## ABSTRACT

We report on the evolution of the X-ray emission of the accreting neutron star (NS) low mass X-ray binary (LMXB), MXB 1659-298, during its most recent outburst in 2015-2017. We detected 60 absorption lines during the soft state (of which 21 at more than  $3\sigma$ ), that disappeared in the hard state (e.g., the Fe XXV and Fe XXVI lines). The absorbing plasma is at rest, likely part of the accretion disc atmosphere. The bulk of the absorption features can be reproduced by a high column density ( $\log(N_H/cm^{-2}) \sim 23.5$ ) of highly ionised ( $\log(\xi/erg\ cm\ s^{-1}) \sim 3.8$ ) plasma. Its disappearance during the hard state is likely the consequence of a thermal photo-ionisation instability. MXB 1659-298's continuum emission can be described by the sum of an absorbed disk black body and its Comptonised emission, plus a black body component. The observed spectral evolution with state is in line with that typically observed in atoll and stellar mass black hole LMXB. The presence of a relativistic Fe K $\alpha$  disk-line is required during the soft state. We also tentatively detect the Fe XXII doublet, whose ratio suggests an electron density of the absorber of  $n_e > 10^{13}\ cm^{-3}$ , hence, the absorber is likely located at  $< 7 \times 10^4\ r_g$  from the illuminating source, well inside the Compton and outer disc radii. MXB 1659-298 is the third well monitored atoll LMXB showcasing intense Fe XXV and Fe XXVI absorption during the soft state that disappears during the hard state.

**Key words:** Neutron star physics, X-rays: binaries, absorption lines, accretion, accretion discs, methods: observational, techniques: spectroscopic

## 1 INTRODUCTION

Winds are fundamental components of accretion onto X-ray binaries (Shakura & Sunyaev 1973; Begelman et al. 1983). In black hole (BH) X-ray binaries, they are observed to have an equatorial geometry and a strong state dependence (Miller et al. 2006; Neilsen & Lee 2009; Ponti et al. 2012; Neilsen et al. 2018). Winds might even affect the effective viscosity of the accretion disc, as well as the X-ray binary (orbital period) evolution (Ponti et al. 2017; Tetarenko et al. 2018).

Analogously to black hole (BH), accreting neutron star (NS) systems also show ionised absorbers with similar equatorial geometry, similar column densities and ionisations (Ueda et al. 2004; Diaz Trigo et al. 2006; 2016; Ponti et al. 2016). It is still an open question whether the highly ionised absorbers (traced by Fe XXV and Fe XXVI) in NS share the same state dependence as the

ones observed in accreting BH. Recent investigations focussed on EXO 0748-676 and AX J1745.6-2901, which are two of the atoll NS systems with the best monitoring in the Fe K band, covering both soft and hard states. In both sources it was observed that the highly ionised absorption is stronger during the soft state, while it is undetected during the hard state (Ponti et al. 2014; 2015; 2018). This might suggest that the state-absorption connection is a common property of NS (atoll) sources.

Although the origin of such state-absorption connection is still debated, the results of photo-ionisation computations clearly showed that whenever the soft state absorber in X-ray binaries is illuminated by the hard state spectral energy distribution (SED), the plasma becomes unstable (Jimenez-Garate et al. 2001; Chakravorty et al. 2013; Higgibottom & Proga 2015; Bianchi et al. 2017). As a result of such photo-ionisation thermal instability the plasma is prone to change its properties (e.g., condensing, expanding, etc.)

and it will likely migrate to other stable solutions (Bianchi et al. 2017).

To further characterise the properties of the absorbers in accreting NS, as well as to further investigate the state-absorption connection in atoll sources, we triggered *XMM-Newton*, *Chandra* and *NuSTAR* observations during the last ( $\sim 1.5$  years long) outburst of MXB 1659-298, that started in August 2015 (Negoro et al. 2015; Bahramian et al. 2015).

MXB 1659-298 is a transient atoll low mass X-ray binary displaying type-I X-ray bursts, therefore indicating a neutron star primary (Lewin et al. 1976; Galloway et al. 2008). MXB 1659-298 is a high inclination system ( $i \sim 73 - 78^\circ$ ; Frank et al. 1987; Ponti et al. 2018), showing dipping and eclipsing events, with an orbital period of  $P_{orb} = 7.1$  hr (Cominski & Wood 1984; 1989; Jain et al. 2017; Iaria et al. 2018). The previous outburst of MXB 1659-298 started on April 1999 and lasted for  $\sim 2.5$  years (Wijnands et al. 2002). During the 1999-2001 outburst, *XMM-Newton* observed MXB 1659-298 twice, showing clear evidence for Fe XXV and Fe XXVI, as well as lower ionisation, absorption lines (Sidoli et al. 2001), however, no *Chandra* HETG observation was performed, to best detail the properties of the absorber in the Fe K band.

We report here the analysis of the *XMM-Newton*, *Chandra*, *NuSTAR* and *Swift* monitoring campaigns of the last outburst of MXB 1659-298.

## 2 ASSUMPTIONS

All spectral fits were performed using the *Xspec* software package (version 12.7.0; Arnaud 1996). Uncertainties and upper limits are reported at the 90 per cent confidence level for one interesting parameter, unless otherwise stated. Using X-ray bursts, a distance to MXB 1659-298 of  $9 \pm 2$  or  $12 \pm 3$  kpc has been inferred by Galloway et al. (2008) for a hydrogen or helium-rich ignition layer, respectively. We noted that MXB 1659-298 appears in Gaia DR2, however without parallax estimate, hence consistent with the large distance suggested by previous estimates (Gaia Collaboration et al. 2018). All luminosities, black body and disc black body radii assume that MXB 1659-298 is located at 10 kpc. To derive the disc black body inner radius  $r_{DBB}$ , we fit the spectrum with the DISKBB model in XSPEC (Mitsuda et al. 1984; Makishima et al. 1986) the normalisation of which provides the apparent inner disc radius ( $R_{DBB}$ ). Following Kubota et al. (1998), we correct the apparent inner disc radius through the equation:  $r_{DBB} = \xi \kappa^2 R_{DBB}$  (where  $\kappa = 2$  and  $\xi = \sqrt{(3/7)} \times (6/7)^3$ ) in order to estimate the real inner disc radius  $r_{DBB}$ . We also assume an inclination of the accretion disc of  $75^\circ$  (Frank et al. 1987; Ponti et al. 2018). We adopt a nominal Eddington limit for MXB 1659-298 of  $L_{Edd} = 2 \times 10^{38}$  erg s $^{-1}$  (appropriate for a primary mass of  $M_{NS} \sim 1.4 M_\odot$  and cosmic composition; Lewin et al. 1993). We use the  $\chi^2$  statistics to fit CCD resolution spectra (we group each spectrum to have a minimum of 30 counts in each bin), while we employ Cash statistics (Cash 1979) to fit the high resolution un-binned ones. We fit the interstellar absorption with the TBABS model in *Xspec* assuming Wilms et al. (2000) abundances and Verner et al. (1996) cross sections.

