**Abstract** We give derivations of two formal models of Gricean Quantity implicature and strong exhaustivity in bidirectional optimality theory and in a signalling games framework. We show that, under a unifying model based on signalling games, these interpretative strategies are game-theoretic equilibria when the speaker is known to be respectively minimally and maximally expert in the matter at hand. That is, in this framework the optimal strategy for communication depends on the degree of knowledge the speaker is known to have concerning the question she is answering. In addition, and most importantly, we give a game-theoretic characterisation of the interpretation rule GRICE (formalising Quantity implicature), showing that under natural conditions this interpretation rule occurs in the unique equilibrium play of the signalling game.

**Keywords** Conversational implicatures · Pragmatics · Game theory

## 1 Introduction

An utterance in context is typically interpreted as having, in addition to its conventional, context-independent meaning, a CONVERSATIONAL IMPLICATURE that goes beyond the truth-conditional meaning. Particularly productive for analysing a large class of implicatures is the COOPERATIVE PRINCIPLE, introduced by Grice (1967): speakers may be assumed to try to contribute to the (jointly) accepted purpose of the conversation. We use simplified versions of Grice's maxim of Quality and his first submaxim of Quantity, as follows:

e-mail: R.A.M.vanRooij@uva.nl

**Definition 1** (Quality) Say only what you know to be true.

**Definition 2** (Quantity) Make your contribution as informative as is required (for the current purposes of the exchange).

Given an utterance, the standard implicature via **Quantity** is that the speaker did not intend to communicate any strictly stronger utterance (in the sense of truth-conditional entailment) from a contextually given set of alternatives.<sup>1</sup> For instance, if the question ‘in the air’ is how many children John has, the utterance “John has two children” standardly implicates that he does not have three or any greater number, i.e., that he has *exactly* two children.<sup>2</sup> However the strongest conclusion that can be drawn via **Quantity** is that the speaker *does not know* that John has more children; the EXHAUSTIVE INTERPRETATION of the utterance says instead that she *knows that he does not* have more children. To reach this stronger interpretation various authors (see for example Spector 2003; van Rooij and Schulz 2004; Sauerland 2004) have suggested a two-stage approach: first the weak epistemic reading is derived by standard Gricean reasoning, then this is strengthened by the assumption that the speaker is an *expert*<sup>3</sup> in the matter at hand.

In this paper we examine a formal implementation of quantity implicature and exhaustive interpretation (originally proposed in the unpublished MA thesis of Katrin Schulz, and extended for exhaustification by van Rooij and Schulz (2004), Schulz and van Rooij (2006)), placed in the contexts of bidirectional optimality theory (Bi-OT) and of signalling games. We show firstly that given strong restrictions on the epistemic state of the speaker, quantity implicatures are *derivable* in Bi-OT. Next we show, under much weaker restrictions in the signalling games context, that (under a natural implementation of ‘being expert’) the interpretation according to quantity implicatures is rational just when the speaker is *inexpert*, and exhaustive interpretation just when she is *expert*.<sup>4</sup> We give, that is, a justification in terms of rational communication for the formalisation of **Quantity** and exhaustive interpretation given by Spector (2003), van Rooij and Schulz (2004), Schulz and van Rooij (2006).

Finally, we show that in the game with an *inexpert* speaker, certain natural restrictions on the form of the interpretative strategy (convexity and faithfulness, defined in Theorem 27) completely characterise the strategy formalising quantity implicature: *only* that strategy can form a Nash equilibrium in the signalling game.

<sup>1</sup> We will see in Sect. 2 that the choice of alternative expressions is crucial for even the simplest cases.

<sup>2</sup> That this is not truth-conditional meaning is easily seen: if the relevant question is *whether* he has (at least) two children—for tax purposes, say—then the utterance no longer carries the implicature and he might just as well have ten.

<sup>3</sup> van Rooij and Schulz (2004) discuss speaker “competence”, however this might give rise to confusion with the standard linguistic notion of the same name. We will therefore use the term “expertise” in this paper.

<sup>4</sup> ‘Rationality’ here is in the game-theoretic sense of playing a Nash equilibrium.

Notation

We write “ $|\cdot|$ ” for the cardinality of a set. We assume throughout a set  $W$  of relevantly distinct possibilities, called for simplicity “worlds”.  $Q$  is always a one-place predicate. If  $w$  is a world, then the valuation  $V_w(Q)$  gives the set of objects satisfying  $Q$  in  $w$ .

We use an abbreviated notation for conditional probability: if  $x \in X$  and  $A \subseteq X$  then we abbreviate  $P(\{x\} | A)$  by  $P(x | A)$ . (If  $P$  is a probability distribution over a set  $X$ , then for  $A, B \subseteq X$  the conditional probability of  $A$  given  $B$ ,  $P(A | B)$ , is standardly defined as  $P(A \cap B) / P(B)$ .)

