The association of Theory of Mind with Language and Visuospatial Abilities in Amyotrophic Lateral Sclerosis: A Pilot Study

Objective: Dysfunction of social cognition is well-recognized as one of amyotrophic lateral sclerosis (ALS) cognitive impairments. Previous studies have mostly associated social cognition subcomponents, including Theory of Mind (ToM), with executive dysfunction using highly demanding tasks. In the present study, we investigate dysfunction of affective ToM in a sample of ALS patients without dementia and evaluate any possible associations both with executive and non-executive dysfunction.

Method: We included 42 ALS patients and 30 healthy controls (HC) and administered the Edinburgh Cognitive and Behavioural Amyotrophic Lateral Sclerosis Screen (ECAS). Affective ToM was examined based on the ECAS judgment of preference task; total score and type of errors (“favourite”, “unclassified”) were recorded for all participants.

Results: A significant proportion of ALS patients (31%) were impaired on ToM task, scoring significantly lower compared to HC. Impairments in ToM task were more frequent (45%) in patients with cognitive impairment compared to those with intact cognition (15%). ALS patients showed significantly more errors on ToM task compared to HC. A significant association was found between ToM score and ECAS language and visuospatial abilities but not fluency, executive or memory function.

Conclusion: Dysfunction of affective ToM appears prevalent in ALS patients without dementia, and associates with language and visuospatial abilities. These associations align with motor and extra-motor symptoms due to the degeneration across corresponding networks. Impaired ToM should be considered in clinical settings, since it might contribute to patients’ social life, as well as the burden of their caregivers and relatives.

Keywords: Amyotrophic Lateral Sclerosis; Social Cognition; Theory of Mind; Language; Visuospatial

Introduction

Cognitive and behavioural deficits are common in Amyotrophic Lateral Sclerosis (ALS), which are mostly related to frontotemporal dysfunction [1-2]. Although only 5-15% of patients meet the criteria for frontotemporal dementia (FTD) [3], approximately 50% or even more show cognitive impairments pertaining to executive functions and language, as well as behavioural changes [4,5]. The emerging cognitive, behavioural, and neuroimaging evidence have led to the proposal of the spectrum of ALS-FTD changes [4,5]. Recently, there has been an interest regarding potential impairments in social cognition in patients with ALS [6] and it has been shown that the social cognition is an inseparable part of the ALS-related cognitive profile [1].

A central part of the social cognition is the Theory of Mind (ToM). ToM refers to the understanding of emotions, desires and beliefs of others and the prevision of their future behaviour [7]. The cognitive ToM is relevant to the beliefs, thoughts and intentions of others [8-10]. The affective ToM is relevant to understanding the emotions of others [8-10]. Although ToM and social cognition deficits have been well-reported in both demented and non-demented patients with ALS [6,11], it remains poorly defined how these deficits are related to other cognitive processes and to patients' clinical characteristics.

Specifically, there are conflicting findings whether the social cognition may be attributed to executive dysfunction [12-13]. Several studies in non-demented ALS patients report significant correlation between executive functions and social cognition [13-15]. However, these studies used tasks with significant executive load such as the three subtests of the Happé's cartoon task, Written Scenarios tasks and the Reading the Mind in the Eyes task (RME) [13-15]. On the other hand, this association has also been

reported when ToM was also examined using tasks with lower executive load, such as the Judgement of Preference task the False Belief task [16-18]. However, some studies found that deficits in ToM are not related to executive functions, while some of them found a significant correlation with long-term memory [19-20]. Also, studies reported a higher frequency of impaired social cognition in patients with a bulbar-onset [14,18,20]. The relationship of social cognition with executive functions and symptoms onset has not become clear due to methodological issues pertaining to the neuropsychological assessment.

The aim of the present study is to examine affective ToM in a sample of non-demented ALS patients and evaluate any possible associations with other cognitive functions and patients' clinical profile.