## 3 OBSERVATIONS AND DATA REDUCTION

At the beginning of the 2015-2017 outburst of MXB 1659-298, we requested a 40 ks *XMM-Newton* observation, to either dis-

cover or rule out the presence of Fe K absorption during the hard state of this source (archival observations only caught the soft state). *XMM-Newton* observed MXB 1659-298 on 2015-09-26 (obsid 0748391601). All EPIC cameras were in timing mode with the thin filter applied. The data were analysed with the latest version (17.0.0) of the *XMM-Newton* (Jansen et al. 2001; Strüder et al. 2001; Turner et al. 2001) Science Analysis System SAS, applying the most recent (as of 2017 September 20) calibrations. We reduced the data with the standard pipelines (EPCHAIN, EMCHAIN and RGSPROC for the EPIC-pn, EPIC-MOS and RGS camera, respectively). Because of the higher effective area, we show EPIC-pn data only, in addition to the RGS. We extracted the EPIC-pn source photons within RAWX 20 and 53 (while the background between 2 and 18), PATTERN $\leq$ 4 and FLAG $==$ 0.

Following a softening of the X-ray emission, we triggered pre-approved *Chandra* observations (performed on 2016 April 21<sup>st</sup>) of MXB 1659-298, to detail the ionised absorber properties during the soft state. The *Chandra* spectra and response matrices have been produced with the CHANDRA.REPRO task, reducing the width of the default spatial mask to avoid overlap of the HEG and MEG boxes at high energy ( $E \geq 7.3$  keV).

*NuSTAR* (Harrison et al. 2013) observed MXB 1659-298 twice during its 2015-2017 outburst, on 2015 September 28<sup>th</sup> (obsid 90101013002), two days after the *XMM-Newton* observation and on 2016 April 21<sup>st</sup> (90201017002), simultaneous with the *Chandra* one. The *NuSTAR* data were reduced with the standard *nupipeline* scripts v. 0.4.5 (released on 2016-03-30) and the high level products produced with the *nuproducts* tool. The source and background photons were extracted from circular regions of 120'' and 180'' radii, respectively, centred on the source and at the corner of the CCD, respectively. Response matrices appropriate for each data-set were generated using the standard software. We did not combine modules. Bursts, dips and eclipses have been removed by generating a light curve in XSELECT with 60 s time binning in the 3-70 keV energy band and cutting all intervals with a count rate outside the persistent value (e.g., 1.7-3.3 and 10-11 ph s $^{-1}$  for the two observations).

The outburst of MXB 1659-298 was monitored with the Neil Gehrels *Swift* Observatory, to characterise the long term evolution of the spectral energy distribution (SED). Full details on the analysis of the *Swift* data will be presented in a forthcoming paper (Degenaar et al. in prep). We analysed the Ultra-Violet/Optical Telescope (Roming et al. 2005) data obtained on the same day of the *XMM-Newton* (obsid: 00034002012; filter w1), the first *NuSTAR* (00081770001; v,B,U,W1,W2,M2) and the *Chandra+NuSTAR* (00081918001; v,B,U,W1,W2,M2) observations. The various filters employed allowed us to cover a wavelength range of  $\simeq 1500 - 8500$  Å (Poole et al. 2008). To extract source photons we used a standard aperture of 3', whereas for the background we used a source-free region with a radius of 9'. For each observation/filter we first combined all image extensions using UVOTIMSUM and then extracted magnitudes and fluxes using UVOTSOURCE.

## 4 TIMING ANALYSIS AND STATE DETERMINATION

To determine the evolution of the state of the source between the various observations, we first extracted light curves in the 3-10 keV energy range, with time bins of 6 ms $^{-1}$ . We computed the fractional

<sup>1</sup> The *Chandra* HETG frame time does not allow to constrain the spectral state through timing.

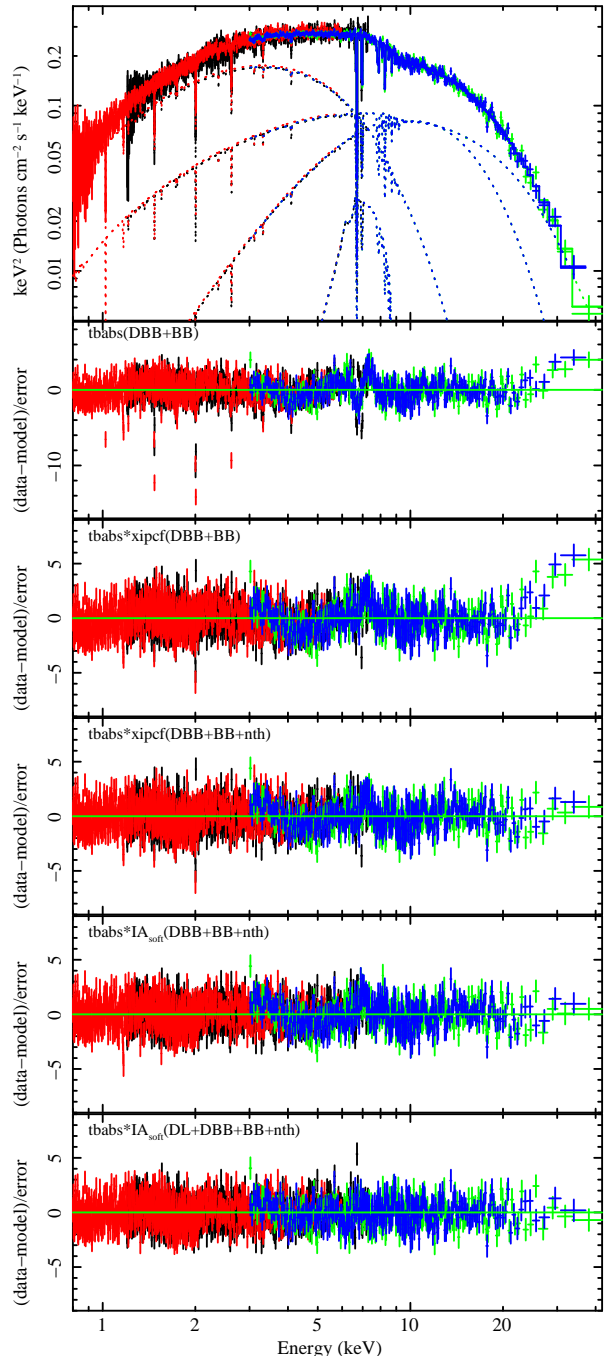

**Figure 1.** *XMM-Newton*, *NuSTAR* and *Chandra* spectra of MXB 1659-298 during the 2015-2017 outburst. Both the *XMM-Newton* (black) and the *NuSTAR* (red and green) spectra accumulated on 2015-09-26 and 2015-09-28, respectively, show a hard power law shape characteristic of the hard state. The simultaneous *Chandra* (light and dark grey) and the *NuSTAR* (light and dark blue) spectra obtained in 2016-04-21 show a significantly softer and brighter emission below  $\sim 20$  keV, with a significant drop above  $\sim 20 - 30$  keV.

rms in the range 0.002-64 Hz for the *XMM-Newton* and *NuSTAR* observations. From the *XMM-Newton* observation we estimated a fractional rms of  $21 \pm 4\%$ , this value being typical of the hard state (Muñoz-Darias et al. 2011, 2014). In the case of *NuSTAR* observations, we followed the method described in Bachetti et al. (2015) in order to properly account for dead time effects. Given the poorer statistics (due to the use of the co-spectrum between the light curves of the two modules) only an upper limit to the 0.002-64 Hz fractional rms of  $< 8\%$  can be derived from the second *NuSTAR* observation, suggesting that MXB 1659-298 was in the soft state at that time. On the other hand, the rms could not be constrained from the first *NuSTAR* observation.