The semantic denotation of an utterance  $f$ ,  $\llbracket f \rrbracket$ , is the set of worlds in which  $f$  is true. We lift this standard notion to the level of information states (sets of worlds):<sup>5</sup>

$$\langle f \rangle \stackrel{\text{def}}{=} \{s \subseteq \llbracket f \rrbracket; s \neq \emptyset\}$$

Just as  $\llbracket f \rrbracket$  gives the worlds in which  $f$  is true,  $\langle f \rangle$  gives the *information states* in which  $f$  is *licensed*, in the pragmatics sense of the maxim **Quality**. (Note that if  $s$  is an information state then  $P(s | \langle f \rangle)$  is concise notation for  $P(\{s\} | \langle f \rangle)$  and should not be confused with  $P(s | \llbracket f \rrbracket)$ ; the latter is only defined given a prior on individual worlds which we generally do not have in this setting.)

Further notation will be introduced as needed.

2 Quantity and GRICE

Formalising **Quantity** requires establishing which utterances count as potential alternatives; if the utterance “John has *exactly* two children” is also an alternative, then this cannot be a **Quantity** implicature from “John has two children”. The standard solution (taken by [Horn \(1972\)](#); [Gazdar \(1979\)](#); [Levinson \(2000\)](#), among others) is to consider only alternative expressions from a linearly ordered scale conventionally associated with the utterance (here the numerical expressions “John has (at least)  $n$  children”), hence the term **SCALAR IMPLICATURE**. The analysis given here generalises this approach to *partially* ordered alternative sets, the **QUANTITY IMPLICATURE** of utterances such as “John or Mary went to the party”. The appropriate alternative expressions are the **POSITIVE SENTENCES**:

**Definition 3** (*Positive sentences*) Given a domain of objects  $D$  and a predicate  $Q$ , we define the set of **POSITIVE  $Q$ -EXPRESSIONS**,  $F_Q$ , as the set  $\{Q(\underline{d}); d \in D\}$  closed under conjunction and disjunction, where we assume for simplicity that each  $d \in D$  has a unique name  $\underline{d}$ .

(The resulting denotations are all upwards monotonic in the question predicate; it is easy to see that introducing downwards-monotonic or non-monotonic expressions in general destroys the predictions. If “John and Mary *and nobody else*” is an alternative

<sup>5</sup> The notation is due to Michael Franke, p.c.. Leaving out the empty set is mainly for convenience.

expression, then we will not strengthen the meaning of “John and Mary” via **Quantity**, as desired.)

Suppose that the question ‘in the air’ is “Who went to the party?” and the answer given is “John or Mary went to the party”. By quantity implicature we derive that the speaker does not know that both John and Mary attended. The stronger EXHAUSTIVE INTERPRETATION is that the speaker knows that John and Mary did not both attend the party.

In the framework described by [van Rooij and Schulz \(2004\)](#), [Schulz and van Rooij \(2006\)](#) and [Spector \(2003\)](#), scalar implicature is a special case of generalised quantity implicature, which is formalised as an interpretative principle “GRICE”, incorporating both **Quality** and **Quantity**. The ‘Gricean interpretation’ of an utterance  $f$  takes place against the background of a question predicate  $Q$ , the ‘matter at hand’, and the utterance is interpreted as meaning the set of *minimal* models with respect to speaker knowledge of  $Q$  (**Quantity**) where  $f$  is known to hold (**Quality**).<sup>6</sup>

**Definition 4** (*Ordering by positive knowledge*) Let  $s, s' \subseteq W$  be information states for the speaker. We say she HAS NO MORE POSITIVE KNOWLEDGE OF  $Q$  IN  $s$  THAN  $s'$ ,  $s \leq_Q^K s'$ , (and analogously ‘has less’,  $<_Q^K$ ) when:

$$s \leq_Q^K s' \stackrel{\text{def}}{\iff} \forall w' \in s' : \exists w \in s : V_w(Q) \subseteq V_{w'}(Q).$$

(The ordering by positive knowledge only takes account of whether two information states differ in the positive  $Q$ -expressions they make true.)

**Definition 5** (*Minimising unstated positive knowledge*) The Gricean interpretation of an utterance  $f$  against a background predicate  $Q$  (according to **Quality** and **Quantity**) is given by:

$$\begin{aligned} \text{GRICE}(f, Q) &\stackrel{\text{def}}{=} \{s \in \{\downarrow f\}; \forall s' \in \{\downarrow f\} : s \leq_Q^K s'\} \\ &= \{s \subseteq \llbracket f \rrbracket; \forall w' \in \llbracket f \rrbracket : \exists w \in s : V_w(Q) \subseteq V_{w'}(Q)\}. \end{aligned}$$

(That is, we restrict **Quantity** to informativity regarding *positive* knowledge; effectively this corresponds to the restriction to a language consisting only of positive expressions. Note also how the restriction to information states in  $\{\downarrow f\}$  corresponds to the requirement that **Quality** be fulfilled.)

As was already mentioned, this definition is not sufficient to derive the strong exhaustive readings standard for utterances like (in answer to “Who went to the party?”) “John went to the party”: not just that the speaker does not know of any other (relevant) individual that they went, but that she knows that they did *not* go. The solution given by [van Rooij and Schulz \(2004\)](#) (also [Spector 2003](#)) is to assume the speaker is *maximally expert* with respect to  $Q$  (as far as this is consistent with the maxims).

<sup>6</sup> We translate here the formal definitions of [van Rooij and Schulz \(2004\)](#) (which were given in a modal logic setting) to a formalism more amenable to the signalling games analysis in the sequel.