Methods

Participants

Forty-two non-demented ALS patients were included in the present study. All patients underwent clinical assessment, including full neurological and electrophysiological examination, and diagnosed with sporadic ALS according to the modified El Escorial diagnostic criteria for ALS [21]. For all patients, we calculated disease progression rate as $(48 - \text{ALSFRS-R})$ disease duration in months. Disease duration was calculated from first symptoms onset to scan date in months. Patients were subsequently referred for neuropsychological assessment as part of their routine clinical care. Also, 30 unrelated healthy volunteer participants comprised the healthy control (HC) group with similar demographic characteristics compared to ALS patients.

Inclusion criteria for the present study were the following: (a) absence of a history of other neurologic conditions affecting cognition (other than ALS for patients),

(b) no serious psychiatric disease (e.g., major depression, schizophrenia), depression in ALS patients was assessed by the ALS-Depression Inventory (ADI-12) [22,23] (c) no family history of ALS, (d) absence of psychoactive drugs or other medication that could affect mental status, and (e) absence of dementia (Mini Mental State Examination score >24), preserved activities of daily living, preserved social and personal conduct and insight based on patients' and caregivers' self-reports; preserved discourse speech based on WAIS Vocabulary score and narrative speech. Patients' disability level was evaluated using the Revised Amyotrophic Lateral Sclerosis Functional Rating Scale (ALSFRS-R) [24]. All participants provided informed consent for the study, which was approved by the ethical committee of our institution.

Material

Theory of Mind (ToM)

The affective component of ToM was assessed using the Judgment of Preference task [15,25], as it is included in the ECAS scale. This task assesses the ability to make a preference judgement based on eye gaze. It consists of a pre-experimental and an experimental condition; where there are six pictures, which one displays four objects of the same semantic category (e.g., animals, fruits, and furniture) positioned in the four corners. In the pre-experimental condition, the participants circle their favourite object from each picture. In the experimental condition, the participants circle the object which a face likes best. The correct answer is scored with 2 points. The errors are categorized as "favourite" (in which participants chose their personal favourite object instead; i.e., an egocentric response) and are scored with 0 points; or as "unclassified" which are scored with 1 point. For the purpose of the present study, the following scores were used: total score; number of "favourite" errors; number of "unclassified" errors.

Other Cognitive Functions

All patients were examined using the Edinburgh Cognitive and Behavioural Amyotrophic Lateral Sclerosis Screen (ECAS) [26], adapted and validated for the Greek speaking population [27]. The Greek ECAS is able to identify cognitive and behavioural changes relevant to ALS [27], and it does not produce significant ceiling effects [28]. It assesses a range of functions typically affected in ALS (ALS-Specific: Fluency, Executive Functions, Language Functions) and not typically affected in ALS but are common in disorders of older adults (ALS Non-specific: Memory, Visuospatial Functions). An ECAS total score, as well as subscores for ALS-specific and ALS Non-specific domains can be extracted. For the purpose of the present study, an ECAS Executive Functions score was also calculated without including the social cognition test. The ECAS also includes a separate semi-structured behavioural interview which yields a separate behavioural score and is undertaken with an informant/ caregiver separately from the patient and is based on the five key behavioural domains for diagnosing FTD using the most recent diagnostic criteria [12].

Statistical analysis

Assumptions for normality were initially evaluated and parametric statistics were then applied. Between-group differences on demographic characteristics were examined using t-test for independent samples (age, education) and chi-square (gender distribution). Between-group differences on ToM and ECAS scores were assessed using t-test for independent samples. Mixed factorial analysis of variance (ANOVA) was used to evaluate main effect and interaction regarding type of errors and diagnosis in two models. In the first model, diagnosis (i.e. ALS; HC) was used as between-subject factor and type of errors (i.e. “favourite”; “unclassified”) was used as within-subject factor.

