ABSTRACT

We present results from the deep *Chandra* observation (105 ks), together with new Giant Metrewave Radio Telescope and Very Large Array data of the AGN outburst in the radio-loud galaxy group 3C 88. The system shows a prominent X-ray cavity on the eastern side with a diameter of ~ 50 kpc at ~ 28 kpc from the nucleus. The total enthalpy of the cavity is 3.8×10^{58} erg and the average power required to inflate the X-ray bubble is $\sim 2.0 \times 10^{43}$ erg s^{-1} . From surface brightness profiles, we detect a shock with a Mach number of $M = 1.4 \pm 0.2$, consistent with the value obtained from temperature jump. The shock energy is estimated to be 1.9×10^{59} erg. The size and total enthalpy of the cavity in 3C 88 are the largest known in galaxy groups, as well as the shock energy. The eastern X-ray cavity is not aligned with the radio jet axis. This factor, combined with the radio morphology, strongly suggests jet reorientation in the last tens of million years. The bright rim and arm features surrounding the cavity show metallicity enhancement, suggesting they originated as high metallicity gas from the group centre, lifted by the rising X-ray bubbles. Our *Chandra* study of 3C 88 also reveals that galaxy groups with powerful radio AGN can have high cavity power, although deep X-ray observations are typically required to confirm the cavities in galaxy groups.

Key words: galaxies: active – galaxies: groups: individual: 3C 88 – galaxies: jets – radio continuum: galaxies – X-rays: galaxies: clusters.

1 INTRODUCTION

The X-ray observations from *Chandra* and *XMM-Newton* have revealed that the radiative cooling time of the X-ray emitting gas at the centres of many groups and clusters is less than 1 Gyr (e.g. O’Sullivan et al. 2017). In the absence of heating, a cooling flow occurs and the hot gas cools, condenses, and flows towards the centre (e.g. Fabian 1994). However, much less cool gas, below 0.5–1 keV, has been found by *Chandra* and *XMM-Newton* than predicted by the cooling flow models (e.g. David et al. 2001; Peterson et al. 2001; Fabian et al. 2006), suggesting there is a heating source which compensates for the radiative cooling. Among many proposed possibilities, the feedback from the central active galactic

nucleus (AGN) appears to be the most promising one (for a review, see McNamara & Nulsen 2007).

There is clear observational evidence of AGN heating. The brightest central galaxies (BCGs) of clusters and groups are more likely to host a radio-loud AGN (e.g. Burns 1990; Best et al. 2007; Mittal et al. 2009; Sun 2009). High-resolution X-ray observations have revealed disturbed structures, such as shocks and cavities, in the cores of clusters, groups, and elliptical galaxies (e.g. Birzan et al. 2004, 2008; Forman et al. 2005; Nulsen et al. 2005a,b; Dunn & Fabian 2006; Fabian et al. 2006; Croston et al. 2008, 2011; Baldi et al. 2009; Kraft et al. 2012; Randall et al. 2015; Su et al. 2017). These features are caused by the radio AGN jets. As the radio jets extend outwards and inflate radio lobes, the X-ray emitting gas is pushed aside, creating cavities (bubbles) visible in the X-ray images (Churazov et al. 2001). The total enthalpy of the buoyantly rising cavities is found to be sufficient to offset the radiative cooling (Birzan et al. 2004; Rafferty et al. 2006;

† Einstein and Spitzer Fellow.

Nulsen et al. 2007; Hlavacek-Larrondo et al. 2012). Meanwhile, weak ‘cocoon’ shocks, as expected from models of jet-fed radio lobes (Scheuer 1974; Heinz, Reynolds & Begelman 1998), provide additional heating from AGN outbursts, although they are difficult to detect and only a few examples have been found (e.g. Nulsen et al. 2005a,b; Forman et al. 2005; Baldi et al. 2009; Gitti et al. 2010; Croston et al. 2011; Randall et al. 2015). However, the details of the AGN feedback process, e.g. how the energy from AGN outburst is deposited in the ambient ICM and the accretion process, are poorly understood.

Ever since the discovery of X-ray cavities in cool cores, they have been an active topic observationally and theoretically. However, AGN heating has not been well studied in galaxy groups (McNamara & Nulsen 2007; Gitti, Brighenti & McNamara 2012), compared to numerous detailed studies in clusters (see also McNamara & Nulsen 2012; Sun 2012). Groups are gas-poor at their centres and group-cool cores are smaller than cluster-cool cores (e.g. see Fig. 5 in Sun 2012). High-resolution 3D hydrodynamic simulations in massive groups show that self-regulated mechanical AGN feedback is key to prevent severe overcooling and overheating (e.g. Gaspari et al. 2011). The heating occurs through bubble inflation, cocoon shocks, and later turbulent mixing (Churazov et al. 2001; McNamara & Nulsen 2007; Soker 2016). The feedback power is directly linked to the X-ray luminosity: the hot plasma halo is the progenitor reservoir out of which multiphase gas condenses and later boosts the supermassive black hole (SMBH) accretion via a process known as chaotic cold accretion (CCA) (Gaspari & Sądowski 2017). Hot Bondi accretion has been shown by many works that it generally produces too low power and has a poor self-regulation disconnected from the X-ray cool core (e.g. Gaspari et al. 2011; Gaspari, Ruszkowski & Sharma 2012; Barai et al. 2016; Yang & Reynolds 2016; Gaspari & Sądowski 2017; Gaspari, Temi & Brighenti 2017; Voit et al. 2017; Gaspari et al. 2018). On the other hand, galaxy groups provide an excellent opportunity to study AGN feedback. The impact of AGN outbursts is much more pronounced in low-mass systems due to their shallow gravitational potentials (e.g. Giodini et al. 2010). The imprint of non-gravitational processes (including AGN feedback) is observed in the scaling relations of e.g. gas fraction and entropy (e.g. Sun et al. 2009). In addition, the outburst interval, typically of the order of the central cooling time which is much shorter in groups than in clusters (e.g. O’Sullivan et al. 2017), is expected to be more frequent and gentle, which is essential to properly solve the cooling flow problem (e.g. Gaspari et al. 2011). Thus, we expect more frequently to detect multiple feedback imprints in the same group, e.g. NGC 5813 (Randall et al. 2015) and NGC 5044 (David et al. 2017). It is, therefore, crucial to build a census of AGN feedback imprints in galaxy groups, which is currently lacking, to understand the evolution of the hot intragroup medium, and the hosted SMBH.

Here, we present a detailed study of a nearby galaxy group, with deep *Chandra* observations, to explore AGN feedback. 3C 88 (UGC 02748) is the brightest central galaxy of a galaxy group at $z = 0.0302$, which is included in the 400 square degree *ROSAT* PSPC galaxy cluster survey catalogue (Burenin et al. 2007). It has been studied at many wavelengths. Optically, it is classified as a low-ionization nuclear emission-line region (LINER; Lewis, Eracleous & Sambruna 2003), containing a low-power AGN with the 2–10 keV luminosity of $\sim 5 \times 10^{41}$ erg s $^{-1}$ (Gliozzi et al. 2008). The *HST* image of 3C 88 shows a faint dust lane within the central ~ 0.4 kpc radius, roughly perpendicular to the radio jet (de Koff et al. 2000). There is H α + [N II] emission detected from an elliptical region roughly centred on the galaxy nucleus

with an extent of $\sim 5''$ (Baum et al. 1988). In the radio band, the FR classification of 3C 88 is arguable. Based on its morphology, 3C 88 is classified as an FR II radio galaxy (e.g. Martel et al. 1999; Marchesini, Celotti & Ferrarese 2004), while based on its radio power it is considered as the transition source between FR I and FR II (e.g. Baum, Heckman & van Breugel 1992; Gliozzi et al. 2008). The radio images of 3C 88, from Giant Metrewave Radio Telescope (*GMRT*) at 610 MHz and Very Large Array (*VLA*) at 1.4 GHz and 4.9 GHz, are shown in Fig. 1. 3C 88 shows a prominent radio core and jet to the northeast. Radio lobes extend from the northeast to the east and from the southwest to the west, which makes 3C 88 appear like a Z-shaped radio source. Some radio features are marked in Fig. 1. There are four ‘hotspot’-like features near the edge of the radio source. However, three of them are not aligned with the prominent northeastern jet. Two of them are indeed aligned, but $\sim 19^\circ$ from the jet. The bolometric radio luminosity is 5.48×10^{41} erg s $^{-1}$ from 10 MHz to 5 GHz, which is close to the FR I/II boundary line. 3C 88’s radio morphology strongly suggests a jet reorientation from east–west to northeast–southwest. As revealed by the shallower *Chandra* observations (Sun 2009; Zou et al. 2016), 3C 88 is a cool core group with an average temperature of ~ 0.9 keV, and a total bolometric X-ray luminosity of 3.6×10^{42} erg s $^{-1}$.

This paper is organized as follows. The *Chandra* and radio observations and data reduction are presented in Section 2. The spatial and spectral analysis are in Section 3. In Section 4, the properties of cavities are discussed. In Section 5, we discussed the warm gas in 3C 88. Sections 6 and 7 contain, respectively, the discussion and the summary of the paper. We assumed the cosmology with $H_0 = 70$ km s $^{-1}$ Mpc $^{-1}$, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$. At a redshift of $z = 0.0302$, the angular diameter distance is 124.7 Mpc and 1" corresponds to 0.604 k per cent. All error bars are quoted at 1σ confidence level, unless otherwise specified.

2 *Chandra* AND RADIO OBSERVATIONS AND DATA ANALYSIS

2.1 *Chandra* observations

3C 88 was observed by *Chandra* for ~ 105 ks split into three observations (Obs. IDs 11751, 11977, and 12007, PI: Sun) in October 2009 with the Advanced CCD Imaging Spectrometer (ACIS). All three observations (aimpoint on chip S3) were taken in Very Faint (VFAINT) mode and centred on the cool core. The details of the *Chandra* observations are summarized in Table 1. There was one ACIS-I observation taken in 2008 with a short exposure of ~ 11 ks (Sun 2012; Zou et al. 2016). In this study, we focus on the new, deep data with ACIS-S. The data were analysed using the CIAO 4.9 and CALDB version 4.7.4 from *Chandra* X-ray Center. For each observation, the level 1 event files were reprocessed using CHANDRA_REPRO script to account for afterglows, bad pixels, charge transfer inefficiency, and time-dependent gain correction. The improved background filtering was also applied by setting CHECK_VF_PHA as yes to remove bad events that are likely associated with cosmic rays. The background light curve extracted from a source-free region was filtered with LC_CLEAN script¹ to identify any period affected by background flares. There were no strong background flares for all observations and the resulting cleaned exposure time is shown in Table 1.