**Definition 6** (*Ordering by expertise*) Let  $s, s' \subseteq W$  be information states for the speaker. We say that she is NO MORE EXPERT (ABOUT  $Q$ ) IN  $s$  THAN  $s'$ ,  $s \leq_Q^E s'$ , (and analogously ‘less expert’,  $<_Q^E$ ) when:

$$s \leq_Q^E s' \stackrel{\text{def}}{\iff} \forall w' \in s' : \exists w \in s : V_{w'}(Q) \subseteq V_w(Q).$$

The ‘strong epistemic’ implicature of exhaustification can now be correctly derived by maximising speaker expertise *after* applying GRICE:

**Definition 7** (*Maximising expertise*) Let  $f$  be a positive  $Q$ -expression. The exhaustive reading of  $f$  is given by

$$\text{EXPERT}(f, Q) \stackrel{\text{def}}{=} \{s \in \text{GRICE}(f, Q); \neg \exists s' \in \text{GRICE}(f, Q) : s <_Q^E s'\}.$$

Next we show that GRICE, formalising both Quantity and Quality, can be derived from Quality alone in bidirectional optimality theory.

### 3 Quantity and Bi-OT

Bidirectional Optimality Theory (Bi-OT), first introduced by [Blutner \(2000\)](#), states that conventional language use is constrained by a *bidirectional* optimisation problem: a speaker should choose an optimal message to express her intent, and a hearer should choose the optimal interpretation for the message he hears. Optimality is expressed in terms of a relation  $\succ$  (“is better than”) between form/interpretation pairs, which we will return to in detail in a moment.

**Definition 8** (*Strong optimality*) Let  $\langle f, s \rangle$  be a form/interpretation pair, where  $s$  is a set of worlds (an information state). We say  $\langle f, s \rangle$  is STRONGLY OPTIMAL iff it satisfies the following two conditions:

$$\neg \exists s' : s' \subseteq \llbracket f \rrbracket \ \& \ \langle f, s' \rangle \succ \langle f, s \rangle, \tag{1}$$

$$\neg \exists f' : s \subseteq \llbracket f' \rrbracket \ \& \ \langle f', s \rangle \succ \langle f, s \rangle. \tag{2}$$

Following [Blutner \(2000\)](#), we define the ordering relation in terms of a complexity-related cost for forms, and the conditional probability of the interpretations given the *semantic* meaning of the form (this second clause gives a preference for stereotypical interpretations):

**Definition 9** (*Bi-OT preference ordering*) Given forms  $f, f'$  and interpretations (information states)  $s, s'$ , the commonly known hearer’s subjective probability distribution  $P$  on worlds and a cost function “cost” mapping forms to numerical costs, the relation IS BETTER THAN, “ $\succ$ ”, is defined by

$$\begin{aligned} \langle f, s \rangle \succ \langle f, s' \rangle &\stackrel{\text{def}}{\iff} P(s \mid \llbracket f \rrbracket) > P(s' \mid \llbracket f \rrbracket), \\ \langle f, s \rangle \succ \langle f', s \rangle &\stackrel{\text{def}}{\iff} P(s \mid \llbracket f \rrbracket) > P(s \mid \llbracket f' \rrbracket) \\ &\text{or } P(s \mid \llbracket f \rrbracket) = P(s \mid \llbracket f' \rrbracket) \ \& \ \text{cost}(f) < \text{cost}(f'). \end{aligned}$$

(in other cases, the pairs  $\langle f, s \rangle$  and  $\langle f', s' \rangle$  are not ordered either way.) We show now how, using strong optimality, we can derive the interpretative function GRICE given above.

### 3.1 Weak Epistemic Quantity in Bi-OT

We will focus in this section on Grice, the weak epistemic implicature (“...and I don’t know that anyone else came”). We will return to EXPERT in the signalling games setting (Sect. 4), where we focus on the difference between the weak epistemic interpretation and full exhaustification.

The following definition gives a probabilistic interpretation to “as informative as is required” in the maxim of Quantity:

**Definition 10** (*Probabilistic quantity implicature*) Take  $F_Q$  to be the set of positive  $Q$ -expressions. Define the following equivalence relation  $\approx$  on worlds:  $w \approx w'$  iff<sub>def</sub>  $\forall f \in F_Q : f$  is true in  $w$  iff  $f$  is true in  $w'$ . Let us assume that for each induced equivalence class there exists exactly one representative. We now let  $W$  be the set of those representative worlds. Let  $P$  a distribution on information states such that all interpretations are held possible.

Let  $f \in F$  be an arbitrary utterance; the interpretations given by (probabilistic) QUANTITY IMPLICATURE from  $f$  are defined by

$$\text{QUANT}(f, F_Q) \stackrel{\text{def}}{=} \{s \in \llbracket f \rrbracket ; \forall f' \in F : s \in \llbracket f' \rrbracket \rightarrow P(s \mid \llbracket f \rrbracket) \geq P(s \mid \llbracket f' \rrbracket)\}.$$

(That is, an information state  $s$  is in  $\text{QUANT}(f, F_Q)$  if no alternative form makes  $s$  more likely than  $f$  does. Compare this to the definition of GRICE, which makes no explicit mention of the set of alternative forms at all.)