Figure 1 shows the *XMM-Newton*, *NuSTAR* and *Chandra* spectra of MXB 1659-298 during the 2015-2017 outburst. In agreement with the timing results, the *XMM-Newton* spectrum (black data) is characterised by a hard power law shape, confirming that MXB 1659-298 was in the hard state at that time. The first *NuSTAR* dataset (red and green data), accumulated two days after, also shows a very similar hard spectrum, suggestive of a hard state (Fig. 1). On the other hand, during the simultaneous *Chandra* (dark and light grey) and second *NuSTAR* (dark and light blue) observations, MXB 1659-298 displays a softer and significantly brighter emission, below  $\sim 20$  keV, while the source emission drops quickly above  $\sim 20 - 30$  keV. In agreement with the timing results, this indicates that the source was in the soft state during these observations.

## 5 BROAD BAND FIT OF THE SOFT STATE WITH APPROXIMATE MODELS

We started by simultaneously fitting the *Chandra* HETG (HEG and MEG first order) + *NuSTAR* data, leaving the cross-normalisation constants ( $C_{MEG}$ ,  $C_{NuA}$  and  $C_{NuB}$ ) free to vary (see Fig. 2; Tab. 1).

**Figure 2.** Soft state persistent emission of MXB 1659-298 fitted with phenomenological models. MEG, HEG, FPMA and FPMB spectra and residuals are shown in red, black, green and blue, respectively. (Top panel) Best fit of the soft state spectrum fitted with disk black-body plus black-body plus Comptonisation plus a disk-line emission absorbed by neutral and ionised material (Tab. 1). From top to bottom the various panels show the residuals for increasingly complex models. The first plot shows the residuals of the fit with a disk black body plus black body model absorbed by neutral material. Then the residuals after the addition of an approximated ionised absorption ZXIPCF component. Then, residuals after the inclusion of a thermal Comptonisation component (NTHCOMP). Subsequently, residuals after the inclusion of a proper ionised absorption component ( $IA_{soft}$ ). Finally, residuals after the inclusion of an additional relativistic Fe K emission line.

We fit the MEG, HEG and FPM(A,B) spectra in the 0.8-6, 1.2-7.3 and 3-45 keV ranges, respectively.

The black, red, green and blue points in Fig. 2 show the *Chandra* HEG and MEG, the *NuSTAR* FPMA and FPMB spectra of the persistent emission, accumulated during the soft state observations (dips, eclipses and bursts have been removed; see black data in Fig. 2 of Ponti et al. 2018). The fit of these spectra with a model composed by a disk blackbody plus a hot blackbody (B1 in Tab. 1), both absorbed by neutral material (TBABS(DISKBB+BBODY) in XSPEC), provided a reasonable description of the continuum, however very significant residuals appeared as clear signatures of ionised absorption lines in the soft X-ray and Fe K band (Fig. 2), making this model unacceptable ( $C - stat = 9777.8$  for 7094 dof, Tab. 1). We also noted an excess of emission at high energy ( $E > 25$  keV; Fig. 2), that does not appear to be an artefact of the background (contributing at  $E \geq 35$  keV).

The observed features (see Fig. 2 and § 6) indicate the presence of ionised absorption. To properly compute the model of the ionised absorption component, the knowledge of the irradiating SED is required. We, therefore, started by first adding an "approximated" ionised absorption component (ZXIPCF), with the main purpose to initially derive the fiducial SED to be used as input for the photo-ionisation computations. After the computation of the proper absorption model the spectra will be re-fitted, obtaining the final best fit.

The addition of an ionised absorption component (B2: TBABS\*ZXIPCF(DISKBB+BBODY)) significantly improved the fit ( $\Delta C - stat = 1616.9$  for the addition of 2 parameters). The ionised absorption component reasonably reproduced both the soft X-ray absorption lines as well as the strong features in the Fe K band with a large column density ( $\log(N_H/cm^{-2}) = 23.6 \pm 0.1$ ) of highly ionised material ( $\log(\xi/erg\ cm\ s^{-1}) = 4.25 \pm 0.02$ ; Tab. 1). However, highly significant residuals were still present (Fig. 2).

We noted that the excess of emission at energies above  $E \geq 25$  keV is likely the signature of an additional Comptonisation component. We therefore added to the model a thermal inverse-Comptonisation component (NTHCOMP in XSPEC). We assumed an asymptotic photon index of  $\Gamma = 2$  and seed photons produced by the disc black-body. The fit with this model (B3: TBABS\*ZXIPCF(DISKBB+BBODY+NTHCOMP)) provided a significant improvement of the fit ( $\Delta C - stat = 197.8$  for the addition of 2 free parameters; Tab. 1), properly reproducing the high energy emission (Fig. 2). However, very significant residuals were still present in the  $\sim 7 - 10$  keV energy range. We noted that part of those residuals might be due to the inaccurate modelling of the ionised absorber. Indeed, the ionised Fe K edges at  $E_{Fe\ xxv} = 8.83$  and  $E_{Fe\ xxvi} = 9.28$  keV can contribute to the observed residuals. We, therefore, defer the discussion of such residuals until after the computation of the proper ionised absorber model (see § 6.3 and 7).

### 5.1 Soft state SED

The red solid line in Fig. 3 shows the de-absorbed best fit (model B2 of Tab. 1) soft state SED. The dotted red lines peaking at  $\sim 3 \times 10^{17}$  and  $\sim 1.5 \times 10^{18}$  Hz show the disk black-body and the black-body components, respectively. The dashed vertical lines indicate the boundaries where the SED is observationally constrained by the *Chandra*+*NuSTAR* data at high energy and by the *Swift*-UVOT observations (performed in various filters) in the optical-UV band. The observed optical-UV magnitudes range between  $m_{V,AB} \sim 18$  to  $m_{UVW2,AB} \sim 20$ . This optical-UV flux is significantly higher

**Figure 3.** In black and red are shown the de-absorbed best fit "bona fide" spectral energy distribution during the hard and soft state, respectively. The dashed lines show the extremes of the X-ray and optical-UV energy ranges constrained by *NuSTAR*, *XMM-Newton*, *Chandra* and the *Swift* filters. The dotted vertical lines show the mean energy of the various filters.

than the extrapolated emission from the disc black body component dominating in the X-ray band (see Fig. 3). Therefore, this extra flux indicates the presence of an additional component, possibly associated with the irradiated outer disc or the companion star (Hynes et al. 2002; Migliari et al. 2010). We reproduced this emission by adding a black-body component peaking at  $\sim 6 \times 10^{14}$  Hz (see Fig. 3).

We used such bona-fide SED as input for the photo-ionisation computations of the absorber that will be presented in § 6.3 and 7. Additionally, we tested that considering any of the best fit continuum models in Tab. 1 produced negligible effects on the ionised absorber photo-ionisation stability and properties. The photo-ionisation computations have been performed with CLOUDY 17.00 (Ferland et al. 2013).

## 6 ABSORPTION LINES: *Chandra* HETG SPECTRUM

We started the characterisation of absorption during the soft state observation, by performing a blind search to hunt for narrow absorption lines in the spectrum of the persistent emission (see § 9.4 for a discussion of possible caveats). We fitted the *Chandra* grating data (HEG and MEG are fitted simultaneously) with the best fit continuum model reproducing the *Chandra*+*NuSTAR* continuum and we added a narrow Gaussian absorption line. We then computed the confidence contours by stepping the energy of the line from  $E = 0.8$  to 9 keV (with 1640 steps logarithmically equally spaced) and the intensity in 10 steps from 0 to  $-3 \times 10^{-4}$  photons  $cm^{-2}\ s^{-1}$  in the line. The red, green and blue contours in Fig. 4 show the 68, 90 and 99 % confidence levels. This plot clearly shows the detection of many very significant absorption lines (Fig. 4).