¹<http://asc.harvard.edu/contrib/maxim/acisbg/>

Figure 1. *GMRT* 610 MHz, *VLA* 1.4 GHz, and 4.9 GHz images with an rms level of 100, 45, and 112 $\mu\text{Jy beam}^{-1}$ (1σ) and contours of 3C 88 (see Section 2.2 for detail). The *GMRT* contours start from 5σ and are spaced by a factor of 2. The 1.4 GHz contours start from 6σ and are spaced by a factor of 2. The 4.9 GHz contours start from 4.5σ to 625σ and the square-root spacing is adopted. The radio images at low and high frequencies show a similar morphology with extended lobes, a narrow jet, and four ‘hotspot’-like features (marked by the blue arrows). The prominent northeastern jet bends near the end, towards the brightest ‘hotspot’, while the other ‘hotspot’ at the northeast is aligned with the ‘hotspot’ at the southwest. The angle between these two blue lines is $\sim 19^\circ$. We also draw a line along the edges of two radio lobes and the angle from it to the radio jet is $\sim 68^\circ$. The radio morphology strongly suggests a jet reorientation projected from roughly east–west to northeast–southwest. The scale-bars in the middle and right panels are the same as the one in the left panel.

Table 1. Summary of *Chandra* Observations of 3C 88 (PI: Sun).

ObsID	Date Obs	Total Exp (kses)	Cleaned Exp (ks)
11977	2009 Oct 06	49.62	49.13
11751	2009 Oct 14	19.92	19.44
12007	2009 Oct 15	34.62	33.77

The point sources were detected in the combined 0.5–7.0 keV count image using the CIAO tool *WAVDETECT*, with the variation of the point spread function across the field considered. The detection threshold was set to 10^{-6} and the scales are from 1 to 16 pixels, increasing in steps of a factor of $\sqrt{2}$. All detected sources were visually inspected and masked in the analysis. The weighted exposure map was generated to account for quantum efficiency, vignetting, and the energy dependence of the effective area assuming an absorbed APEC model with $kT = 1.0$ keV, $N_{\text{H}} = 1.12 \times 10^{21} \text{ cm}^{-2}$, and abundance of $0.3 Z_{\odot}$ at the redshift $z = 0.0302$ in the 0.7–2.0 keV. The instrumental background was estimated using the stowed background, which contains only the particle background. The blank sky files contain both the particle background and the cosmic X-ray background. Rescaling blank sky background to remove the particle background may over- or under-estimate the cosmic X-ray background, and would generally require a double-subtraction. While the stowed background includes only the particle background, we can remove it and then model local X-ray background. In our studies, we preferred the stowed background. For each observation, the standard stowed file for each chip was reprojected to match the time-dependent aspect solution, and normalized to match the count rate in the 9.5–12.0 keV band.

Proper background modelling is essential for spectral analysis, especially in low-surface brightness regions. Since the diffuse emission from the galaxy group 3C 88 does not extend over the entire field of view, the region beyond $\sim 8'$ from 3C 88, where the surface brightness is approximately constant as shown in Fig. A1, can be used to model the local X-ray background. For each observation, we extracted the spectrum from the region ($>9'$)

from ACIS-S1, ACIS-S2, and ACIS-I chips separately (I2 and I3 chips are also active for our ACIS-S observations), since the CCD response varies for different chips. All nine spectra were fitted simultaneously with two thermal components at solar abundance and zero redshift plus an absorbed power law with an index of 1.5 to determine the ‘local’ X-ray background from this region in our observations. One thermal component is unabsorbed with the temperature fixed at 0.1 keV to account for the emission from the Local Hot Bubble (Snowden et al. 1998; Sun et al. 2009; Liu et al. 2017), the other thermal component is absorbed with the temperature allowed to vary to account for the emission from the Galactic halo. The absorption model is TBABS with a fixed column density of $N_{\text{H}} = 1.12 \times 10^{21} \text{ cm}^{-2}$. All normalizations are allowed to vary. The best fitting model gives the Galactic halo temperature of $kT = 0.20^{+0.01}_{-0.02}$ keV. We also compared the derived soft X-ray background flux with the *ROSAT* All-Sky Survey (RASS) R45 values around the galaxy group (see details in Sun et al. 2009). We found the observed soft X-ray background flux of $2.94^{+0.37}_{-0.34} \times 10^{-12} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ deg}^{-2}$ in the 0.47–1.21 keV band and R45 value of 113.3 ± 8.0 , which is consistent with the relation in fig. 2 of Sun et al. (2009). For spectral fitting, we used XSPEC version 12.9.1 and AtomDB 3.0.8, assuming the solar abundance table by Asplund et al. (2009).

We also examined the X-ray absorption column density towards 3C 88. The weighted column density of the total Galactic hydrogen is $1.12 \times 10^{21} \text{ cm}^{-2}$ (versus the weighted HI column density of $0.79 \times 10^{21} \text{ cm}^{-2}$), calculated by the ‘NHTot’ tool² including both the atomic hydrogen and the molecular hydrogen column density (Willingale et al. 2013). We fitted the spectra extracted from a circular region of radius $6'$ centred on the central AGN for each observation (the central $1.5'$ was excluded). The model includes an absorbed thermal component for the diffuse emission from the group plus the diffuse X-ray background component. The background was modelled and re-scaled based on the local X-ray background estimation. The absorption parameter, the temperature, abundance,

Figure 2. *Left:* The combined background-subtracted, exposure-corrected *Chandra* image of 3C 88 in the 0.5–3.0 keV band, smoothed with a 2D Gaussian 9-pixel kernel (0.492''/pixel) and overlaid with the *VLA* 1.4 GHz radio contours (in red as in Fig. 1). The X-ray point sources have been removed and filled with the local background. The radio contours show a narrow jet, two bright radio lobes, and hotspots on each side of the radio nucleus. The prominent eastern X-ray cavity does not fully overlap with the brightest part of the radio lobe. *Middle:* The same *Chandra* image as in the left panel smoothed with a 2D Gaussian 8-pixel kernel (0.984''/pixel). The image shows the prominent cavity to the east of the central AGN, the surrounding bright rims, and the edges associated with the cavity. X-ray decrement to the west is also likely in the position of the radio lobe. *Right:* The same *Chandra* image further zoomed out, smoothed with a 2D Gaussian 5-pixel kernel (3.936''/pixel), to show the elliptical edge just outside of the radio lobes. It is identified as a weak shock in this paper.

and the normalization of the source component were allowed to vary. We obtained the best-fitting value of $N_{\text{H}} = 1.21 \pm 0.16 \times 10^{21} \text{ cm}^{-2}$, which is consistent with the weighted total hydrogen column density. We found that our results are not very sensitive to the value of the column density, e.g. the uncertainties of the temperature and the Mach number are generally within 5 per cent, and in some cases ~ 10 per cent.

2.2 Radio observations

3C 88 was observed with the *GMRT* at 610 MHz on 2010 May 7 (project 18_009, PI: Sun). The data were collected using the software correlator and default spectral-line observing mode. The data sets were calibrated and reduced using the NRAO Astronomical Image Processing System package (AIPS) as described in Giacintucci et al. (2011). Self-calibration was applied to reduce residual phase variations and improve the quality of the final images. Due to the large field of view of the *GMRT*, we used the wide-field imaging technique at each step of the phase self-calibration process to account for the non-planar nature of the sky. The final image was produced using the multi-scale CLEAN implemented in the AIPS task IMAGR, which results in better imaging of extended sources compared to the traditional CLEAN (e.g. Greisen, Spekkens & van Moorsel 2009). The final image at 610 MHz has a resolution of $7.1'' \times 5.4''$ and an rms noise level (1σ) of $100 \mu\text{Jy beam}^{-1}$ (Fig. 1). A total flux of $8.8 \pm 0.7 \text{ Jy}$ is measured for 3C 88 in this image.

NRAO *VLA* observations of 3C 88 were obtained on 2011 April 15 as part of program SB0517 (PI: Sun). Data presented in this paper were taken in the *VLA* B configuration with two tunings of bandwidth 128 MHz each centred on frequencies of 1327 and 1455 MHz. The data were observed in spectral-line mode. The observations were calibrated within a modified Common Astronomy Software Applications (CASA) pipeline in version 5.1.2–4 of CASA following standard calibration procedures. Minor modifications to the pipeline were required to enable it to accurately recognize observing intents for calibrators. The flux scale was set using 3C 48. The imaging was undertaken using the multiscale cleaning to accurately recover emission on scales relevant to the

source structure. Imaging algorithms also included both multifrequency synthesis with two Taylor terms to more accurately represent the spectral dependence of the emission and w-projection to enable wide-field imaging corrections for non-coplanar effects. The image presented in Fig. 1 has a resolution of $3.9'' \times 3.7''$ and an rms level of $45 \mu\text{Jy beam}^{-1}$ (1σ).

We also show the archival *VLA* image at 4.9 GHz in Fig. 1. The observation was taken on Apr. 22, 1984 with the C configuration. This image was produced as part of the NRAO *VLA* Archive Survey, (c) AUI/NRAO.³ The beam size is $4.30''$ and the rms level is $112 \mu\text{Jy beam}^{-1}$ (1σ).

3 SPATIAL AND SPECTRAL ANALYSIS

3.1 Image analysis and radial profiles

We reprojected and summed the count images, background images, and exposure maps, respectively, from three observations using the CIAO tool `reproject_image`. Fig. 2 (left) shows the combined background-subtracted, exposure-corrected image overlaid with the *VLA* 4.9 GHz radio contours. Fig. 2 (middle) is the zoomed-out image to show the prominent cavity to the east of the central AGN and the surrounding bright rims. Fig. 2 (right) shows the further zoomed-out image with high contrast to highlight the shock edges.

The images show one prominent cavity at $\sim 28 \text{ kpc}$ (projected distance) to the east of the nucleus with surrounding bright rims. The cavity does not fully overlap with the brightest part of the radio lobe. The current radio jets and hotspots are not aligned with the cavity and have passed through it to larger radii, at least in projection. Beyond the bright rim of the cavity, there is a sharp surface brightness edge at $\sim 65 \text{ kpc}$ to the south and north and at $\sim 80 \text{ kpc}$ to the east and west. As shown in the next section, the gas temperature drops outwards across the edge, which rules out the possibility that the edge is due to a cold front.