In the remainder of this section we show firstly that this definition corresponds (under a strong condition on the probability distribution over information states) to strong optimality, and finally that as an interpretative strategy it is equivalent to GRICE (thus retroactively justifying the name!).

**Lemma 11** *If the probability distribution  $P$  over information states is uniform ( $P(s) = P(s')$  for all  $s, s' \subseteq W$ ), and all forms are taken to have the same cost, then*

$$\text{QUANT}(f, F_Q) = \{s \subseteq W; \langle f, s \rangle \text{ is strongly optimal}\}.$$

[ Take  $s \in \text{QUANT}(f, F_Q)$  arbitrary. Now  $\langle f, s \rangle$  is not strongly optimal if there is a better  $\langle f', s \rangle$  or  $\langle f, s' \rangle$ . Suppose the former; then for some  $f' \neq f$  such that  $s \subseteq \llbracket f' \rrbracket$ ,  $P(s \mid \llbracket f' \rrbracket) > P(s \mid \llbracket f \rrbracket)$  (since messages have equal cost)—but then  $s \in \text{QUANT}(f, F_Q)$  is a contradiction. Suppose instead the latter; then for some  $s' \neq s$  such that  $s' \subseteq \llbracket f \rrbracket$ ,  $P(s' \mid \llbracket f \rrbracket) > P(s \mid \llbracket f \rrbracket)$ , which is impossible since the distribution on information states is uniform.

For the converse, take  $\langle f, s \rangle$  an arbitrary strongly optimal pair. Then  $\neg \exists f' \in F_Q : s \subseteq \llbracket f' \rrbracket \ \& \ P(s \mid \llbracket f' \rrbracket) > P(s \mid \llbracket f \rrbracket)$ ; that is,  $\forall f' \in F_Q : s \subseteq \llbracket f' \rrbracket \rightarrow P(s \mid \llbracket f \rrbracket) \geq P(s \mid \llbracket f' \rrbracket)$ , thus  $s \in \text{QUANT}(f, F_Q)$ . ]

This simple proof is included because it can easily be adopted to prove the simpler scalar implicature version of the above:

**Corollary 12** *Take only messages arranged in a linear order by entailment (for instance the numerical expressions “John has  $n$  children” in the “at least” reading), and take single worlds as interpretations; as before, all messages are of equal cost and the distribution on worlds is uniform. Then only the pairs  $\langle$ “John has  $n$  children”,  $w$  $\rangle$  where “John has exactly  $n$  children” is true in  $w$  are strongly optimal.<sup>7</sup>*

(That is, precisely the standard—exhaustive—scalar implicature is produced by BIOT; adapting QUANT to probabilities of single worlds conditional on the semantic denotation gives the same result, by the proof given above. In fact, taking information states as interpretations leads to a weak epistemic version of scalar implicature, and maximising expertise in the sense of Definition 7 gives again the same result. We omit the details.)

Now the claim is that the interpretative principle QUANT formalises the maxims of Quantity and Quality. Recall that the interpretative principle GRICE, Definition 5, is taken as a formalisation of precisely these maxims. We will now show that GRICE and QUANT are equivalent.

We define first a piece of helpful notation:

**Definition 13** (*Q-minimality*) Let  $X$  be a set of worlds and  $Q$  a question predicate. The  $Q$ -MINIMAL WORLDS in  $X$  are given by

$$\min_Q(X) \stackrel{\text{def}}{=} \{w \in X; \neg \exists w' \in X (V_{w'}(Q) \subset V_w(Q))\}$$

Using  $\min_Q(\cdot)$ , for any information state  $s$  we can define a positive  $Q$ -expression  $f_s$  with the useful properties  $s \subseteq \llbracket f_s \rrbracket$  and  $\min_Q(\llbracket f_s \rrbracket) = \min_Q(s)$  (that is,  $\llbracket f_s \rrbracket$  is the upward completion of  $s$  in the ordering  $\leq_Q^K$ ). We omit the details.

<sup>7</sup> More formally, let  $\langle f_1, \dots, f_k \rangle$  be a set of messages linearly ordered by entailment,  $\llbracket f_n \rrbracket \subset \llbracket f_m \rrbracket \Leftrightarrow n > m$ . Take the possible worlds instead of information states as interpretations, and assume all worlds are equally likely. Then  $\langle f_n, w \rangle$  is strongly optimal iff  $w \in \llbracket f_n \rrbracket \setminus \llbracket f_{n+1} \rrbracket$ .

To prove this, let  $\langle f_n, w \rangle$  be a pair corresponding to an interpretation by scalar implicature:  $w \in \llbracket f_n \rrbracket \setminus \llbracket f_{n+1} \rrbracket$ . The pair  $\langle f_n, w \rangle$  is not strongly optimal if there is a better  $\langle f_m, w \rangle$  or  $\langle f_n, w' \rangle$ . Take  $f_m$  for  $m \neq n$ . If  $m > n$  then  $w \notin \llbracket f_m \rrbracket$ , so  $P(w \mid \llbracket f_m \rrbracket) = 0 < P(w \mid \llbracket f_n \rrbracket)$ , thus  $\langle f_n, w \rangle > \langle f_m, w \rangle$ . Suppose instead that  $m < n$ , then while  $w \in \llbracket f_m \rrbracket$ , since  $w \in \llbracket f_n \rrbracket \subset \llbracket f_m \rrbracket$  we have  $P(w \mid \llbracket f_n \rrbracket) > P(w \mid \llbracket f_m \rrbracket)$ , so  $\langle f_n, w \rangle > \langle f_m, w \rangle$ .