For the second model, ALS patients were categorized as impaired and non-impaired based on the ECAS total score and a cut-off score of 2SD using available normative data [27]. Thus, three groups (i.e. impaired ALS; non-impaired ALS; HC) were considered in the diagnosis which was used as the between-subject factor while type of errors was the within-subject factor. Post-hoc Bonferroni comparisons between impaired ALS, non-impaired ALS and HC were applied. Correlation analyses between ToM total score and ECAS subscores (ECAS Language; ECAS Verbal Fluency; ECAS Executive Functions (without ECAS social cognition subtest); ECAS Memory; ECAS Visuospatial Functions), as well as clinical variables (disease duration, ALSFRS-R, progression rate) was conducted using Pearson's *r*. Comparisons on ToM total score between peripheral- and spinal-onset ALS patients was conducted using t-test for independent samples. The level of statistical threshold was set at $p < 0.05$ and all analyses were conducted using IBM SPSS 20.

Results

Table 1 displays the descriptive statistics for ALS and HC groups.

Table 1. Descriptive Statistics of ALS patients and Healthy Controls

	ALS	HC	p-value
Age (yrs)	60.57 (9.90)	60.67 (7.36)	0.965
Education (yrs)	10.55 (3.68)	11.97 (3.42)	0.102
Gender (M/F)	24/18	13/17	0.255
ALSFRS-R	39.83 (5.377)	-	-
Disease duration (m)	22.11 (32.36)	-	-
Progression rate	0.57 (0.82)	-	-
Cognition (P / Imp)	21 / 21	30 / 0	< 0.001
ECAS total score	89.55 (20.55)	106.53 (9.77)	< 0.001
ECAS ALS-specific score	64.98 (16.97)	78.23 (7.68)	< 0.001
ECAS ALS-nonspecific score	24.57 (5.55)	28.30 (3.23)	0.002
ECAS Behavioural score	1.21 (1.28)	0.0 (0.0)	< 0.001

Figure 2. "Unclassified" Errors in ALS and Healthy Controls.

Significant differences in social cognition total score ($F = 8.600$; $p < 0.001$; $\eta^2 = 0.200$) and number of total errors ($F = 8.086$; $p < 0.001$; $\eta^2 = 0.190$) were revealed. Impaired ALS patients performed significantly worse compared to non-impaired ALS patients ($p = 0.018$) and HC ($p < 0.001$; see Figure 3). No other significant difference between the groups was found.

Figure 3. Theory of Mind Score per Diagnosis

Note. ALS - NCI = ALS patients with intact cognition; ALS - CI = ALS patients with cognitive impairments; HC = healthy controls

Significant main effects of diagnosis (HC; impaired ALS; non-impaired ALS) ($p < 0.001$; $\eta^2 = 0.190$) and type of errors ($p < 0.001$; $\eta^2 = 0.172$) were detected, while the interaction effect was non-significant ($p = 0.954$; $\eta^2 = 0.001$). Post-hoc comparisons revealed that ALS patients with cognitive impairments made significantly more “unclassified” ($p = 0.027$; see Figure 4) and “favourite” ($p = 0.008$; see Figure 5) errors compared to HC, while the rest of differences were not significant.

Figure 4. “Unclassified” Errors per Diagnosis

Note. ALS - NCI = ALS patients with intact cognition; ALS - CI = ALS patients with cognitive impairments; HC = healthy controls

Figure 5. “Favourite” Errors per Diagnosis

Note. ALS - NCI = ALS patients with intact cognition; ALS - CI = ALS patients with cognitive impairments; HC = healthy controls

Correlations between ToM and ALS Clinical profile

ECAS Language ($r = 0.047$; $p = 0.003$) and ECAS Visuospatial Functions ($r = 0.455$; $p = 0.002$) were significantly correlated with the social cognition total score. However, no association were found between social cognition total score and ECAS Executive Functions ($r = 0.221$; $p = 0.159$), ECAS Verbal Fluency ($r = 0.175$; $p = 0.273$) or ECAS memory ($r = 0.184$; $p = 0.249$).