To more accurately determine the significance of the detection of the expected absorption features and to measure the equivalent width of the lines, we first divided the spectrum into intervals of  $\sim 2$  Å width and fitted it with the same continuum model (allowing for variations of the normalisation). We then added to the model a narrow absorption line with Gaussian profile for each observed residual. We then tested the significance of the residual and we re-

**Table 1.** Best fit parameters of the simultaneous *Chandra* HETG and *NuSTAR* spectra. The *Chandra* HEG and MEG first order as well as *NuSTAR* FPMA and FPMB spectra (in black, red, green and blue, respectively) are fit simultaneously, leaving a cross-normalisation constant free to vary ( $c_{MEG}$ ,  $c_{nuA}$  and  $c_{nuB}$ ). The first model, B1, DBB+BB is composed by TBABS(DISKBB+BBODY), the second, B2, is additionally absorbed by an approximate ionised absorption component (TBABS\*XIPCF(DISKBB+BBODY)). Model B3 additionally considers the emission from a thermal Comptonisation component (TBABS\*XIPCF(DISKBB+BBODY+NTHCOMP)). The continuum emission components in model B6 correspond to the ones of B3, however the ionised absorption is substituted by a self consistent one ( $IA_{soft}$ : TBABS\*IA(DISKBB+BBODY+NTHCOMP)). Finally, model B7 additionally consider the emission from a relativistic Fe K $\alpha$  line (TBABS\*IA(DISKBB+BBODY+NTHCOMP+DISKLINE)). See text for description of the various parameters. b In keV units. \* In units of  $10^{22}$  cm $^{-2}$ . ‡ Normalisation  $N = R^2 \cos(\theta)$ , where  $R^2$  is the apparent disc inner disc radius (or blackbody radius) in km, and  $\theta$  the angle of the disc ( $\theta = 0$  face on,  $\cos(\theta) = 1$  for blackbody).

**Figure 4.** Residuals to the presence of narrow ( $\sigma = 1$  eV) absorption lines in the *Chandra* HETG (HEG+MEG) spectra. The red, green and blue solid lines show the 68, 90 and 99 % confidence contours. Sixty absorption lines are detected. We highlight with a vertical line each detected absorption feature. The same colour is used for features associated to the same series. In particular, the energies of the  $\alpha$ ,  $\beta$  and  $\gamma$  transitions are reported with dashed, dash-dotted and dotted lines, respectively. Absorption lines associated with Fe L features are highlighted with magenta dot-dot-dot-dashed lines (in violet is the density sensitive Fe XXII doublet). Unidentified lines are shown with grey dotted lines.

ported in Tab. 2 all lines detected at more than 90 % significance, with associated velocity shifts and equivalent widths. We also highlight with bold characters in Tab. 2 the lines detected at more than  $3\sigma$ .

Sixty lines are significantly detected, of which we identified 51. Of these 21 lines are detected at more than  $3\sigma$ . The strongest lines are due to the Ly-like and He-like transitions of many ele-

ments such as: Ne, Na, Mg, Al, Si, S, Ar, Ca, Fe, and Ni, as well as lines of the Fe L and Ni L complexes. Interestingly, for several elements the entire series from the  $\alpha$  to the  $\gamma$  lines are detected and identified. Wherever possible we separately reported the equivalent widths of the inter-combination and resonance lines of the He $\alpha$  triplets.

Below  $\sim 1.8$  keV, we detected several absorption features

consistent with Fe L transitions including the Fe XXII density sensitive doublet. In particular, the lower energy line of the Fe XXII doublet ( $\lambda = 11.920$ ) is formally detected at more than  $2.5\sigma$  confidence, while the higher energy transition (at  $\lambda = 11.77$ ) is detected with a significance just above  $1\sigma$ . Therefore, we fixed its energy to the expected value<sup>2</sup> and we reported the  $1\sigma$  uncertainties in Tab. 2.

We marked with a question mark the Al XII He $\beta$  and  $\gamma$  lines, because both have intensities close to the detection limit. Additionally, the Al XII He $\beta$  line is affected by the wings of the more intense Si XIII He $\alpha$  line. For these reasons, we could not robustly constrain its energy through fitting, and therefore chose to fix its energy to the theoretical value. We also marked with a question mark the  $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\delta$  lines of the Mg XI He-like series. Indeed, we observed that the higher order transitions (e.g.  $\gamma$  and  $\delta$ ) are detected at low significance, but have strengths and equivalent widths comparable to or higher than the respective  $\alpha$  line. We considered this doubtful. The same occurred for the Ca XIX He $\alpha$ ,  $\beta$  and  $\gamma$  lines.

We note that nine lines remained unidentified. A few of these might be associated with spurious detections.

### 6.1 The density sensitive Fe XXII doublet

The ratio of the intensities of the Fe XXII L lines at  $\lambda$  11.92 Å and 11.77 Å is a good density diagnostic (Mauche et al. 2003). The Fe XXII line at 11.92 Å was observed with an equivalent width of  $-0.38_{-0.27}^{+0.15}$  eV ( $1\sigma$ ), while the line at 11.77 Å was barely detected with  $EW = -0.28_{-0.23}^{+0.19}$  eV. The uncertainty on the line ratio was estimated by assuming that both lines have the same widths and that their equivalent widths follow the relation:  $EW_{11.92} = f \times EW_{11.77}$ . The violet region in Fig. 6 represents the  $1\sigma$  uncertainty on the line ratio (computing the  $1\sigma$  error on the value of  $f$  directly from the spectrum), corresponding with  $EW_{11.92} > 0.73EW_{11.77}$ .

By performing extensive CLOUDY simulations, we computed the doublet line ratio as a function of the plasma density for various values of the column density of the absorbing material (see solid, dashed and dot-dashed lines in Fig. 6). We confirmed that the ratio is a sensitive probe of the plasma density. In particular, the observed line ratio suggests a plasma density of  $n > 10^{13}$  cm<sup>-3</sup>. This result will be used in § 9.3 to estimate the location of the ionised absorber.

### 6.2 Line shifts

The absorption line centroids in MXB 1659-298 are observed to shift with orbital phase, with a semi-amplitude of  $\sim 90$  km s<sup>-1</sup> (Ponti et al. 2018). Such modulation is thought to trace the radial velocity curve of the primary. We note that the HETG observation analysed here covered two complete orbital periods. Therefore, we expect to see no systematic shift of the absorption lines, due to such orbital modulation (the main consequence being an artificial broadening of the lines). We also note that Sidoli et al. (2001) investigated the evolution of the Fe XXV and Fe XXVI line intensities as a function of orbital phase, finding no significant variation (despite intensity variations as large as a factor of two were not excluded).

The line centroids of all lines in the average spectrum are consistent with being at rest, with outflow or inflow velocities lower

than  $\sim 200$  km s<sup>-1</sup> (Tab. 2). In particular, we observed that the lines with the highest signal to noise indicated upper limits to any bulk flow velocity of less than  $\sim 50 - 70$  km s<sup>-1</sup> (Tab. 2). Therefore, the observed ionised absorption is not due to a wind, it is instead associated with an ionised disc atmosphere.