³The NVAS can [currently] be browsed through <http://archive.nrao.edu/nvas/>

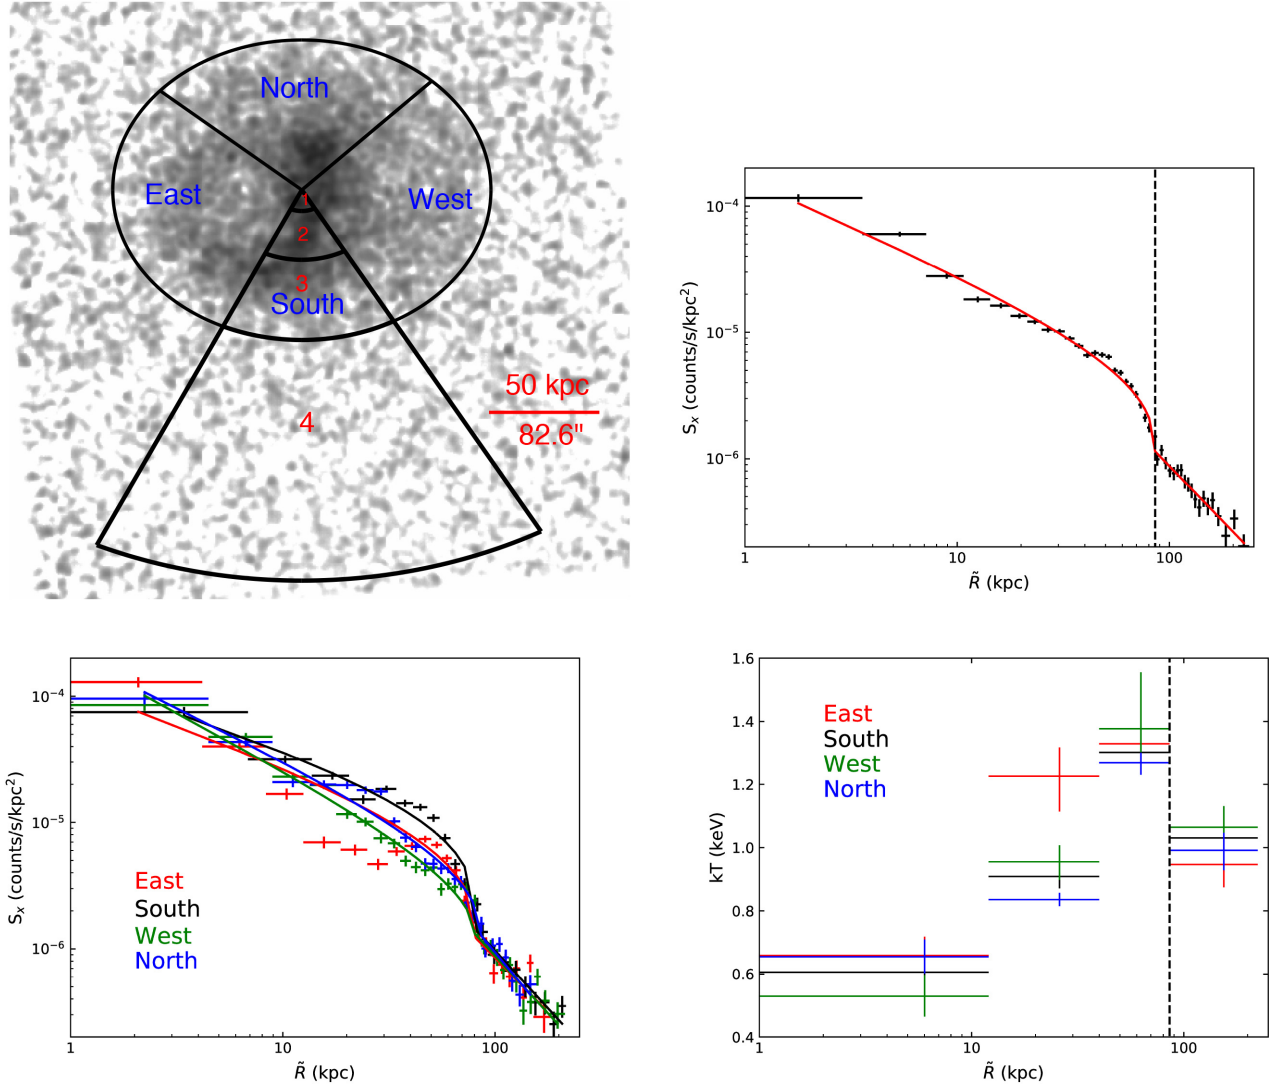

Figure 3. Top left: The combined background-subtracted, exposure-corrected *Chandra* images of 3C 88 in the 0.7–2.0 keV band, smoothed with a 2D Gaussian 10-pixel kernel (0.984'' pixel). The surface brightness profiles are extracted in the same ellipse region from four wedges, with angles (measured counterclockwise from the west) of 145°–240° for the eastern wedge, 240°–305° for the southern wedge, 305°–400° for the western wedge, and 40°–145° for the northern wedge. The ellipse shown in the image has a semimajor axis of 85.7 kpc and a major to minor axial ratio of 1.26. The regions marked in red are used for spectral analysis (we only show regions in the southern wedge). \tilde{R} denotes the semimajor axis of the ellipse. Top right: The averaged surface brightness profile across the edge in the 0.7–2.0 keV band. The red solid line shows the best-fit surface brightness model for an ellipsoidal emissivity edge. The vertical dashed line shows the position (semimajor axis of ~ 85 kpc) of the shock edge. Bottom left: The surface brightness profiles in the 0.7–2.0 keV band for the four sectors shown in the top left-hand panel. The solid lines show the best-fit surface brightness model. Bottom right: the deprojected temperatures in region 1, 2, 3 and 4 for four wedges.

To examine if the surface brightness edge surrounding the cavity is consistent with a shock discontinuity, we extracted the surface brightness profiles in the 0.7–2.0 keV band in the same ellipse region from four different wedges to match the shock edge. The centre is chosen to coincide with 3C 88's radio nucleus. As shown in the top left-hand panel in Fig. 3, the angles (measured counterclockwise from the west) are 145°–240° for the eastern wedge, 240°–305° for the southern wedge, 305°–400° for the western wedge, and 40°–145° for the northern wedge. We also extracted the averaged surface brightness profile within the full ellipse. We used the semimajor axis of the ellipse as the X -axis for all the surface brightness profiles. The particle background was subtracted using the normalized stowed background. We modelled the sky background (see Section 2) and estimated a flux of 1.8×10^{-7} count s $^{-1}$ arcsec $^{-2}$ which is subtracted

from the surface brightness. The radial bins were chosen to ensure a minimum of 200 source counts per bin for the averaged surface brightness profile, and a minimum of 100 source counts per bin for those from four wedges. From the surface brightness profile, the X-ray emission from the galaxy group is traced to ~ 220 kpc. We can clearly see the depression of surface brightness in the eastern wedge from ~ 5 –50 kpc because of the prominent X-ray cavity (Fig. 3 bottom left).

To fit the surface brightness discontinuity, we assumed a simple, self-similar ellipsoidal model for the X-ray emissivity, which is a power-law function of the elliptical radius (e.g. $\epsilon \propto r^{-p}$) inside and outside of the discontinuity (Sarazin et al. 2016). The best-fit surface brightness model is shown as the solid line in Fig. 3 top right panel for the averaged profile, and in the bottom left-hand panel for the

Note: *a*: the inner slope of emissivity power law; *b*: the outer slope of emissivity power law; *c*: the emissivity jump at the edge; *d*: Mach number from density jump; *e*: Mach number from temperature jump; see Section 3.1 for detail.

profiles from different wedges. For the eastern wedge, we ignored the data corresponding to the cavity. The best-fitting parameters are summarized in Table 2 (notice that the larger errors in eastern and northern wedges are due to the fewer surface brightness data points used in fitting). The edges are roughly located at ~ 80 – 86 k per cent. For the averaged surface brightness profile, the best-fit model gives the inner and outer power-law slope (p_i and p_o , respectively) of 1.37 and 0.87, and an emissivity jump ($R_{\text{em}} = \varepsilon_i/\varepsilon_o$) of 3.11 ± 0.30 at the edge. Based on the best-fit model of the emissivity distribution, we can obtain the related density distribution $n_e(r) = [\varepsilon(r)/\Lambda(T, Z)]^{1/2}$, where $\Lambda(T, Z)$ is the X-ray emissivity function which depends on gas temperature T and abundance Z . The density jump across the shock edge is $\rho_{\text{post}}/\rho_{\text{pre}} = 1.57 \pm 0.31$, where suffix pre- and post- denote quantities upstream and downstream of the shock. We calculated the Mach number of the shock based on the density jump (e.g. Landau & Lifshitz 1959):

$$M^2 = \frac{2C}{(\gamma + 1) - (\gamma - 1)C}, \quad (1)$$

where M is the Mach number, $C = \rho_{\text{post}}/\rho_{\text{pre}}$ is the compression ratio, and $\gamma = 5/3$ is the adiabatic index. We obtained a Mach number of $M = 1.39 \pm 0.23$.

3.2 Spectral analysis

3.2.1 Radial spectral analysis

Spectra were extracted from the same circular annuli for the three observations separately using the CIAO tool `specextract`. For each spectrum, the weighted response files and matrices were made, and a corresponding background spectrum was extracted from the same region from the normalized stowed background data. The sky background model obtained from the local background estimation (Section 2) was scaled by the area of each region and subtracted. The spectra were fitted in the energy range 0.5–5.0 keV with XSPEC 12.9 using the C-statistic. The spectra from the same region from three observations were fitted simultaneously to an absorbed thermal APEC model, i.e. `TBABS*APEC`. The temperature, metallicity, and the normalization were allowed to vary freely. For regions where the abundances cannot be well constrained due to the fewer counts, we fixed it at the best-fitting value or at the value obtained in nearby regions.