Social cognition was significantly associated with the performance on language tasks. The ToM score was found to be substantially associated with ECAS Naming ($r = 0.435$; $p = 0.002$), ECAS Comprehension ($r = 0.343$; $p = 0.013$), and ECAS Spelling ($r = 0.300$; $p = 0.028$). Also, a significant correlation was detected between the ToM score and the ECAS Sentence Completion (i.e., executive function task; $r = 0.343$; $p = 0.013$). Finally, the ToM score was correlated with the ECAS Cubes (i.e., visuospatial task; $r = 0.413$; $p = 0.003$).

The “favourite” errors showed significant negative correlation with the ECAS Naming ($r = -0.437$; $p = 0.002$), ECAS Comprehension ($r = -0.446$; $p = 0.002$), ECAS Sentence Completion (i.e., executive function task; $r = -0.287$; $p = 0.034$), and ECAS Cubes (i.e., visuospatial task; $r = -0.288$; $p = 0.032$). In contrast, the “unclassified” errors were substantially negatively associated only with the ECAS Spelling ($r = -0.398$; $p = 0.005$) and the ECAS Cubes ($r = -0.340$; $p = 0.014$).

Finally, the ToM score showed substantial negative correlations with the behavioural disinhibition item (i.e., loss of manners; $r = -0.384$; $p = 0.031$) and the ECAS Psychosis score ($r = -0.384$; $p = 0.031$). Notably, the “favourite” errors showed robust positive correlations with behavioural disinhibition – loss of manners ($r = 0.456$; $p = 0.002$) and the ECAS Psychosis score ($r = 0.456$; $p = 0.002$), while the

“unclassified” errors were not correlated with any behavioural change. Also, there was no significant correlation between social cognition total score and patients’ clinical parameters (disease duration, ALSFRS-R, progression rate). We did not find any significant difference between peripheral and bulbar onset subgroups.

Discussion

The present study provided further evidence regarding impaired affective ToM in a well-characterized group of non-demented ALS patients, revealing that approximately one out of three non-demented patients shows impaired affective ToM, as determined by eye gaze in Judgement of Preference task of the ECAS scale. In our group, this impaired performance was unrelated to patients’ clinical status and was not driven by any executive dysfunction; yet, it was more evident in patients with impaired cognition in general and was predominantly associated with patients’ language and visuospatial abilities.

ToM and type of errors in ALS

31% of patients had impaired performance on affective ToM and ALS patients performed worse than HC. Our findings are in line with the amassed findings of recent meta-analysis and review papers [1, 6, 11], which further signify the importance of measuring social cognition in ALS [5]. A significant proportion of cognitively impaired ALS patients were also impaired in ToM (45% vs. 15% in cognitively non-impaired ALS patients). These findings postulate that impairments in ToM are prevalent in ALS patients with cognitive impairments.

ALS patients produced significantly more “unclassified” than “favourite” errors (a pattern which was also observed in HC) and made significantly more errors of both

types compared to HC. This may suggest that our non-demented ALS patients did not have significant difficulties in inhibiting egocentric processing, a deficit which is prominent in patients with the behavioural variant of FTD (bvFTD). Notably, all patients complied with tasks instructions in pre-experimental task condition, which indicates that failures in the experimental condition are unlikely to be due to comprehension impairment.

Previously, non-demented ALS patients were found to make equal number of “favourite” and “unclassified” errors [18]. These findings may underlie difficulties in inhibiting egocentric processes and shifting attention, which might be associated with the executive component of social cognition [29]. FTD patients produce a higher number of “favourite” errors than patients with Huntington’s disease, due to their impaired inhibition of egocentric impulses [15].

In our study, the ALS patients with cognitive impairments produced significantly more “favourite” errors than the healthy controls, while the ALS patients with intact cognition did not differ significantly from healthy controls. However, similar significant differences were also found in the production of “unclassified” errors. Nevertheless, the differences appear greater regarding the “favourite” errors, rather than the “unclassified” errors. Furthermore, while significant negative correlations were identified between ToM score and ECAS Psychosis score and Behavioural disinhibition item (i.e., loss of manners), only the “favourite” errors were found to be substantially correlated with them. Of note, these behavioural changes are prevalent in ALS-FTD [5], hence, the quantity of “favourite” errors may be an early indicator of FTD. Nevertheless, considering that the type of errors has not been thoroughly studied in ALS specifically without dementia, further investigation is definitely needed in larger sample sizes with additional neuroimaging techniques to

identify the anatomical substrate of each type of errors.