### 6.3 The line-rich HETG spectrum fitted with self-consistent photo-ionisation models

In this paragraph, we present the separate fit of only the *Chandra* HETG spectrum (0.8-7.3 keV; Tab. 3). In this way, the fit will be driven by the absorption lines only (e.g., without strong contamination from either the ionised Fe K edges, the broad Fe K line or the shape of the high energy continuum).

As already evidenced from § 5, we observed that the addition of an approximated ionised absorption component (model C2) to the disk black-body and hot black-body emission (C1) significantly improved the fit of the HETG spectrum of MXB 1659-298, during the soft state ( $\Delta C - stat = 1549.2$  for the addition of 2 new free parameters; see Tab. 3). Based on the observed soft state SED, we built a fully auto consistent photo-ionisation model (IA<sub>soft</sub>). The model table was computed through a CLOUDY computation, assuming constant electron density ( $n_e = 10^{14}$  cm<sup>-3</sup>), turbulent velocity  $v_{turb} = 500$  km s<sup>-1</sup> and Solar abundances.

We then substituted the approximated photo-ionised component with this self-consistent ionised absorber (C4). By comparing model C4 with C2, we observed a significant improvement of the fit ( $\Delta C - stat = 207.3$ ) for the same degrees of freedom (Tab. 3). This confirms that the array of absorption lines is better described by the self-consistent photo-ionisation model, producing an acceptable description of the data. The ionised plasma is best described by a relatively large column density ( $\log(N_H/cm^{-2}) = 23.6 \pm 0.1$ ) of highly ionised ( $\log(\xi/erg\ cm\ s^{-1}) = 3.85_{-0.11}^{+0.04}$ ) material. We note that these values are in line with what measured from *XMM-Newton* observations of MXB 1659-298 during the previous outburst (Sidoli et al. 2001; Diaz Trigo et al. 2006).

We then tested whether the ionised absorber is composed of multiple and separate components with, for example, different ionisation parameters. We performed this by adding a second ionised absorber layer to the fit. We observed a slight improvement of the fit ( $\Delta C - stat = 29.0$  for the addition of 2 free parameters; Tab. 3). The two components of the ionised absorbers were split into a very high column density and ionisation parameter component ( $\log(N_H/cm^{-2}) \sim 24.2$  and  $\log(\xi/erg\ cm\ s^{-1}) > 4.5$ ) and a much lower column density and ionisation one ( $\log(N_H/cm^{-2}) < 22.5$  and  $\log(\xi/erg\ cm\ s^{-1}) \sim 3.3$ ), leaving the best fit parameters of the continuum emission consistent with the previous fit (Tab. 3).

Since the fit with two ionised absorption layers provided only a marginal improvement of the fit from a statistical point of view, we concluded that a single ionised absorption layer provided a good description of the absorption lines.

### 6.4 Stability curve

The red line in Fig. 7 shows the thermal equilibrium conditions of the absorber, once the ionised plasma is illuminated by the soft state SED (Fig. 3). The thermal equilibrium is the result of the competition between heating and cooling and the corresponding stability curve is inferred through extensive CLOUDY computations in the same way as described in Bianchi et al. (2017).

<sup>2</sup> We also tried fixing the energy of this transition to that expected if the line experienced the same shift as the  $\lambda = 11.920$  line (§ 6.2), which did not change our result.

**Figure 5.** The red and black data display the *Chandra* HETG MEG and HEG spectra at the energies of some of the strongest lines, respectively, fitted with the best fit model (B7 in Tab. 1). (*Top panels*) from left to right show the Mg XII Ly $\alpha$ , Si XIV Ly $\alpha$  and S XVI Ly $\alpha$  lines. The profile of all lines is well reproduced by the best fit photo-ionised absorption component. (*Bottom panels*) from left to right show the two lines of the Fe XXIV L complex and the Fe XXVI Ly $\alpha$  transition. Only data of the MEG and HEG instruments are shown because of their higher effective area at low and high energies, respectively.

**Figure 6.** Ratio of equivalent widths of the absorption lines of the Fe XXII L doublet ( $EW(11.92)/EW(11.77\text{\AA})$ ) as a function of the plasma density ( $n$ ). The various lines indicate the relation between plasma density and line ratio for different column densities of the absorber. The violet area indicates the region consistent (at  $1\sigma$ ) with the observed line ratio.

As expected, we observed that the ionised absorber (i.e., disc atmosphere) is in thermal equilibrium during the soft state (see red point in Fig. 3). Actually, any equilibrium solution with plasma

**Figure 7.** Photoionisation stability curves of the ionised absorbing plasma when illuminated with the soft (red) and hard (blue) SEDs. The thick segments indicate the thermally unstable branches of the curves. The red circle indicates the position of the ionised absorber during the soft state. The absorber is thermally stable. The blue square indicates the expected condition of the absorber when illuminated by the hard state SED. Such conditions are thermally unstable.

temperatures higher than  $kT \sim 55$  eV or lower than 3.4 eV would be stable, with only two small instabilities present between these two ranges.

## 7 BROAD BAND FIT OF THE SOFT STATE SPECTRA

We started the broad band fit of the soft state spectra of MXB 1659-298, by substituting the approximated photo-ionised absorber model (ZXIPCF) employed in model B3 (§5), with the fully auto consistent photo-ionised absorber model (B6; TBABS\* $IA_{soft}$ (DISKBB+BBODY+NTHCOMP)) described in §6.3. We observed a significant improvement of the fit ( $\Delta C - stat = -184.3$  for the same dof), in agreement with the fact that the  $IA_{soft}$  model provides a superior description of the *Chandra* HETG spectra and the absorption lines. However, we noted that the best fit column density ( $\log(N_H/cm^{-2}) = 24.25 \pm 0.02$  instead of  $23.6 \pm 0.2$ ) and ionisation parameter ( $\log(\xi/erg\ cm\ s^{-1}) = 4.54 \pm 0.01$  instead of  $3.85^{+0.04}_{-0.11}$ ) of the ionised absorber were significantly larger than the best fit of the HETG data only. This variation was induced by the attempt of the model to reproduce the large residuals at  $\sim 6 - 8$  keV (see Fig. 2). The resulting best fit was therefore driven to an increased column density and ionisation parameter of the absorbing plasma (compared with what was required by the absorption lines) in an attempt to enhance the depth of the ionised Fe K edges ( $E_{FeK\alpha} = 8.83$  and  $E_{FeK\beta} = 9.28$  keV).

We noted that the remaining significant residuals in the  $\sim 6 - 12$  keV band were resembling a broadened Fe K $\alpha$  emission line (Fig. 2). We, therefore, added to the model a disk line component (B7; TBABS\* $IA_{soft}$ (DISKLINE+DISKBB+BBODY+NTHCOMP)). We assumed the line energy to be  $E = 6.4$  keV (although the material in the inner accretion disc might be ionised), a disk inclination of  $75^\circ$  (Ponti et al. 2018), inner and outer radii of  $r_{in} = 6 r_g$  and  $r_{out} = 1000 r_g$  (where  $r_g = GM_{NS}/c^2$  is the gravitational radius,  $G$  is the Gravitational constant,  $M_{NS}$  the NS mass and  $c$  is the light speed). The free parameters of the model were the disc emissivity index  $\alpha_d$  and the line normalisation. This provided a significant improvement, resulting in an acceptable fit ( $C - stat = 7584.7$  for 7088 dof). The best fit line emissivity index and equivalent widths  $\alpha_d \sim -2.6$  and  $EW \sim 250$  eV are consistent with the expected values from a standard irradiated accretion disc (Matt et al. 1991; George & Fabian 1991).