We focused our analysis on the ACIS-S3 chip and extracted a set of 11 circular annuli from the centre to a radius of ~ 220 kpc. The deprojected temperature profiles are shown in Fig. 4 (top left). For temperature deprojection, we adopted a model-independent approach (e.g. Dasadia et al. 2016) assuming spherical symmetry and the cluster temperature is uniform in each spherical shell. The approach is very similar to the ‘onion-peeling’ method, but with a different way to estimate the emission contribution to each annulus

from the outer spherical shells. We used Monte Carlo simulations to populate the 3D shells and create the projected images where each pixel represents the number of events that fell within each shell. By applying the respective masks (e.g. the included and excluded regions) to the simulated images, we can calculate the emission contribution factor from the outer spherical shell based on the sum of the pixel values. Using this method, we can account for point sources and chip gaps. We noted that our results are consistent with the results obtained by using the `PROJECT` model in XSPEC.

The deprojected temperature profile increases from ~ 0.6 keV in the centre (within 10 k per cent) up to 1.45 keV at ~ 62 k per cent ($\sim 0.1r_{180}$, r_{180} is the virial radius and r_{Δ} is defined as the radius where the mean mass density equals to Δ times of the critical density.), then declines towards large radii. This behaviour is very similar to the temperature profiles observed in other galaxy groups (e.g. Gastaldello et al. 2007; Sun et al. 2009). We noticed that the temperature peak is located just inside the shock region, which may complicate the detection of the actual temperature jump due to the shock itself, as found in other systems, e.g. in Hydra A (Gitti et al. 2011). The abundances (Fig. 4 middle left) are not well constrained in a few annuli and therefore are fixed. The abundance within ~ 20 k per cent is relatively flat at a low value of ~ 0.3 . The low abundance at the centre of cooling flow clusters is mainly due to fitting multiple temperature spectra with a single thermal model (the so-called ‘Fe bias’ effect, Buote 2000). The abundance in the fifth data bin where the cavity is located shows a jump, but with a large uncertainty.

We also present various quantities in Fig. 4. The electron density was obtained directly from the deprojected normalization of the APEC component assuming $n_e = 1.22n_H$, where n_e and n_H are the electron and proton densities. A dip is shown in the density profile at ~ 28 k per cent corresponding to the location of the cavity (Fig. 4 bottom left). Based on the deprojected gas temperature and density, we calculated the pressure in each annulus as $P = nkT$ (where $n = 1.92n_e$) and the entropy as $S = kT/n_e^{-2/3}$. As shown in Fig. 4 middle right, the entropy profile declines all the way to the centre. The entropy profile can be well represented by a constant plus a power law as $S = S_0 + S_1(r/100 \text{ kpc})^p$, with the best-fitting slope of 1.19 ± 0.09 and the central entropy floor $S_0 = 7.31 \pm 1.68 \text{ keV cm}^2$. We found the best-fitting entropy slope of 0.79 ± 0.07 between 30 k per cent and $0.15r_{500}$, which is consistent with the values found in galaxy groups and clusters (e.g. Sun et al. 2009), and the slope of 1.19 ± 0.05 between $0.15r_{500}$ and r_{2500} (e.g. 65–206 k per cent).

We calculated the gas cooling time as

$$t_{\text{cool}} = \frac{3P}{2n_e n_H \Lambda(T, Z)}, \quad (2)$$

where $\Lambda(T, Z)$ is the cooling function determined by the gas temperature and metallicity. The cooling time at the centre of 3C 88 is below 0.5 Gyr (Fig. 4 bottom right). Conventionally, the cooling radius is defined as the radius where the cooling time is shorter than

Figure 4. The azimuthally averaged radial profiles of the deprojected temperature, abundance Z , electron density, pressure, entropy, and cooling time. For comparison, we also show the projected temperature and abundance profiles in red.

1 Gyr or the lookback time to $z = 1$ (7.7 Gyr), which corresponds to a radius of ~ 11 k per cent or 50.5 k per cent for 3C 88. We estimated a bolometric X-ray luminosity of 3.3×10^{41} erg s $^{-1}$ within the cooling radius (11 k per cent, corresponding to the cooling time of 1 Gyr) for this strong cool core group.

Assuming hydrostatic equilibrium and spherical symmetry, we calculate the gravitational acceleration, g , as

$$g = \frac{d\Phi}{dr} = -\frac{1}{\rho} \frac{dP}{dr}, \quad (3)$$

where Φ is the gravitational potential, $\rho = 1.92n_e\mu m_p$ is the particle density, $\mu = 0.60$ is the mean particle weight, and m_p is the proton mass. To obtain a smooth pressure profile, we fitted it with a generalized NFW model, where $P \propto r^{-3}$ at large radii and the inner slope is allowed to vary. We found the best-fitting inner slope of 0.58 ± 0.11 . Once the gravitational acceleration is determined, we calculated the free fall time $t_{\text{ff}} = \sqrt{\frac{2r}{g}}$ (e.g. Gaspari et al. 2012). As shown in Fig. 5, the minimum value of $t_{\text{cool}}/t_{\text{ff}}$ at the centre of 3C 88 is close to the threshold (~ 10 – 20), below which the hot gas becomes thermally unstable (Gaspari et al. 2012; Sharma et al. 2012; Voit et al. 2015). We also checked the turbulent eddy time scale t_{eddy} (defined as $2\pi \frac{r^{2/3} L^{1/3}}{\sigma_{v,L}}$, where L is the injection scale, $\sigma_{v,L}$ is the velocity dispersion at the injection scale) since the locus of the eddy time and cooling time provides a robust criterion for the physical state of the hot gas (e.g. Gaspari et al. 2018). We found a minimum $t_{\text{cool}}/t_{\text{eddy}} \approx 1.0$, consistent with the presence of

Figure 5. Radial profile of $t_{\text{cool}}/t_{\text{ff}}$.

multiphase gas (Section 5) with an origin related to the turbulent CCA condensation process (e.g. Gaspari et al. 2018).

3.2.2 Temperature and abundance map

To study the thermal structure of the group, we performed a 2D spectroscopic analysis using contour binning (Sanders 2006). We generated 32 regions with a signal-to-noise ratio of 50 for 3C 88 using counts image in 0.7–2.0 keV band. We used the model TBABS*APEC to model the gas emission in each region in 0.5–5.0 keV band. The resulting projected temperature and abundance

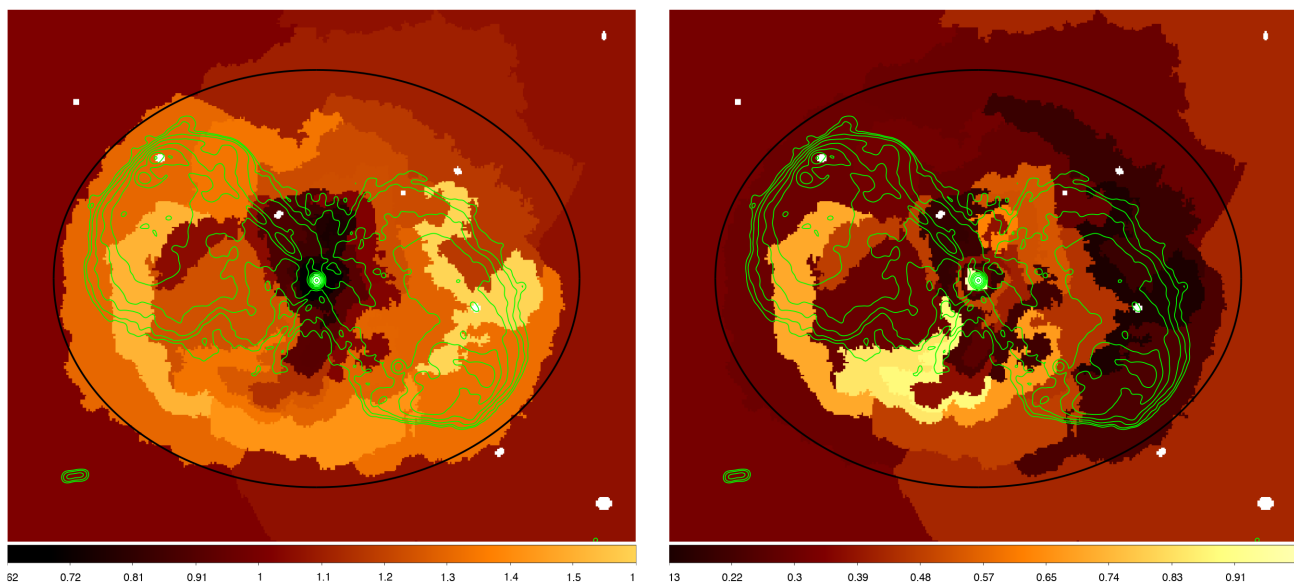

Figure 6. Temperature (left) and abundance (right) map of the central region overlaid with the VLA 1.4 GHz radio contours (in green) as in Fig. 1. The black ellipse in the map is the same as in Fig. 3 to approximate the shock front.

maps are shown in Fig. 6. The temperature map shows the high-temperature region surrounding the eastern cavity, at the location of the shock edges. The abundance map shows low-abundance regions close to the central AGN, which again is possibly due to the ‘Fe bias’, and the high-abundance regions surrounding the cavity, which we will discuss later in Section 6.6.

3.2.3 Shock spectral analysis

In Section 3.1, the shock features are derived mainly from the surface brightness profile. Here, we present the spectral analysis of the shock. As shown in Fig. 3 (top left), each wedge was divided into four small regions (1, 2, 3, and 4). For each region, the spectra were extracted from individual observations and were fitted simultaneously in the 0.5–5.0 keV band. The deprojected temperature values were shown in Fig. 3 (bottom right), obtained by assuming ellipsoidal symmetry with one of the principal axes along the line-of-sight. We estimated the Mach number of the shock based on the temperature jump (e.g. Landau & Lifshitz 1959; Sarazin et al. 2016):

$$M^2 = \frac{(8\frac{T_2}{T_1} - 7) + [(8\frac{T_2}{T_1} - 7)^2 + 15]^{1/2}}{5}, \quad (4)$$

where M is the Mach number, T_1 and T_2 are the pre- and post-shock temperature, and we assumed $\gamma = 5/3$. As shown in Table 2 we obtain Mach numbers of 1.41 ± 0.10 , 1.27 ± 0.06 , 1.30 ± 0.14 , and 1.30 ± 0.09 for eastern, southern, western, and northern wedges, respectively.

4 THE X-RAY CAVITY

In Fig. 2 (left) the smoothed *Chandra* X-ray image of 3C 88 shows a pronounced cavity to the east of the core, which is also evident from the surface brightness profile extracted from the eastern wedge as in Fig. 3. The corresponding cavity to the west is not significant.