ToM and clinical features in ALS

Previous studies identified a significant correlation between symptoms' onset and social cognition performance; patients with bulbar onset scored worse than patients with spinal onset as determined by the Reading in the Eye Task [20,30]. However, we did not find any association between patients' clinical status and their performance in ToM. This disagreement may be a result due to the substantial differences between the two tasks. In our study, the Judgment of Preference task examines the egocentric biases in recognising the preference of others. On the other hand, the Reading in the Eye Task pertains to reading facial features for recognising diverse emotional states of the others. This discrepancy hence may indicate that the recognition of emotional states may be related with the symptoms' onset, while the egocentric biases are not.

ToM and other cognitive functions in ALS

Recent studies indicate an association between social cognition and executive functions (e.g., [13,14]) and verbal fluency [12,19] in non-demented ALS patients. However, other studies have failed to find such an association (e.g., [20]). In our study, performance on a ToM task with low executive demands was predominantly associated with language and visuospatial abilities, which may suggest the independence between executive abilities and ToM performance. Affective ToM involves medial prefrontal networks [7,16] in contrast to executive dysfunction which is related to dorsolateral prefrontal networks [31]. ToM appears to mediate not from a single set of brain regions, but from a distributed brain network [32], where at least two white matter tracts in the right hemisphere may be involved in face-based mentalizing (i.e., a component of social cognition) [33].

In our study, the performance on ToM and the production of “favourite” errors were predominantly associated with the performance on several language tasks, as well as with the performance on a visuospatial task (i.e., cube counting) which requires three-dimensional perceptual processes. These findings highlight the involvement of language and three-dimensional visuospatial abilities in affective ToM). From a developmental point of view, social cognition is required for language acquisition, deduce word meanings and communicate pragmatically [34,35]. Also, Thakkar & Park (2010) provide similar findings in healthy participants suggesting a common link between the ability of visuospatial transformation and the internal representations and interactions with the physical world [36]. In addition, the role of visuospatial abilities in ToM has been reported in patients with Parkinson’s disease, supporting that visuospatial deficits are associated with patients’ social interaction and activities in daily living [37]. ToM, language, and visuospatial abilities, appear to share common pathways due to evolutionary changes in brain regions connectivity [38-39]. Similarly, in ALS and ALS-FTD, the study of evolutionary adaptations in brain connectivity [40], assists with interpreting motor and extra-motor deficits based on the progressive degeneration over interlinked networks [41-45].

Limitations

Limitations of the present study includes the evaluation of only one subcomponent of social cognition, which is the affective ToM requiring preference judgement based on eye gaze from a picture and inferences regarding one’s emotions. Also, this task requires two-dimensional visuospatial abilities (i.e., following the eye gaze from a picture), which may have affected the associations between ToM and visuospatial performance. However, the ToM performance was only associated with the three-dimensional task and not with the two-dimensional visuospatial tasks. Nevertheless,

future studies should include more sophisticated measures to test the type of errors and also addresses the issue of impaired ToM and other social cognition components in experimental environments (such the ones related to neuropsychological evaluation) and patients' everyday life.

Conclusion

This study demonstrated evidence of affective ToM dysfunction in non-demented ALS patients, which was associated with language and visuospatial abilities. These associations possibly tap onto common evolutionary patterns of these cognitive functions, and align with the evolutionary perspective of motor and extra-motor symptoms due to the degeneration across corresponding networks. Our findings highlight the importance of impaired ToM that should be considered in clinical settings, since this might contribute to patients' social life, as well as the burden of their caregivers and relatives.