The addition of the disk-line component to the model allowed a better fit of the Fe K band, decreasing the depth of the ionised Fe K edges, therefore leading to best fit ionisation parameter and column density of the ionised absorber consistent with the fit of the HETG data alone ( $\log(N_H/cm^{-2}) \sim 23.5$  and  $\log(\xi/erg\ cm\ s^{-1}) \sim 3.8$ ).

The observed and un-obscured 0.1-100 keV flux are  $F_{0.1-100} = 9.8 \times 10^{-10}$  and  $11.2 \times 10^{-10}$  erg cm $^{-2}$  s $^{-1}$ , respectively. The disc black body, black body and Comptonisation components carry  $\sim 50\%$ ,  $\sim 17\%$  and  $\sim 30\%$  of the un-obscured 0.1-100 keV flux. The best fit continuum is described by a disk black body component with temperature of  $kT_{DBB} \sim 1.3$  keV with an associated inner radius of  $r_{DBB} \sim 10$  km, therefore comparable with the NS radius. The best fit black body emission  $kT_{BB} \sim 2.5$  keV is hotter than the one of the accretion disc and is produced from a small region with a surface area of  $r_{BB} \sim 1.5$  km $^2$ , likely associated with the boundary layer. At high energy ( $E \geq 20 - 30$  keV) a small contribution due to thermal Comptonisation appears significant. Assuming an asymptotic photon index of  $\Gamma = 2$ , the best fit temperature of the Comptonising

**Figure 8.** 0.5-10 keV *XMM-Newton* light curve of MXB 1659-298 performed on 2015-09-26. The EPIC-pn exposure starts just before the eclipsed period (shown with dark grey squares). During the observation a clear burst is observed (shown with dark grey colours) as well as intense dipping activity (light grey colours). The black points show the persistent emission. The dotted line indicates the lower bound we use to identify persistent flux, with intervals dipping below this being selected as dips. Time bins of 10 s are used.

electrons is  $kT_e \sim 4$  keV. This value is significantly lower than what is typically observed during the hard state or in BH systems. This is possibly induced by the cooling power of the abundant soft photons produced by the disc and/or boundary layer (Done & Gierlinski 2003; Burke et al. 2018).

## 8 HARD STATE OBSERVATIONS

To investigate the evolution of the disc atmosphere as a function of the accretion disc state and its response to the variation of the SED, we analysed the *XMM-Newton* observation that caught MXB 1659-298 in the hard state. The *NuSTAR* hard state observation (taken two days after) will be presented in a Degenaar et al. (in prep).

Figure 8 shows the light curve of the hard state *XMM-Newton* EPIC-pn observation. One bright burst (dark grey peak), two eclipses (lasting  $\sim 930$  s) as well as intense dipping activity are observed and removed. The black data in Fig. 9 show a clear drop, in the spectrum, at energies below  $\sim 1$  keV, suggesting the presence of neutral absorbing material. We fitted the persistent spectrum with an absorbed power law spectrum (TBABS\*POWERLAW in XSPEC). Although this model can reasonably reproduce the bulk of the observed X-ray emission ( $N_H = 2.42 \pm 0.02 \times 10^{21}$  cm $^{-2}$ ,  $\Gamma_{PL} = 1.82 \pm 0.05$ ), large residuals make the fit unacceptable ( $\chi^2 = 2351.8$  for 1782 dof; Tab. 4).

Therefore, we added a disc black-body component (DISKBB) and substituted the power law emission with a Comptonisation component (NTHCOMP) absorbed by neutral material. We assumed a temperature of  $kT_e = 17$  keV for the Comptonising electrons. This temperature corresponds to the best fit value of the fit of the *NuSTAR* data, accumulated two days after the *XMM-Newton* observation (see Degenaar et al. in prep). This model well reproduced the data ( $\chi^2 = 1844.5$  for 1780 dof). The spectrum was dominated by the Comptonisation component with  $\Gamma \sim 1.8$  and a cold

**Figure 9.** (Top panel) *XMM-Newton* EPIC-pn hard state spectrum fitted by the best fit model (disc black body plus blackbody and a dominant Comptonisation components absorbed by neutral material). No signs of ionised absorption is present. (Centre top panel) Residuals once the data are fitted with an absorbed power law. (Centre panel) Residuals after fitting with an absorbed disk black body plus Comptonisation model. (Centre bottom panel) Residuals after the addition of a black body component. (Bottom panel) Residuals after the consideration of a gain offset in the response files.

( $kT_{DBB} = 0.19 \pm 0.01$  keV) disk blackbody component, with a large inner disk radius ( $r_{DBB} \sim 150 - 200$  km) required by the data.

The further addition of a blackbody emission component slightly improved the fit ( $\chi^2 = 1820.9$  for 1778 dof, with associated F-test probability  $\sim 1 \times 10^{-5}$ ). The best fit blackbody component was hotter ( $kT_{BB} = 0.45 \pm 0.05$  keV) than the disk blackbody one (however colder than what is typically observed during the soft state) and produced by a small area with a radius of  $\sim 9$  km.

We noted a significant excess occurring at  $\sim 2.2$  keV, where the effective area experiences a drop due to the Au M edge. To determine the nature of such excess, we modified<sup>3</sup> the gain in the response files until reaching the best fit. We observed a significant improvement of the fit ( $\Delta\chi^2 = 36.1$  for 1 dof) with a gain offset of  $gain_{off} = 12 \pm 3$  eV. Such offset is smaller than the uncertainty on the calibration of the EPIC energy scale (see XMM-SOC-CAL-TN-0018). This suggested that such residual is instrumental and it will not be discussed further<sup>4</sup>.

Based on this best fit hard state model and the constraints from *Swift*-UVOT and *NuSTAR* (see Degenaar et al. in prep) data, we reconstructed the “bona-fide” hard state SED (black line, Fig. 3). The observed and un-obscured 0.1-100 keV flux are  $F_{0.1-100} = 2.9 \times 10^{-10}$  and  $3.9 \times 10^{-10}$  erg cm<sup>-2</sup> s<sup>-1</sup>, respectively. The disc black body, black body and Comptonisation components carry  $\sim 15\%$ ,  $\sim 1\%$  and  $\sim 84\%$  of the un-obscured 0.1-100 keV flux.

No absorption line due to ionised iron appeared in the data. Indeed, we added a narrow ( $\sigma = 1$  eV) absorption line with a Gaussian profile at the energy of the Fe xxv and Fe xxvi transitions and we obtained upper limits to their equivalent width of  $EW_{Fe\ xxv} > -10$  eV and  $EW_{Fe\ xxvi} > -13$  eV, respectively. The addition of a diskline with the same profile as observed during the soft state ( $\alpha_d = -2.6$ ) did not improve the fit, with an upper limit on the line equivalent width of  $EW < 80$  eV.

No ionised emission or absorption line are detected in the RGS spectra, with upper limits of  $\sim 4 - 8$  eV on the Ly $\alpha$  transitions of the most abundant elements. We note, however, that such upper limits do not exclude that soft X-ray lines as observed during the soft state are present in the hard state.