We estimated the lower limit of the total jet power based on the enthalpy and buoyant rise time of the cavities (Churazov

et al. 2001), to ensure the direct comparison with previous studies. We assume the cavity has a spherical geometry centred at $3:27:57.327, +2:33:33.623$ with a radius of $0.633'$. The projected distance of the centre of the eastern cavity to the nucleus is ~ 28 kpc, with a radius of 23 kpc. The buoyant rise time of the bubble is calculated at its terminal velocity $\sim (2gV/SC)^{1/2}$, where V is the volume of the bubble, S is the cross-section of the bubble, and $C = 0.75$ is the drag coefficient (Churazov et al. 2001). The gravitational acceleration is calculated as $g \approx 2\sigma^2/R$, with the central stellar velocity dispersion of 189 km s^{-1} (Smith, Heckman & Illingworth 1990). Thus, the age of the bubble to its present position is 6.0×10^7 yr. The total cavity enthalpy ($H = 4PV$, where P is the azimuthally averaged pressure at the radius of the centre of the cavity) is calculated from the deprojected temperature and the electron density profile. The total enthalpy and the cavity power for the eastern are 3.8×10^{58} erg and 2.0×10^{43} erg s^{-1} . We noted that the cavity power to the cooling luminosity ratio is ~ 61 , showing that the mechanical power is sufficient to offset the cooling. If we instead use g at the centre of the cavity derived from Section 3.2, the age of the bubble is ~ 40 per cent lower and the resulting cavity power is ~ 60 per cent higher.

For comparison, we estimated the jet power using another technique based on the observed parameters of the jet terminal hotspots, which is calculated as (e.g. Godfrey & Shabala 2013)

$$Q_{\text{hs}} = Ac \frac{B_{\text{eq}}^2}{8\pi} \times g_{\text{hs}}, \quad (5)$$

where A is the area of the jet hotspots, c is the speed of light, B_{eq} is the equipartition magnetic field strength (Worrall 2009), and g_{hs} is the normalization factor which can be empirically determined. From the VLA 4.9 GHz radio map, we estimated the radii of the hotspots on both sides as ~ 2.4 kpc. We estimated an equipartition magnetic field of $\sim 5 \mu\text{G}$ based on the radio data using equation (2) in Miley (1980) (We need to be aware of the uncertainties in this determination). With a g_{hs} factor of 2 (e.g. Godfrey & Shabala 2013), we estimated a jet power of $\sim 2.1 \times 10^{43}$ erg s^{-1} . As the plasma in the hotspots is likely to be relativistic, their properties are thought to be variable on time-scales comparable to the light crossing time

Figure 7. Spectra at the position of the eastern cavity from three observations, with the best-fit single temperature model (see more detail in Section 4).

of a hotspot. While the jet power estimated from above equation could vary on a time-scale much shorter than that used to estimate the cavity power, we note that jet power is about the same as the cavity power.

The spectra in Fig. 7 were extracted from each observation of the eastern cavity region (see Fig. 2), together with response files and background spectra. We fitted the spectra with a one temperature model as `TBABS*APEC` and obtained the best fitting projected temperature of $1.22^{+0.06}_{-0.07}$ keV and the abundance of $0.22^{+0.09}_{-0.06}$ solar. Although the one temperature model provides a good fit to the spectra, it is lower than the data above ~ 3 keV as shown in Fig. 7. Thus, we added another thermal component to place constraints on any hot gas in the cavity. We fixed the temperature of the first thermal component to 1.05 keV at the radius of the cavity obtained from the projected fitting to account for the projected emission. The second component accounts for any thermal emission inside the cavity. The temperature is constrained between 1.5 and 10 keV. The metallicities of the two components are tied together.

We found that adding a hotter component improves the fit with a significance of 99 per cent using F -test, implying the existence of hot gas in the cavity. Assuming the hot gas in the cavity is in pressure balance with the cooler gas, we can place constraints on the volume-filling factor based on the temperature and normalizations of the cool and hot gas. We found that, as the temperature of the second component increases, the metallicity increases and reaches above ~ 1.0 , which is a typical value for group centres. This may be the result of ‘Fe bias’, which typically occurs when fitting a single-temperature model to the spectrum of the multiphase gas. The volume-filling factor increases rapidly from 0.72 for 1.5 keV to 0.99 for temperatures greater than ~ 5.5 keV.

5 WARM GAS IN 3C 88

Narrow-band imaging data on 3C 88 were taken on December 16, 2009, with the Seaver Prototype Imaging camera (*SPICam*) on the Astrophysical Research Consortium 3.5-m telescope at the Apache Point Observatory. *SPICam* is a general purpose, optical imaging CCD camera with a field of view $4.78'$ square. Two 900 s $H\alpha$ + [N II] observations were taken with the NMSU-677.6 filter (central λ : 6776 Å, width: 75 Å). Two 540 s observations with the

NMSU-665 filter (central λ : 6650 Å, width: 80 Å) were taken for the continuum (or $H\alpha$ off). Both filters are 2 inch square, so only the central $\sim 3'$ square is unvignetted. The seeing was $\sim 1.1''$ and the sky was photometric during our observations.

We follow the standard CCD analysis for the *SPICam* data. Dome flats were used and the spectrophotometric standard was Feige34. The Galactic extinction was 0.259 mag for the NMSU-665 filter and 0.252 mag for the NMSU-677.6 filter, with the extinction law from Fitzpatrick (1999) and assuming $R_V = 3.1$. A software issue with the *SPICam* shutter in 2007 – 2010 adds 0.7505 s to the requested exposure. This was identified at the end of 2010 and was corrected for our analysis.

For continuum subtraction, we generally follow the isophote fitting method described in Goudfrooij et al. (1994), by studying the $H\alpha$ / off ratio profile. The net $H\alpha$ + [N II] emission of the galaxy is shown in Fig. 8. 3C 88 hosts a nuclear source with $H\alpha$ + [N II]. A diffuse extension, beyond the nuclear source, is detected to at least 5 k per cent from the nucleus. The presence of multiphase gas with ~ 5 k per cent extent (and fairly low t_{cool} compared with the free-fall/eddy time-scales; Sec. 3.2.1) can be understood in the CCA scenario (cf. Gaspari et al. 2018), in which cold/warm gas originates from the *in situ* condensation cascade and recurrently triggers the AGN jets. Further away from the nucleus, a compact knot is detected 16 k per cent NE of the nucleus, with potentially a faint filament to its north. Within the central 6 k per cent radius, where most of the central diffuse emission lies, we measure a total $H\alpha$ luminosity of 6.6×10^{39} erg s^{-1} , assuming no intrinsic extinction. The small blob, 16 k per cent NE of the nucleus, has a total $H\alpha$ luminosity of 5.3×10^{39} erg s^{-1} , if it is associated with 3C 88. The following line ratios are assumed, $[N II]6583/H\alpha = 1.5$ and $[N II]6548/[N II]6583 = 1/3$, which are consistent with the typical values in Goudfrooij et al. (1994). Deeper narrow-band imaging data with good seeing and spectroscopic data are required to better understand the state of warm gas in this system. Nevertheless, 3C 88 does host some warm gas near the nucleus and the radio jet.

Since 3C 88 was not observed by *Herschel* or *Spitzer/MIPS* and it was not detected in *Galaxy FUV AIS* data, we estimate its SFR solely from the *Wise 22 μm data. Based on the SFR calibration by Lee, Hwang & Ko (2013), the SFR for 3C 88 is $0.96 M_{\odot} \text{ yr}^{-1}$ for the Kroupa IMF. However, one can only view this estimate as an upper limit, as the nuclear emission may dominate the 22 μm emission. Star formation in 3C 88 is at most weak.*

6 DISCUSSION

6.1 The central AGN

Fig. 9 shows the subpixel (0.0984"/pixel) *Chandra* X-ray image of the central region. We extracted spectra of the central X-ray source from each observation in a circular region with a radius of $2''$, and the background spectra from an annulus from $2''$ to $4''$. The spectra from the three observations were fitted simultaneously between 0.4 and 8.5 keV. The nuclear spectrum is flat and the power-law photon index is ~ 0.6 from a simple power-law model (Table 3). We confirmed that pileup is negligible even for the brightest ACIS pixel. As the local background is simply scaled by the solid angle, the residual thermal emission is expected in the nuclear spectrum. As the spectrum is flat, simply adding a thermal component results in a negligible contribution. We attempted models with an obscured AGN plus a soft component, which indeed improves the fits (Table 3). If the canonical value of 1.7 for the power-law index of the AGN

Figure 8. Optical continuum ($H\alpha$ off) and net $H\alpha + [N\ II]$ images of the centre with the 3.5m *APO* telescope. The *VLA* 4.9 GHz contours (red, same as the ones shown in Fig. 2) and optical contours (green) of the bright part are also shown. There is an $H\alpha + [N\ II]$ extension beyond the central nucleus. Blue arrows in the right panel mark a compact emission-line feature (solid blue line) and a potential emission-line diffuse feature (dashed blue line) close to the NE jet, more than 16 k per cent away from the nucleus.

Figure 9. The 0.7–7.0 keV subpixel (0.0984"/pixel) image of the central region, smoothed with a 2D Gaussian 4-pixel kernel. The spectrum of the central AGN is extracted from a circle with a radius of $2''$ that is shown in red. Despite the limited statistics of the data, some features are revealed around the centre, including a linear feature to the northeast on the same direction of the radio jet (inner X-ray jet?) and extension to the east and west.

is preferred, 3C 88's AGN is obscured with a moderate intrinsic absorption column density of $\sim 2 \times 10^{22} \text{ cm}^{-2}$. The rest-frame 2–10 keV luminosity of the AGN is $\sim 4 \times 10^{41} \text{ erg s}^{-1}$.