Take  $w' \neq w$ . Suppose  $w' \notin \llbracket f_n \rrbracket$ ; then  $P(w' \mid \llbracket f_n \rrbracket) = 0 < P(w \mid \llbracket f_n \rrbracket)$ , so  $\langle f_n, w \rangle > \langle f_n, w' \rangle$ . Suppose  $w' \in \llbracket f_n \rrbracket$ ; then by our assumption that all worlds are equally probable,  $P(w' \mid f_n) = P(w \mid f_n)$  so  $\langle f, w \rangle \not> \langle f, w' \rangle$ .

That is, the two conditions of Definition 8 hold: the pair in question is strongly optimal. The same arguments are almost sufficient to show that *only* these pairs are strongly optimal: we have only to consider the case of  $\langle f_n, w \rangle$  where  $w \in \llbracket f_{n+1} \rrbracket$  (all other possibilities were already excluded above by strict inequality with some strongly optimal pair). But this, too, has a better alternative: above we considered only variations in  $w$ , but if we take the pair  $\langle f_{n+1}, w \rangle$  then since  $w \in \llbracket f_{n+1} \rrbracket \subset \llbracket f_n \rrbracket$  we have  $P(w \mid \llbracket f_{n+1} \rrbracket) > P(w \mid \llbracket f_n \rrbracket)$  so  $\langle f_{n+1}, w \rangle > \langle f_n, w \rangle$ , that is,  $\langle f_n, w \rangle$  is not strongly optimal.

That is, all and only those pairs corresponding to the scalar implicature are strongly optimal.

**Lemma 14** Using  $\min_Q(\cdot)$  we can formulate  $\text{GRICE}(f, Q)$  in two equivalent ways:

$$\text{GRICE}(f, Q) = \{s \in \langle f \rangle; \min_Q(\llbracket f \rrbracket) \subseteq s\} \tag{3}$$

$$= \{s \in \langle f \rangle; \min_Q(\llbracket f \rrbracket) = \min_Q(s)\}. \tag{4}$$

Now we are ready to show that  $\text{QUANT}$  and  $\text{GRICE}$  are equivalent.

**Proposition 15** Let  $Q$  be a one-place question predicate and  $f$  a positive  $Q$ -expression. Take all positive  $Q$ -expressions as alternatives to  $f$ , and information states (subsets of  $W$ ) as interpretations. Assume that all information states have non-zero probability. Then

$$\text{GRICE}(f, Q) = \text{QUANT}(f, F_Q).$$

*Proof* We prove this via lemmas 16 and 17 by reducing  $\text{QUANT}(f, F_Q)$  to the reformulated definition of  $\text{GRICE}(f, Q)$  given in (3).

**Lemma 16** If  $s$  and  $s'$  are arbitrary sets and  $\min_Q(s) \subseteq s' \subseteq s$  then  $\min_Q(s) = \min_Q(s')$ .

[ If  $w$  is  $Q$ -minimal in  $s$ , then no world in  $s'$  can give  $Q$  a smaller denotation; if  $w$  is not  $Q$ -minimal in  $s$  then some  $w' \in \min_Q(s)$  gives  $Q$  a smaller denotation and  $w' \in s'$ . ]

**Lemma 17** If  $f$  and  $f'$  are positive  $Q$ -expressions, then  $\llbracket f \rrbracket = \llbracket f' \rrbracket \iff \min_Q(\llbracket f \rrbracket) = \min_Q(\llbracket f' \rrbracket)$ .

[ For any positive  $Q$ -expression  $f$ , an easy induction shows that  $f_{\llbracket f \rrbracket} = f$ . (In other words, positive  $Q$ -expressions are monotonic in  $Q$ .) The result follows immediately. ]

Now for the reduction. First, take  $s$  and  $f$  such that  $s \in \langle f \rangle$  but  $s \notin \text{GRICE}(f, Q)$ ; by (3), then,  $\min_Q(\llbracket f \rrbracket) \not\subseteq s$ . We will show that the form  $f_s$  (with denotation the upward completion of  $s$ ) is preferable for  $s$  in  $\text{QUANT}$ , just as it is in  $\text{GRICE}$ .

Let  $s'$  be the (non-empty) information state  $\min_Q(\llbracket f \rrbracket) \setminus s$ . Since  $\min_Q(f_s) = \min_Q(s)$ ,  $s' \not\subseteq \llbracket f_s \rrbracket$  so  $\llbracket f_s \rrbracket \subset \llbracket f \rrbracket$  (by monotonicity of forms,  $\min_Q(\llbracket f_s \rrbracket) \subseteq \llbracket f \rrbracket \Rightarrow \llbracket f_s \rrbracket \subseteq \llbracket f \rrbracket$ ). But now by the assumption that no information state in  $\langle f \rangle$  is considered impossible, and since  $s \subseteq \llbracket f_s \rrbracket \subset \llbracket f \rrbracket$  (so  $s \in \langle f_s \rangle \subset \langle f \rangle$ ), we have  $P(s \mid \langle f \rangle) < P(s \mid \langle f_s \rangle)$ , which implies  $s \notin \text{QUANT}(f, F_Q)$ .