## 9 DISCUSSION

We studied the evolution of the X-ray emission of MXB 1659-298, throughout the states, during its most recent outburst. We observed that a three component continuum model (disk black body and Comptonisation in addition to thermal emission from, e.g., the boundary layer) provided an adequate description of the data in both spectral states. The observed trends of the best fit parameters (i.e., lower disc temperatures, larger disc inner radii and larger Comptonisation fractions in the hard state) are in line with what is typically observed in accreting BH and/or other atoll sources (Lin et al. 2007; Dunn et al. 2010; Munoz-Darias et al. 2014; Armas-Padilla et al. 2018).

The normalisation of the disk black body component suggests that the accretion disc extends to radii comparable to the NS radius during the soft state, while it might be truncated during the hard state. In line with this, we observed broad residuals in the Fe K band, in the soft state. Such residuals are well reproduced by a relativistic disc line model with a standard line equivalent width ( $EW \sim 250$  eV), with a disc emissivity  $\alpha_d \sim -2.6$ , off an highly inclined accretion disc ( $i = 75^\circ$ ) extending to few gravitational radii. Such broad feature appears less prominent during the *XMM-Newton* and *NuSTAR* hard state observations.

<sup>3</sup> We performed this by employing the GAIN model to the response files. The GAIN command shifts the energies on which the response matrix is defined as well as the effective area in such a way that  $E_{new} = E/sl - gain_{off}$  (where  $E$  and  $E_{new}$  are the original and shifted energies). We searched for the best fit offset in the gain, however we kept the slope fixed to the default value ( $sl = 1$ ).

<sup>4</sup> Please note that we did not use the GAIN model any further in this work.

The persistent source emission is absorbed by a moderate column density of lowly ionised material that appears to vary from the soft ( $N_H \sim 0.21 \pm 0.01 \times 10^{22} \text{ cm}^{-2}$ ) to the hard state ( $N_H \sim 0.33 \pm 0.01 \times 10^{22} \text{ cm}^{-2}$ ). The observed variation is of the same order of magnitude of the one observed by Cackett et al. (2013) (i.e., from  $N_H \sim 0.2 \pm 0.01 \times 10^{22} \text{ cm}^{-2}$  to  $N_H \sim 0.47 \pm 0.13 \times 10^{22} \text{ cm}^{-2}$ ) during quiescence. Despite the origin of such variation is uncertain, it is clear that during outbursts dipping X-ray binaries can display variations of the column density of neutral absorption, by orders of magnitude (White & Mason 1985; Frank et al. 1987; Ponti et al. 2016). Therefore, despite we analysed only the persistent emission, the observed variation (of  $\sim 40\%$ ) is not surprising. Indeed, the observed fast variation suggests that at least the variable part of the column density of absorbing material is local to the source. If so, such material can potentially change its physical conditions (e.g., ionisation, location), producing the observed variation. Additionally, we note that part of such difference could be driven by the distorting effects of dust scattering (e.g., induced by combination of the energy dependence of the dust scattering cross section and the different spectral extraction regions; Trümper & Schönfelder 1973; Predehl & Schmitt 1995; Jin et al. 2017; 2018). Therefore, we caution the reader from deriving conclusions from this difference<sup>5</sup>.

### 9.1 Ionised absorber - state connection

MXB 1659-298 shows clear evidence for highly ionised (Fe K) absorption during the soft state that disappears (at least the Fe XXV and Fe XXVI lines) during the hard state. This similar behaviour is shared also by two of the best monitored atoll sources (Ponti et al. 2014; 2015; 2017) and it is ubiquitous in accreting BH binaries (Ponti et al. 2012)<sup>6</sup>. We note that, in BH systems, the observed wind - state connection has been occasionally ascribed to a variation of the geometry of the wind, or a variation of the magnetic field configuration, or a variation of the launching mechanism, etc. (Ueda et al. 2010; Miller et al. 2012; Neilsen et al. 2012).

### 9.2 Stability of the disc atmosphere

As discussed in § 6.4, the best fit ionised absorber parameters ( $\log(\xi/\text{erg cm s}^{-1}) = 3.76$ ;  $\log(N_H/\text{cm}^{-2}) = 23.48$ ) correspond to a thermally stable solution during the soft state (Fig. 7). Given the properties of the disc atmosphere observed during the soft state, we can predict its behaviour during the hard state, under the reasonable assumption that the variations of the absorber are solely due to the different illuminating SED. Indeed, as a consequence of the variation of the SED, the ionisation parameter is expected to vary following  $\xi = L/(nR^2)$ , if the density ( $n$ ) and location ( $R$ ) of the absorber remain unchanged (or that they

both vary keeping  $nR^2$  constant). Indeed, in such a situation, the ionisation parameter of the atmosphere would change in response to the variations of the source luminosity ( $L$ ) following the relation:  $\xi = L/(nR^2)$ . Hence, we can estimate the expected ionisation parameter during the hard state as:  $\xi_h = (\xi_s L_h)/L_s$  (where  $L_s$ ,  $L_h$ ,  $\xi_s$  and  $\xi_h$  are the soft and hard luminosities in the 0.1-100 keV energy band and ionisation parameters, respectively), corresponding to  $\log(\xi_h) \sim 3.30$  (see Fig. 7). Therefore, during the hard state the ionisation parameter is lower than during the soft state. Indeed, despite the shape of the SED is harder, the lower hard state total luminosity implies lower ionisation. Clearly, the hard state spectrum rules out the presence of an absorber with  $\log(\xi_h/\text{erg cm s}^{-1}) = 3.30$  and  $\log(N_H/\text{cm}^{-2}) = 23.48$ . This implies that the ionised absorber must have changed (i.e.,  $nR^2$  or both) as a result of the variation of the SED. Indeed, we note that the estimated hard state parameters of the ionised absorbers fall onto an unstable branch of the thermal photo-ionisation stability curve (Fig. 7). Therefore, most likely the absorber will migrate away from such unstable equilibrium, possibly towards a stable higher and/or lower ionisation parameter (see Bianchi et al. 2017 for more details). We note that such behaviour is common to the classical hard (and hard-intermediate) state SED of BH LMXB. Therefore, this mechanism could be responsible for the observed ionised absorber - state connection.

### 9.3 Distance to the ionised absorber

The constraints on the ionised absorber density obtained in § 6.1 from the Fe XXII doublet ratio can be used to estimate its distance from the irradiating X-ray source ( $R$ ). Indeed, using the equation:  $R^2 = L/n\xi$ , we derived  $R < 1.5 \times 10^{10} \text{ cm}$ , for a source luminosity  $L \sim 1.3 \times 10^{37} \text{ erg s}^{-1}$  and plasma ionisation parameter  $\log(\xi/\text{erg cm s}^{-1}) \sim 3.76$ , as observed during the soft state. Such distance corresponds to  $R \lesssim 7 \times 10^4 r_g$  and it is a significant fraction of the accretion disc size.