We examined the variability of the central point source based on the flux from the 0.5–10 keV band. As shown in Table 1 the time separations for three observations are ~ 7 and ~ 1 day. Since the AGN variabilities have different time-scales, we also include the

old, short ACIS-I observation (Obs. ID 9391) taken more than 1-year earlier. We found that there are small variations between the four observations and the 0.5–10 keV flux changes by ~ 20 per cent. We also checked the possible X-ray emission associated with the radio features, e.g. radio jet and the hot spots. Like Massaro et al. (2015), we chose a circular region for the hot spots and a box region for the radio jet to measure the observed X-ray emission. Background regions of the same shape and size were chosen to avoid emission from other sources, with one box for the radio jet, and two circles for the hot spots. X-ray emission from the radio jet ($\sim 25''$ northeast to the nucleus) is detected with a significance of $\sim 4.0\sigma$, and with a significance level of $\sim 4.7\sigma$ from the eastern hotspot ($\sim 109''$ to the nucleus; note that this feature is marked as ‘jet knot’ in Massaro et al. 2015). There is no detection of X-ray emission associated with the western hotspot. The hardness ratio (2.0–7.0 keV flux divided by 0.5–2.0 keV flux) of the eastern hotspot is ~ 0.17 , which corresponds to a power-law index of ~ 2.5 assuming an absorbed power-law model. We estimated a 0.5–10 keV X-ray luminosity of $6.0 \pm 1.3 \times 10^{39} \text{ erg s}^{-1}$ for the eastern hotspot. Assuming the same spectral shape, we obtained an upper limit luminosity of $\sim 10^{39} \text{ erg s}^{-1}$ for the western hotspot.

Based on the core flux density measured by the *VLA* (Morganti, Killeen & Tadhunter 1993) at 5 GHz, we calculated a radio luminosity at 5 GHz of $L_R = 1.68 \times 10^{40} \text{ erg s}^{-1}$. Using the black hole Fundamental Plane (Gültekin et al. 2009), or the relation between the radio luminosity at 5 GHz, the X-ray 2–10 keV luminosity, and the black hole mass, we estimated a black hole mass of $\sim 7.4 \times 10^8 M_\odot$, which is comparable to the black hole mass of $\sim 5.0 \times 10^8 M_\odot$ estimated from the $M_{\text{bulge}} - M_{\text{BH}}$ relation (Bettoni et al. 2003).

6.2 Jet/cavity geometry

Fig. 10 is a schematic diagram showing the geometry of the jets and cavities, viewed from the positive z -axis. The jets propagate

Table 3. Spectral fits of the central AGN.

Model	Γ_1^a	kT/Γ_2^b (keV)	$N_{\text{H,intr}}^c$ (10^{22} cm^{-2})	$L_{0.5-2.0}^d$ ($10^{40} \text{ erg s}^{-1}$)	L_{2-10}^e ($10^{41} \text{ erg s}^{-1}$)	$[C, C_e, C_\sigma]^f$
tbabs*POW	$0.60^{+0.04}_{-0.04}$				$5.71^{+0.21}_{-0.21}$	[157.8, 131.0, 16.3]
tbabs*(ztbabs*POW + APEC)	$1.40^{+0.14}_{-0.14}$	$0.73^{+0.07}_{-0.14}$	$1.6^{+0.3}_{-0.3}$	$1.78^{+0.23}_{-0.22}$	$4.57^{+0.20}_{-0.19}$	[115.9, 131.1, 16.0]
tbabs*(ztbabs*POW + APEC)	1.70	$0.77^{+0.06}_{-0.07}$	$2.1^{+0.2}_{-0.2}$	$1.97^{+0.23}_{-0.21}$	$4.19^{+0.15}_{-0.14}$	[120.3, 131.4, 15.9]
tbabs*(ztbabs*POW + POW)	1.70	$1.13^{+0.22}_{-0.19}$	$3.1^{+0.4}_{-0.4}$		$2.79^{+0.32}_{-0.36}$	[118.3, 131.6, 16.4]

Note: *a*: the photon index for the first power-law component; *b*: the temperature for the thermal component (we assumed an abundance of $0.3 Z_\odot$. The fits are not sensitive to the assumed abundance value.) or the photon index for the second power-law component; *c*: the column density for the intrinsic absorption; *d*: the rest-frame 0.5–2.0 keV luminosity for the thermal component; *e*: the rest-frame 2–10 keV luminosity for the power-law component; *f*: C , C_e , C_σ are the fitted C -statistic, its expected value, and its standard deviation computed based on Kaastra (2017). 68% of the time the acceptable spectral models should have $-1 < \frac{C-C_e}{C_\sigma} < 1$.

Figure 10. The schematic plot of the jet/counterjet geometry. ψ is the half-jet cone angle, θ_1 is the angle between the jet axis and the line-of-sight, and θ_2 is the angle between the cavity and the line-of-sight. P is the previous jet axis, and P' is the current jet axis.

out from the origin of the 3D axes into cones with half-angle ψ . The angle between the jet and the line-of-sight (LOS) is θ_1 . Two symmetric cavities lie on each side with an angle of θ_2 to the LOS. The jet axis is assumed to be aligned with cavity previously (axis marked as P) and realigned to the current axis (marked as P').

Assuming that the jets are intrinsically symmetric, we can place constraints on jet velocity and the angle to the LOS based on the jet to counterjet brightness ratio (e.g. Giovannini et al. 1994):

$$R_{\text{jet}} = (1 + \beta \cos \theta_1)^{(2+\alpha)} (1 - \beta \cos \theta_1)^{-(2+\alpha)}, \quad (6)$$

where R_{jet} is the jet to counterjet brightness ratio, β is the ratio of the jet velocity to the speed of light, θ_1 is the angle to the LOS as shown in Fig. 10, and α is the spectral index. In Fig. 11, we show the constraints on the intrinsic jet velocity and the angle between the jet and the LOS with a spectral index of 0.5 for 3C 88. The radio counterjet to the southwest is not detected. Based on the VLA 4.9 GHz image (Fig. 1 right), we put a lower limit of 20 for R_{jet} , with the bright NE jet patch at ~ 16 k per cent from the nucleus and its counter position at the SW. As shown in Fig. 11, the maximum value for θ_1 is 57° for $R_{\text{jet}} = 20$.

Can the narrow jet produce such a wide cavity as shown in Fig. 2? Here, we list some possibilities. First, the light jets with

Figure 11. The constraints on the jet speed and the angle to the line-of-sight for the jet to counterjet brightness ratio R_{jet} of 20 (the solid line). Two dashed lines show the constraints for R_{jet} of 15 and 25. Only the parameter space above the lines is allowed.

relativistic cosmic rays (CRs) can create fat cavities. The CR-dominated jets are so light that they are quickly decelerated in the ICM due to their low inertia and momentum, then the CR pressure drives the lateral jet expansion to form fat lobes, which are mainly formed by jet backflows and supported by the CR pressure (Guo & Mathews 2011). Second, the jet intermittency can also help. The recent study shows that multiple jets produce a single, large cavity system if the reorientation angle between two successive jets is small and the time interval is sufficiently short so that they can keep inflating the same cavity (Cielo et al. 2018). This is consistent with the fact that the current radio jet is misaligned with the X-ray cavity in 3C 88. Another possibility to create fat bubbles is through ultrafast outflows (UFOs, $v > \text{a few } 10^4 \text{ km s}^{-1}$) (e.g. Sternberg, Pizzolato & Soker 2007; Soker 2016, and references therein). In general-relativistic, radiative magneto-hydrodynamic simulations (GR-RMHD, e.g. Gaspari & Sądowski 2017), the accretion energy is transformed within 100s of gravitational radii into the UFOs, which become more massive at the k per cent scale and decelerate, inflating the bubble and thermalizing the kinetic energy mainly through turbulent mixing.

Previous studies (e.g. Rafferty et al. 2006; Hlavacek-Larrondo et al. 2012) found that the shapes of cavities vary from almost perfectly circular to elongated. Shin, Woo & Mulchaey (2016) found that the shapes of non-circular cavities follow a bimodal distribution, in that cavities are elongated either along the jet direction or perpendicular to the jet direction. In a recent study, Guo

(2015) showed that the shapes of young cavities are closely related to various jet properties, e.g. jet density, velocity, energy density, and duration. In general, very light internally subsonic jets produce bottom-wide cavities elongated along the perpendicular direction to the jet, while the heavier internally supersonic jets produce top-wide cavities elongated along the jet direction. The long-term evolution of cavity depends significantly on the viscosity of the hot ICM, and on the amount of entrainment along the jet/outflow path from the per cent to 10 k per cent scale. From Fig. 2, the eastern cavity in 3C 88 appears more elongated in the direction perpendicular to the jet (although projection effects may make the cavities appear more circular). However, the cavity is located away from the jet axis and the angle between the jet axis and the radial direction from the AGN centre to the cavity centre is $\sim 50^\circ$. This is suggested to be due to jet reorientation (see Section 6.3), which makes it hard to infer the jet properties directly from the cavity shape.

The region of the eastern cavity seen in Fig. 2 can be approximated as a circle with a radius of 23 k per cent, projected at a distance of 28 k per cent from the AGN. Assuming that the cavity is a sphere in 3D space, we can make a rough estimate of the angle between the LOS and the cavity. For an angle θ_2 between the LOS and cavity, the real distance of the cavity to the centre is therefore $28 \text{ k per cent} / \sin(\theta_2)$. We first simulated the 3D gas distribution with its temperature and density following the deprojected profiles. The cavities are assumed to be spheres devoid of the gas. Then, we projected the simulated data on the sky plane with a different angle θ_2 . We used two circular regions with the same size, with one free of the cavity and the other overlaid with the projected cavity, and calculated their surface brightness ratio. As expected, we found that the surface brightness ratio increases with the angle θ_2 , e.g. the surface brightness ratio increases by about ~ 50 per cent as θ_2 ranges from 30° to 90° . We can place constraints on the angle θ_2 based on the surface brightness ratio, e.g. a threshold of 1.1 giving a lower limit on $\theta_2 = 32^\circ$. Notice that in real observations, the surface brightness contrast between the ambient region and the cavity region is more striking due to the bright surrounding rims or enhancements, with a much larger surface brightness ratio than in our simulations.

6.3 Jet reorientation

With deep X-ray observations, systems with multiple pairs of X-ray bubbles (or cavities) at different positional angles have been observed (e.g. Bogdán et al. 2014; Randall et al. 2015). One scenario for the formation of multiple pairs of X-ray bubbles is jet reorientation model, in which the jet axis was initially along the direction of one pair of bubbles, and along a different direction later (the jet activity may switch off before changing directions). The jet reorientation models include the conical precession, which reproduces well the observed radio structures in some radio sources (e.g. Gower et al. 1982; Cox, Gull & Scheuer 1991; Dunn, Fabian & Sanders 2006), and other realigning mechanisms, e.g. due to the binary black hole merger or the instabilities of accretion disc (e.g. Dennett-Thorpe et al. 2002; Gopal-Krishna et al. 2012). 3C 88 provides a great case to study jet reorientation and two methods are discussed in this section.