Next, take  $s$  such that  $\min_Q(\llbracket f \rrbracket) \subseteq s$ , so  $s \in \text{GRICE}(f, Q)$ , and suppose towards a contradiction that for some  $f'$  such that  $s \in \langle f' \rangle$  we have  $P(s \mid \langle f' \rangle) > P(s \mid \langle f \rangle)$  (so  $s \notin \text{QUANT}(f, F_Q)$ ). Since  $s \in \langle f \rangle$ , for all alternative forms such that  $\llbracket f' \rrbracket \not\subseteq \llbracket f \rrbracket$  we have  $P(s \mid \langle f' \rangle) \leq P(s \mid \langle f' \wedge f \rangle)$  so without loss of generality we restrict ourselves to strengthenings of  $f$ .

Then by the probabilities  $\llbracket f' \rrbracket \neq \llbracket f \rrbracket$ , so Lemma 17 gives us  $\min_Q(\llbracket f \rrbracket) \neq \min_Q(\llbracket f' \rrbracket)$ . But we have  $\min_Q(\llbracket f \rrbracket) \subseteq \llbracket f' \rrbracket \subseteq \llbracket f \rrbracket$  which by Lemma 16 implies  $\min_Q(\llbracket f' \rrbracket) = \min_Q(\llbracket f \rrbracket)$ , a contradiction by Lemma 17. So no such  $f'$  can exist, which implies  $s \in \text{QUANT}(f, F_Q)$ .

That is,  $s \in \text{QUANT}(f, F_Q) \iff \min_Q(\llbracket f \rrbracket) \subseteq s \iff s \in \text{GRICE}(f, Q)$ .  $\square$

This means that under Bi-OT we can *derive* Quantity (represented by GRICE) from Quality (required for optimality), at least under the assumption of a uniform distribution over information states. A Bayesian approach would suggest a *roughly* uniform prior in the absence of other information, but as long as we use Bi-OT as a predictive theory we (think we) require exact uniformity.

In the following we will model an inexpert speaker as having a non-negligible probability of making inexact observations; then Bayesian ignorance can be seen as a special case of this notion, but exact uniformity is clearly far too strong a requirement.

The important thing to note about Proposition 15 is that, unlike Lemma 11, the probability distribution need not necessarily be uniform, only everywhere non-zero. We show now, via the equivalence of GRICE and QUANT, that the same Gricean strategy is selected in a game-theoretic setting, under much more reasonable restrictions on the distribution.

## 4 Quantity and Signalling Games

Signalling games were introduced by Lewis (1969) to explain the existence of conventionalised meanings of linguistic expressions. In this context a typical model has multiple equilibria, and the choice of one among them is a matter of convention; Lewis's aim was indeed to show how such conventions might spontaneously arise without prior agreement (which would itself rely on a pre-existing conventional language). In this paper we use signalling games instead for *pragmatics*, in the tradition of Parikh (2001), Benz et al. (2006): we assume a predetermined (conventional) semantic meaning for the signals and show which (pragmatic) refinements of the semantic meaning are optimal in a game-theoretic sense. In contrast to the games of Lewis, here we have as desideratum a *single* equilibrium: given a pre-existing *semantic* convention, the *pragmatic* refinement should be uniquely determined. We will see that this goal is not reached in the basic model, but the addition in Sect. 5 of a structural constraint on the interpretative strategies gives us the refinement we are looking for.

Formally, a signalling game is a game of asymmetric incomplete information between a sender S and a receiver R, with chance moves by Nature. Given is a set of worlds  $W$ , a set of messages  $F_Q$ , and a probability distribution  $P$  over information states (the moves of Nature). Nature shows an information state to the Sender, she sends a message  $f$  to the Receiver, and he plays an INTERPRETATION ACTION, a set of information states which we read as “the (perhaps pragmatically enriched) interpretation of  $f$ ”.<sup>8</sup>

**Definition 18** (*Interpretation signalling game*) An INTERPRETATION SIGNALLING GAME is a tuple  $\langle Q, W, F_Q, \llbracket \cdot \rrbracket, \text{utility}_n, P \rangle$  with the following properties:

- $Q$ , as above, is a one-place predicate;
- $W$  is the full set of possibilities (“worlds”) differing in the extension of  $Q$ ;
- $F_Q$  is the set of positive  $Q$ -expressions;

<sup>8</sup> Rather than define interpretation games in full generality, we include here the refinements specific to this application. A fully general definition would specify neither the objects taken as observations (and interpretations) nor the form of the utility function.

- $\llbracket \cdot \rrbracket$  is the standard semantic denotation function (from which we derive also the lifted version  $\langle \cdot \rangle$ );
- $\text{utility}_n : \wp(W) \times \wp(\wp(W)) \rightarrow \mathbb{R}$  is a function parameterised by  $n$  (as given below) which specifies the utility of each interpretation (by the receiver) in each information state (of the sender);
- $P$  is a probability distribution on information states, such that all states in  $\wp(W)$  occur with positive probability.