Assuming the outer disc radius ( $R_D$ ) to be  $\sim 80\%$  of the primary's Roche-lobe radius ( $R_L 1$ ), calculated by the approximate formula:  $R_D = 0.8a \times (0.46q^{-2/3})/[0.6q^{-2/3} + \log(1+q^{-1/3})]$ , where  $q$  is the mass ratio  $m_2/m_1$  between the masses of the primary and companion star in Solar masses (Eggleton 1983) and  $a$  is the binary separation which can be conveniently expressed in the form:  $a = 3.5 \times 10^{10} (1+q)^{1/3} m_1^{1/3} P_{orb}^{2/3} \text{ cm}$ , where  $P_{orb}$  is the orbital period in days (King et al. 1996), we computed the outer disc radius (for  $P_{orb} = 7.11611 \text{ hr}$ ,  $m_1 = 1.4$  and  $m_2 = 0.6 M_\odot$ ; Ponti et al. 2018) to be  $R_D = 6.2 \times 10^{10} \text{ cm}$  or  $\sim 3.0 \times 10^5 r_g$ . Therefore, the ionised plasma sits well inside the disc.

We also note that the plasma is located inside the Compton radius too. To estimate the latter, we first computed the Compton temperature ( $T_C$ ) by integrating the observed soft state SED and obtaining:  $T_C = 1.57 \times 10^7 \text{ K}$ . We then derived the Compton radius ( $R_C$ ) and the critical luminosity ( $L_{cr}$ ) from the formulae:  $R_C = (10^{18} \times m_1)/T_C \text{ cm}$  and  $L_{cr} = 0.03 L_{Edd}/\sqrt{T_C/10^8}$ , where  $L_{Edd}$  is the Eddington luminosity (Begelman et al. 1983). The Compton radius resulted to be  $R_C = 8.9 \times 10^{10} \text{ cm}$  and  $L_{cr} = 1.5 \times 10^{37} \text{ erg s}^{-1}$ . We note that both the ionised plasma sits well inside the Compton radius ( $R < 0.17 \times R_C$ ) and the soft state luminosity ( $L \sim 0.87 \times L_{cr}$ ) is comparable if not smaller than the critical luminosity, therefore hampering the generation of a thermally driven wind. For these reasons, no thermal wind can

<sup>5</sup> In theory, by characterising the shape and the variability of the dust scattering halo, it is possible to correct the spectrum of the source, therefore to verify the reality of the column density variation (see for example the case of AX J1745.6-2901; Jin et al. 2017; 2018). Despite we recently developed such spectral corrections for various extracting regions of modern X-ray telescopes, unfortunately these are not applicable to first order grating data, because of the complexity of the source extraction in dispersed spectra; Jin et al. 2017; 2018).

<sup>6</sup> Exceptions to this trend have been reported during the hard state outburst of V404 Cyg (King et al. 2015) and in some Z-sources (Homan et al. 2016). The latter class of sources are characterised by more complex behaviours and state classification as well as larger luminosities, compared to atoll NS.

be generated in MXB 1659-298<sup>7</sup> and the absorber can be at rest, forming an accretion disc atmosphere.

#### 9.4 Single or multi-layer absorber and other approximations

The best fit model suggests that a single layer absorber with high column density and ionisation parameter can reproduce the bulk of the absorption features in the average spectrum. At first, this appears rather surprising. Indeed, the large array of different transitions with significantly different ionisation potential might carry information of a radial stratification of the ionisation of the absorber, or be the consequence of significant variations over time of the plasma parameters. However, before properly addressing these very interesting scenarios, a detailed understanding of secondary effects impacting the expected results need to be fully carried out. Indeed, several of the strongest absorption lines are saturated (Ponti et al. in prep), the ionised absorber is likely variable, the line broadening might be different from the value assumed in this work ( $v_{turb} = 500 \text{ km s}^{-1}$ ). We therefore leave such questions for future investigations.

## 10 CONCLUSIONS

We studied the evolution of the X-ray emission of the accreting NS LMXB MXB 1659-298, comparing the soft and hard accretion states. During the soft state, we detected 60 absorption lines (of which 21 at more than  $3\sigma$ ), that is about one order of magnitude more lines compared to previous works (6 lines were detected by Sidoli et al. 2001; Diaz Trigo et al. 2006). This allows us to place tighter constraints on the physical properties of the absorbing plasma ( $\log(\xi/\text{erg cm s}^{-1}) \sim 3.8$ ,  $\log(N_H/\text{cm}^{-2}) \sim 23.5$ ), to demonstrate that both the low energy transitions and the Fe K lines are at rest, without the requirement to invoke a mildly outflowing disc atmosphere. The repeated detection of an high ionisation absorber during the soft states in two different outbursts (Sidoli et al. 2001; Diaz Trigo et al. 2006; this work) suggests the persistent presence of such component during the soft state. The new data show that the high ionisation absorption (traced by the Fe XXV and Fe XXVI lines) significantly weakens/disappears during the hard state, indicating a physical change of the absorber (disc atmosphere) between the two states. This is likely a consequence of a photo-ionisation thermal instability that drives the Fe K absorber to new equilibria consistent with fully or lowly ionised plasma (Bianchi et al. 2017). Thanks to the tentative detection of one of the lines of the Fe XXII doublet, we also constrained the density of the absorber ( $n_e > 10^{13} \text{ cm}^{-3}$ ).

#### Comparison with similar works

*While this work was refereed, a similar paper has been accepted (Sharma et al. 2018) and another has been submitted and posted on arXiv (Iaria et al. subm.). Sharma et al. (2018) finds very similar results to the ones presented here. Different components are, instead, investigated by Iaria et al. However, we refrain from performing a detailed comparison, because that work is still in the refereeing process.*

## ACKNOWLEDGMENTS

The authors wish to thank Norbert Schartel and Fiona Harrison for approving the *XMM-Newton* and *NuSTAR* DDT observations of MXB 1659-298. GP acknowledges financial support from the Bundesministerium für Wirtschaft und Technologie/Deutsches Zentrum für Luft- und Raumfahrt (BMWi/DLR, FKZ 50 OR 1812, FKZ 50 OR 1715 and FKZ 50 OR 1604) and the Max Planck Society. SB acknowledges financial support from the Italian Space Agency under grants ASI-INAF I/037/12/0 and 2017-14-H.O. BDM acknowledges support from the Polish National Science Center grant Polonez 2016/21/P/ST9/04025 and from the European Unions Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 798726. **Table 2.** Best fit energies ( $E_O$ ), equivalent widths ( $EW$ ) and outflow velocity ( $v_{out}$ ) of lines detected in the HETG (HEG+MEG) spectra. For each identified transition the expected wavelength of the transition ( $\lambda$ ) is reported. The energies of the doublets are averaged over the oscillator strengths. We only list velocities for the strongest transitions. † The energy of these transitions have been fixed, in the fit, to the expected values.

**Table 4.** Best fit parameters of the *XMM-Newton* EPIC-pn hard state spectrum. A variety of spectral components, described in the text, are employed. Model H1 (TBABS(POWERLAW)) is composed by a powerlaw absorbed by neutral material (TBABS). Model H2 (TBABS(DISKBB+NTHCOMP)) considers the emission from a disk black body plus a thermal Comptonisation component. Model H3 additionally considers the emission from a black-body component (BBODY: TBABS(DISKBB+BBODY+NTHCOMP)). Model H3gain applies a fit to the offset of the gain (with fixed slope) of the response matrices (GAIN \* TBABS(NTHCOMP+DISKBB+BBODY)). The following symbols mean: † Fixed parameter; | In eV units; ◇ Units of  $10^{-2}$ . Other symbols as in Tab. 1. Error bars indicate 90 % confidence, unless stated otherwise.