6.3.1 Method I: X-ray cavity + radio jet

Although only a single pair of X-ray cavities was found in 3C 88 (in fact only the eastern cavity is pronounced), the eastern cavity

is misaligned with the radio lobe. The position angle of the cavity, relative to the central AGN, also differs from that of the radio jet. The radio jet of 3C 88 was assumed to be previously lying in the direction from the nucleus to the cavity centre, and currently aligned with the observed radio jet. If both the X-ray cavity and the radio jet are in the plane of sky (or $\theta_1 = \theta_2 = 90^\circ$), the angle between the eastern cavity and the current radio jet is about 50° . If we assume this is the change of the angle between the previous and current jet axis during the span of eastern bubble rising, the jet reorientation rate is $\sim 8^\circ$ per 10^7 yr, which is between the precession rates found in Abell 3581 (Canning et al. 2013) and NGC 1275 (Dunn et al. 2006). However, since the inclination angles (angle between the jet and the LOS or between the cavity and LOS) can be different from 90° , we need to estimate the projection effect on the estimated rate. In Fig. 10, if we view the system along the polar axis (z -axis), the polar angles for jet and cavity are θ_1 and θ_2 , respectively, and the separation between them in azimuth is $\delta A \sim 50^\circ$. Therefore, the real angular separation $\delta\phi$ between them in 3D is given as:

$$\cos(\delta\phi) = \cos(\theta_1)\cos(\theta_2) + \sin(\theta_1)\sin(\theta_2)\cos(\delta A), \quad (7)$$

which can be expressed as:

$$\sin^2(\delta\phi/2) = \sin^2(\delta\theta/2) + \sin(\theta_1)\sin(\theta_2)\sin^2(\delta A/2), \quad (8)$$

where $\delta\theta = \theta_2 - \theta_1$. When $\delta\theta$ is small compared to δA (e.g. $\theta_1 \sim \theta_2$), we have $\sin(\delta\phi/2) \simeq \sin(\theta)\sin(\delta A/2)$. Assuming the same inclination angle of 40° for jet and cavity, the real angle between the previous and current jet axis is 63 per cent of the separation angle between the cavity and radio jet on the plane of sky. Since the actual distance from the AGN to the centre of cavity is now 56 per cent longer, the actual jet reorientation rate is only 40 per cent of the estimated value without accounting for the projection effect. Generally with the constraints derived for θ_1 and θ_2 in the last section, we estimate $\delta\phi\sin(\theta_2)/50$, which measures the correction factor on the jet reorientation rate from the projection. This ratio ranges from ~ 0.25 to 1.65, which can be applied on the baseline reorientation rate of $\sim 8^\circ$ per 10^7 yr estimated above.

6.3.2 Method II: radio jet curvature

In Fig. 1 the northeastern radio jet starts to bend at a projected distance of ~ 55 k per cent with a deflection angle of $\sim 15^\circ$. Two hotspots at the northeast and at least one hotspot at the southwest are detected. This type of radio morphology, also observed in other systems, (e.g. 3C 123, Cygnus A) can be explained by jet reorientation (e.g. Cox et al. 1991; Steenbrugge & Blundell 2008; Pyrzas, Steenbrugge & Blundell 2015). In this scenario, the jet initially strikes the wall of the cocoon producing the jet curvature as it feeds the primary hotspot. The jet then interacts with the cocoon at a very sharp angle and generates a new primary. The old primary is then observed as a secondary hotspot. In this picture, the radio jet of 3C 88 was previously lying in the direction from the nucleus to the secondary hotspot, and it is currently aligned with the observed radio jet.

Based on the eastern bent jet we can make a rough estimation of the time-scale. As seen in the radio image, the narrow radio jet maintains its width and does not widen even at a large radius (~ 55 kpc). We do not expect a significant jet deceleration due to the low ICM density and expected low stellar mass loss rates. Therefore, the jet remains relativistic until it is close to the hotspot. Assuming a constant speed of $\sim 0.5c$ (see Fig. 11) for jet travelling from the centre to 55 k per cent, and a lower speed from the bent point to

the hotspots, we can estimate the traveltime, which depends mostly on the latter speed. Assuming a jet speed of $0.01c$ or $0.05c$ (e.g. Scheuer 1995; Carilli & Barthel 1996), we obtained a traveltime of 4.3 Myr or 1.2 Myr, corresponding to a jet reorientation rate of 4° or 15° per Myr.

We notice that the estimated jet reorientation rates from two methods differ a lot, since they are probing different epochs, e.g. method I probes the average rate whereas method II probes the instantaneous one. The origin of jet reorientation is likely tied to the accretion history of the central SMBH. An intriguing scenario is related to the transition between FR I and FR II radio sources (e.g. Garofalo, Evans & Sambruna 2010). On the other hand, in the framework of the CCA, warm/cold clouds and filaments collide inelastically, which can boost the accretion rate and suddenly alter the SMBH spin and thus the jet orientation (e.g. Gaspari et al. 2012). In fact, only CCA can likely drive such a large variability able to alter rapidly the BH spin: this is because of the random orientation of the raining clouds (see also King & Pringle 2006; King, Pringle & Hofmann 2008). Hot accretion is too smooth to rapidly change the spin (and is also spherically symmetric); disc-driven jets have quite fixed orientation perpendicular to the disc and it takes very long time to alter the disc morphology and fully change its direction as in a merger (rather than accreting different already inclined clouds as in CCA).

6.4 Cavity power in radio loud groups

X-ray cavities provide a direct estimate of the power output of the central AGN, from the cavity enthalpy (the minimum energy required to form a cavity) and the time-scale over which the cavity has formed. The mechanical power of the cavities is found to be correlated with the AGN radio luminosity, e.g. $P_{\text{radio}} - P_{\text{cav}}$ relation (Birzan et al. 2008; Cavagnolo et al. 2010; O’Sullivan et al. 2011). In general, a large cavity power is expected for luminous radio galaxies. However, as shown in Fig. 12, the cavity power found in radio-loud galaxy groups (e.g. $P_{1.4\text{GHz}} \sim 1-10 \times 10^{24} \text{ W Hz}^{-1}$, and $kT < 1.3 \text{ keV}$) in the previously studied samples (e.g. Birzan et al. 2008; Cavagnolo et al. 2010; O’Sullivan et al. 2011) is less than $10^{43} \text{ erg s}^{-1}$. For 3C 88 with $L_{1.4\text{GHz}} \sim 10^{25} \text{ W Hz}^{-1}$, we measured the total mechanical power of cavities of $\sim 2 \times 10^{43} \text{ erg s}^{-1}$, which is at least two or three times higher than what is found in other radio luminous groups, except for PKS B2152-699 (Worrall et al. 2012). The cavity power of PKS B2152-699 is $\sim 3 \times 10^{43} \text{ erg s}^{-1}$ using the dynamical time, or $\sim 1 \times 10^{43} \text{ erg s}^{-1}$ using the buoyant rise time as for 3C 88. In either case, the cavity power of the two radio luminous galaxy groups, 3C 88 and PKS B2152-699, are comparable. X-ray cavities in PKS B2152-699 are over two times smaller than 3C 88’s in radius as 3C 88’s X-ray cavity is the largest known in galaxy groups.

If the cavity centre does not lie in the plane of sky, we need to estimate the projection effect on the estimated cavity power. Since the actual distance from the AGN to the centre of cavity and the size of cavity would increase, the pressure at the centre of cavity would be lower, while the volume of cavity would increase, hence affecting the estimation of total enthalpy. In addition, the estimated age of the cavity will increase. Assuming a low limit of $\sim 30^\circ$ for inclination angle θ_2 , we obtained a new cavity power of $5 \times 10^{43} \text{ erg s}^{-1}$.

Despite the uncertainties in estimating the cavity powers, e.g. the estimation of the cavity volume, a natural question is why the measured cavity powers in groups are generally low, even for those radio luminous systems. Sun et al. (2009) showed that groups

Figure 12. Cavity power versus radio power at 1.4 GHz for galaxy groups and clusters (red: $kT < 1.3 \text{ keV}$, green: $1.3 < kT < 3.0 \text{ keV}$, blue: $kT > 3.0 \text{ keV}$) from Birzan et al. (2008), Cavagnolo et al. (2010), and O’Sullivan et al. (2011). The dotted, dashed, and solid lines are the best-fitting relations from their work, respectively. For some repetitive systems, we used the values from O’Sullivan et al. (2011). The differences in cavity power are generally within a factor of 2 for all repetitive systems, except for NGC 6269, whose cavity power is about seven times smaller in Cavagnolo et al. (2010). New studies on NGC 5813 found three pairs of X-ray cavities (Randall et al. 2011, 2015). However, the total cavity power is consistent with the value used in the plot. We included four additional systems, PKS B2152-699 (Worrall et al. 2012, the cavity power is estimated using the buoyant rise time as for other systems in the plot), 3C 310 (Kraft et al. 2012), 3C 444 (Croston et al. 2011) and Abell 3581 (Canning et al. 2013) in the plot. The large solid red circle denotes the location of 3C 88, whose cavity power is among the largest in galaxy groups (please see Section 6.4 for discussion). The empty red circle represents 3C 88 assuming there are a pair of cavities with the same power.

with a luminous cool core ($L_{0.5-2\text{keV}} \geq 10^{41.7} \text{ erg s}^{-1}$) do not host luminous radio AGN ($L_{1.4\text{GHz}} > 10^{24} \text{ W Hz}^{-1}$). The groups with luminous radio AGN only have small coronae or small cool cores, so the extended X-ray atmosphere that encloses the radio lobes is faint. As both cavities and shocks are easier to detect in high-density regions, these features become subtle in groups, especially for groups hosting strong radio AGN. The *Chandra* constraints on the cavity power may only include the power deposited in cool cores and the estimated power should be taken, generally, as a lower limit.