A PLAY of the game is a triple  $\langle X, f, \mathcal{Y} \rangle$  where  $X \subseteq W$  is an information state (the OBSERVATION given by Nature to the Sender),  $f \in F_Q$  is a MESSAGE (sent by the Sender) and  $\mathcal{Y} \subseteq \wp(W)$  is a set of information states (the INTERPRETATION of the Receiver).

The UTILITY FUNCTION has the form

$$\text{utility}_n(X, \mathcal{Y}) \stackrel{\text{def}}{=} \begin{cases} P(X | \mathcal{Y}) & \text{if } X \in \mathcal{Y}, \\ -n & \text{otherwise,} \end{cases}$$

where the parameter  $n$  is a large integer, the PENALTY for unsuccessful communication. This gives the PAYOFF of a play  $\pi = \langle X, f, \mathcal{Y} \rangle$  directly:<sup>9</sup>

$$U(\pi) \stackrel{\text{def}}{=} \text{utility}_n(X, \mathcal{Y}).$$

We will frequently wish to discuss families of games that vary only in their penalty values or observation distributions. Given a game  $G = \langle Q, W, F_Q, \llbracket \cdot \rrbracket, \text{utility}_n, P \rangle$ , penalty value  $m$  and distribution  $P'$ , we write

$$\begin{aligned} G_m &\stackrel{\text{def}}{=} \langle Q, W, F_Q, \text{utility}_m, P \rangle, \\ G^{P'} &\stackrel{\text{def}}{=} \langle Q, W, F_Q, \text{utility}_n, P' \rangle, \quad \text{and} \\ G_m^{P'} &\stackrel{\text{def}}{=} \langle Q, W, F_Q, \text{utility}_m, P' \rangle. \end{aligned}$$

The penalty models the intuition that communicative failure is always the worst outcome, no matter how much effort is saved in arriving *efficiently* at a wrong interpretation. To see this, however, we need to be able to describe the strategies the two players use to produce their moves.

**Definition 19 (Strategies)** A SENDER STRATEGY is a (total) function  $\sigma : \wp(W) \rightarrow F_Q$  giving a message in each information state. A RECEIVER STRATEGY is a (total) function  $\rho : F_Q \rightarrow \wp(\wp(W))$  giving an interpretation, a set of information states, for each message in  $F_Q$ . A LANGUAGE is a pair  $\langle \sigma, \rho \rangle$  where  $\sigma$  is a sender strategy and  $\rho$  is a receiver strategy.

A play  $\langle X, f, \mathcal{Y} \rangle$  is ACCORDING TO THE STRATEGIES  $\sigma$  and  $\rho$  if  $\sigma(X) = f$  and  $\rho(f) = \mathcal{Y}$ .

<sup>9</sup> In comparison to standard signalling games, this definition corresponds to the “cheap talk” assumption that messages are costless.

(The definitions of strategies for S and R express the information asymmetry of the game. The sender observes (partially) the state of the world, but the receiver must use only the message in arriving at an interpretation.)

Now we can explain the necessity of the penalty value. Suppose this was absent (in the current model, simply set the penalty value  $n$  to zero). Now imagine that the same message,  $f$ , is sent in two information states  $s$  and  $s'$  that occur with equal (relatively high) probability. Then the interpretations  $\rho(f) = \{s\}$ ,  $\rho(f) = \{s'\}$  and  $\rho(f) = \{s, s'\}$  all have equal payoff, so the third strategy, which never gives rise to communicative failure, is not preferred. Worse yet, if  $s$  is (even only very slightly) more probable than  $s'$ , then this strategy is actually *worse* than  $\rho(f) = \{s\}$ : the strategy giving rise to communicative failure almost half the time is actually preferred. Setting a numerical value on the penalty for communicative failure turns out to be crucial for the analysis of expertise, as we will see in Sect. 4.1.

**Definition 20** (*Payoffs*) Given a game  $G = \langle Q, W, F_Q, \llbracket \cdot \rrbracket, \text{cost}, \text{utility}, P \rangle$  and a language  $L = \langle \sigma, \rho \rangle$  for  $G$ , the EXPECTED UTILITY (or PAYOFF) of  $L$  in  $G$ ,  $EU_G(\sigma, \rho)$ , is given by

$$\sum \{P(X) \cdot U(X, f, \mathcal{Y}); (X, f, \mathcal{Y}) \text{ is a play according to } \sigma \text{ and } \rho\}.$$

A sender strategy  $\sigma$  is a BEST SENDER RESPONSE to a receiver strategy  $\rho$  in  $G$  if for all  $\sigma' \neq \sigma$ ,  $EU_G(\sigma, \rho) \geq EU_G(\sigma', \rho)$ , a STRICT BEST RESPONSE if the inequality is everywhere strict, and analogously for best receiver responses.

We define also the expected utility of  $\sigma$  and  $\rho$  AT AN INFORMATION STATE  $X$  (or AT A MESSAGE  $f$ ) by taking expectations over only those plays according to  $\sigma$  and  $\rho$  that include the information state (or message), and write this  $EU(\sigma, \rho)(X)$  (or  $EU(\sigma, \rho)(f)$ ).

