015 and references therein), where low-density bubbles forms and are accreted by the neutron star in a sort of 'breathing mechanism', alternating between low- and higher density matter.

5 CONCLUSIONS

SAX J1818.6−1703 has been observed, for the first time in soft X-rays, around periastron. The observed luminosities seen in both *INTEGRAL* and *XMM–Newton* place this source in a highly active state with periods of fast flaring followed by a longer duration flare event reaching a peak luminosity of ∼6 × 10^{35} erg s^{-1}. The large increase in activity is coincident with a significant hardening of the source spectrum from a photon index $\Gamma \sim 1.9$ to $\Gamma \sim 0.3$, suggesting a change in accretion mechanism compared to the earlier flaring activity. Although other mechanisms cannot be ruled out, we note that the luminosity of the main flare period exceeds the critical luminosity required for a transition between the radiative and Compton cooling regimes in the theory of quasi-spherical accretion proposed by Shakura et al. 2012. We also report an initial lower luminosity state with $L_X \sim 10^{34}$ erg s^{-1} that could be generated either by the source entering a subsonic propeller regime as outlined by Bozzo et al. (2008a) or by a decrease in density of material accreting on to the neutron star.

Spectral analysis indicates high intrinsic absorbing column densities of $n_H \sim 5 \times 10^{23}$ cm^{-2}; an order of magnitude higher than previous observations of the source. These column densities are amongst the highest measured in an SFXT and comparable to those found in highly obscured HMXBs discovered by *INTEGRAL* (Walter et al. 2006).

Further detailed investigation of this source relies upon a determination of the neutron star characteristics, principally its spin period and magnetic field strength, as has recently been demonstrated by *NuSTAR* observation of IGR J17544−2619 (Bhalerao et al. 2015). We therefore encourage further observations of SAX J1818.6−1703 with these aims in mind.