6.5 Shock energy

During an AGN outburst, the radio jets inflate the cavities in the ICM and drive shocks. The energy released by the AGN is partitioned between the total internal energy of the cavities and the work done by them as they expand. The latter part drives the shock. Following Randall et al. (2011), we estimated the shock energy from the pressure increase across the shock front. Assuming a total energy E is added to a gas of volume V , the pressure increase is roughly $\Delta P \sim E/V$. For a shock with a known Mach number M , the ratio of the post- and pre-shock pressure $(P + \Delta P)/P$, the total shock energy is therefore given as:

$$E \approx P_1 V \left(\frac{P_2}{P_1} - 1 \right), \quad (9)$$

where P_1 and P_2 are the pre- and post-shock pressure, respectively, and their ratio depends on M . The estimated shock energy from equation (9) is expected to modestly underestimate the total shock

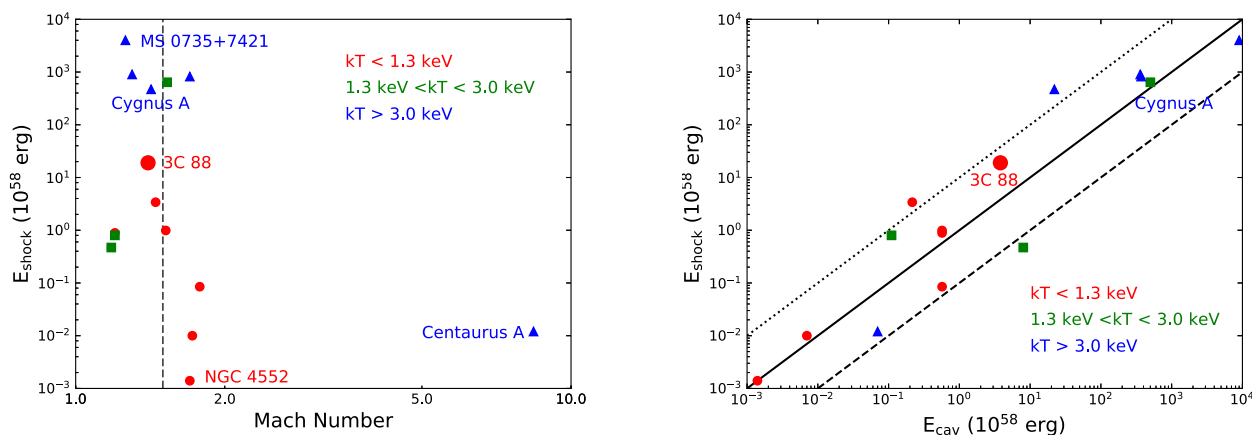

Figure 13. Shock energy versus Mach number (left) and shock energy versus cavity enthalpy (right) for galaxy groups and clusters (red circle: $kT < 1.3$ keV, green square: $1.3 < kT < 3.0$ keV, and blue triangle: $kT > 3.0$ keV) from the literature (see details in Section 6.5). The dashed line on the left panel represents Mach number = 1.5. The dotted, solid, and dashed lines on the right panel represent $E_{\text{shock}}/E_{\text{cav}} = 10, 1, \text{ and } 0.1$, respectively. The large red circle denotes 3C 88.

energy since the Mach number is expected to be somewhat higher at earlier times. The shock energy estimated using equation (9) is found to agree reasonably well within a factor of a few with the shock energy calculated from the hydrodynamical central point explosion model based on the surface brightness (e.g. Randall et al. 2011).

Using an ellipsoidal geometry for the volume contained within the shock front with semi-major and semi-minor axes of 85.7 kpc and 68.0 kpc (as shown in Fig. 3) and the azimuthally averaged pressure profile from Fig. 4, we estimated a shock energy of 1.9×10^{59} erg. To make a comparison, we checked through the literature for the systems with available Mach numbers, shock energies, and cavity enthalpies, e.g. Hydra A (Nulsen et al. 2005b; Wise et al. 2007), MS 0735 + 7421 (McNamara et al. 2005; Vantghem et al. 2014), Centaurus A (Croston et al. 2009), Cygnus A (Birzan et al. 2004; Snios et al. 2018), 3C 444 (Croston et al. 2011), M87 (Churazov et al. 2001; Forman et al. 2005, 2007, 2017), Abell 2052 (Blanton et al. 2009), 3C 310 (Kraft et al. 2012), NGC 4552 (Machacek et al. 2006), NGC 4636 (Baldi et al. 2009), HCG 62 (Gitti et al. 2010), NGC 5813 (Randall et al. 2011, 2015, notice NGC 5813 shows three distinct AGN outbursts.). In Fig. 13 (left), we show the Mach number versus shock energy. The shock energies span almost 7 orders of magnitude, with a shock energy of 4×10^{61} erg for MS 0735 + 7421 and $\sim 10^{55}$ erg for NGC 4552, while the Mach numbers range from 1–2, except for Centaurus A. The shock energy in 3C 88 is the largest among the low temperature groups. Although it has a similar Mach number and shock radius to 3C 88, Cygnus A, by far the nearest powerful radio galaxy, has a shock energy about 20 times larger than that of 3C 88. In Fig. 13 (right), we show the cavity enthalpy versus the shock energy. Either shock energy or cavity enthalpy can be the most significant form of mechanical energy produced by AGN outbursts, with their ratio generally varying within 0.1–10.0. In 3C 88, the ratio of the shock energy to the total cavity enthalpy is about 5.0.

6.6 Bright rims and arms

The abundance map shown in Fig. 6 suggests enhanced abundance along the eastern bright rim and arm. Several interesting regions with enhanced X-ray surface brightness are defined in Fig. 14. There are two possible explanations for the presence of the enhanced

Figure 14. 0.7–2.0 keV *Chandra* image of 3C 88 to show the regions and the measured abundances that are discussed in Section 6.6.

X-ray features. One explanation is the rims could be shells of gas shocked during the supersonic expansion of the bubbles (e.g. Fabian et al. 2003; Forman et al. 2007). Alternatively, if the bubbles are rising in a subsonic phase of expansion, the dense and cool gas from the cluster centre could be lifted by the rising bubbles (as in, e.g. M87: Churazov et al. 2001, Simionescu et al. 2008, Hydra A: Kirkpatrick et al. 2009, Gitti et al. 2011; Werner et al. 2010; NGC 4472: Gendron-Marsolais et al. 2017; NGC 1399: Su et al. 2017).

The spectra for each region, from all three observations, were then fitted simultaneously with the model TBABS*APEC with fixed absorbing column density. We found temperatures of $1.36_{-0.03}^{+0.10}$ and $1.33_{-0.07}^{+0.21}$ keV for the eastern and western rims, respectively, which are higher than those from adjacent regions. The metallicity in the western rim is $0.16_{-0.06}^{+0.07}$ solar, while it is $0.67_{-0.17}^{+0.24}$ in the eastern rim. The metallicity enhancement surrounding the eastern cavity implies that the hot, metal rich gas was lifted by the rising X-ray bubble from the group centre (e.g. Kirkpatrick & McNamara 2015). The relation between the radius of the eastern rim (taken as the ‘iron radius’, the

maximum radius at which a significant enhancement in metallicity has been detected) and the cavity enthalpy is generally consistent with that found in a previous study (Kirkpatrick & McNamara 2015). The pronounced cavity and high abundance in the eastern rim show that the gas remains unmixed with the nearby material. On the other hand, the less significant western cavity and the relatively low abundance in the western rim suggest the gas has been well-mixed with the surrounding gas.

In addition to the bright rims, we also observed an enhanced spiral-arm-like feature in the south in Fig. 14. We performed a similar spectral analysis for the arm as for the rims and found the projected temperature of 1.03 ± 0.02 keV and metallicity of $0.65^{+0.26}_{-0.18}$. The arm is connected with the eastern rim. Its relatively high abundance suggests it also has not well mixed with the surrounding material. It should be noted that the measured abundances in this section are projected values and the actual abundance enhancement with the eastern rim and arm should be stronger.

7 SUMMARY

We have analysed 105 ks *Chandra* observation of the radio-loud galaxy group 3C 88 and presented the properties of the hot gas related to AGN feedback. Our results are summarized as follows:

(i) The eastern X-ray cavity is very prominent with a diameter of ~ 50 kpc and is centered ~ 28 kpc away from the nucleus. The enthalpy of the eastern cavity is 3.8×10^{58} erg. Both the cavity size and enthalpy are the largest known in groups. We estimate that the cavity age is about 60 Myr. The power of the eastern cavity is $\sim 2.0 \times 10^{43}$ erg s $^{-1}$, among the largest known in galaxy groups.

(ii) From the surface brightness discontinuity, we infer a Mach ~ 1.4 shock front. The estimated shock energy is 1.9×10^{59} erg, which is about five times larger than the cavity enthalpy.

(iii) The rest-frame 2 - 10 keV luminosity of the central AGN is $\sim 4 \times 10^{41}$ erg s $^{-1}$. The X-ray spectrum shows a moderate intrinsic absorption with a column density of $\sim 2 \times 10^{22}$ cm $^{-2}$.

(iv) The eastern cavity is not well matched spatially with the radio lobe and is not aligned with the jet axis, which suggests jet reorientation. We used different methods to estimate the average and instantaneous jet reorientation rates.

(v) The rim and arm features surrounding the X-ray cavities with enhanced X-ray surface brightness show metallicity enhancement, suggesting the gas was lifted by the rising X-ray bubbles from the group center.

(vi) Warm gas is detected in the central region, extending to at least ~ 5 k per cent, and from a compact knot about 16 k per cent northeast of the nucleus with potentially more diffuse features. The multiphase gas state, low minimum condensation ratios, rapid jet precession, and large mechanical power are consistent with the scenario of CCA boosting mechanical AGN feedback.

There is no reason to believe 3C 88 is special as strong radio AGN exist in many low-mass haloes and jets can reorient. This detailed study of 3C 88 also suggests that galaxy groups with powerful radio AGN can indeed have large cavity power. As groups have shallower potential, smaller core size and less hot gas than clusters (e.g. Sun 2012), X-ray cavities in groups can easily extend beyond the small, dense core. Deep *Chandra* observations are then required to reveal the subtle features in groups. On the other hand, these heating events also leave imprints on the X-ray properties of groups over time (e.g. McNamara & Nulsen 2012; Sun 2012).

ACKNOWLEDGEMENTS

Support for this work was provided by the National Aeronautics and Space Administration through *Chandra* Award Number GO4-15115X, GO5-16115X, GO5-16146X, GO7-18121X, and AR7-18016X issued by the *Chandra* X-ray Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of the National Aeronautics Space Administration under contract NAS8-03060. APPENDIX:

Fig. A1 shows the surface brightness profile of galaxy group 3C 88 in the 0.7–2.0 keV band. The surface brightness is approximately constant beyond $\sim 8'$ from the centre of 3C 88.

Figure A1. The surface brightness profile of galaxy group 3C 88 in the 0.7–2.0 keV band. The red dashed line represents the surface brightness of the local X-ray background.