We use the standard game-theoretic notion of Nash equilibrium to single out certain preferred strategies: a pair of rational agents will play a language that is a Nash equilibrium because if the language is *not* an equilibrium, then some player has a payoff incentive to change their strategy.

**Definition 21** (*Nash equilibrium*) A language  $\langle \sigma, \rho \rangle$  is a NASH EQUILIBRIUM for the game  $G$  if  $\sigma$  is a best reply to  $\rho$  and vice versa. It is a STRICT NASH EQUILIBRIUM if  $\sigma$  and  $\rho$  are mutual *strict* (i.e., unique) best replies.

Now we give two related games, representing respectively an inexpert and an expert speaker, and show that the Nash equilibrium solution concept selects the strategies we want in each case.

#### 4.1 Expertise in Signalling Games

The translation of the notion of ‘expertise’ to the signalling game proceeds via the probability distribution on observations (with appropriate adjustments of the penalty parameter in the utility function). The intuition is that an expert speaker is more likely to

make precise observations, whereas with an inexpert speaker we cannot know whether their utterance was prompted by exact knowledge of the situation or by an extremely vague observation. So for a maximally inexpert speaker we expect all information states to appear with non-negligible probability.

As was stated earlier, we model **Quality** via the semantic denotation function taking messages to the set of worlds in which they are true. That is, we consider only sender strategies  $\sigma$  that satisfy, for all information states  $s$ ,  $s \subseteq \llbracket \sigma(s) \rrbracket$ . We will take **GRICE** and **EXPERT** as *interpretative* strategies, defining receiver strategies  $\rho_G$  and  $\rho_E$ :

$$\begin{aligned} \rho_G(f) &\stackrel{\text{def}}{=} \text{GRICE}(f, Q), \\ \rho_E(f) &\stackrel{\text{def}}{=} \text{EXPERT}(f, Q). \end{aligned}$$

**Definition 22** (*Inexpert speaker*) Take  $\delta \in [0, 1]$  a “reasonably large” value. The distribution  $P$  represents an **INEXPERT SPEAKER** (with respect to  $\delta$ ) if  $\forall s \subseteq W: P(s) \geq \delta$ .<sup>10</sup>

Let  $P_\delta$  represent an inexpert speaker for some given value of  $\delta$ . Then by choice of  $n$  we can always construct a game  $G_n^{P_\delta}$  such that for any sender strategy  $\sigma$  utilising all messages, the *unique* best receiver reply  $\rho_{\text{BR}(\sigma)}$  is given by  $\rho_{\text{BR}(\sigma)}(f) = \sigma^{-1}(f) \stackrel{\text{def}}{=} \{s \subseteq W; \sigma(s) = f\}$ . We call such a game a **GAME WITH INEXPERT SPEAKER**.

**Theorem 23** *Let  $G$  be a game with inexpert speaker. Then in  $G$ ,*

1.  $\rho_G$  has a unique best sender reply  $\sigma_G$ , and  $\langle \sigma_G, \rho_G \rangle$  is a strict Nash equilibrium; and
2. for no sender strategy  $\sigma$  is  $\langle \sigma, \rho_E \rangle$  a Nash equilibrium.

*Proof of clause 23* Let  $\rho$  be an arbitrary receiver strategy for the game  $G_{\epsilon, n}$ . Then the speaker’s best reply  $\sigma_{\text{BR}(\rho)}$  is given by

$$\sigma_{\text{BR}(\rho)}(s) = \arg \max_{f \in F_Q} \{P(s \mid \rho(f)); s \in \rho(f)\}.$$

For  $\rho_G$ , the receiver strategy assigning to each message  $f$  its Gricean interpretation  $\text{GRICE}(f, Q)$ , this is

$$\sigma_{\text{BR}(G)}(s) = \arg \max_{f \in F_Q} \{P(s \mid \rho(f)); s \in \text{GRICE}(f, Q)\}.$$

But now a property of **GRICE** makes this apparent optimisation problem trivial: each information state  $s$  occurs in  $\text{GRICE}(f, Q)$  for *exactly one message*  $f$ . The set  $\{f; s \in \text{GRICE}(f, Q)\}$  is a singleton. So the “arg max” is redundant, the best reply is selected simply by being uniquely  $s$ -optimal.

To see this, recall that the form  $f_s$  is the minimal (in terms of set inclusion) message whose denotation contains  $s$ :  $s \subseteq \llbracket f \rrbracket \Rightarrow \min_Q(s) \subseteq \llbracket f \rrbracket \Rightarrow \llbracket f_s \rrbracket \subseteq \llbracket f \rrbracket$ , since  $\min_Q(s) = \min_Q(\llbracket f_s \rrbracket)$  generates  $\llbracket f_s \rrbracket$  by the  $Q$ -monotonicity condition on forms.

<sup>10</sup> Clearly for values of  $\delta$  larger than the reciprocal of the number of information states no distribution will satisfy the condition.

Now if we assume that all information states are held possible,  $s \subseteq \llbracket f_s \rrbracket \subset \llbracket f \rrbracket \Rightarrow P(s \mid \llbracket f_s \rrbracket) > P(s \mid \llbracket f \rrbracket)$ , so  $s \notin \text{GRICE}(f, Q)$ . That is, under these assumptions, each information state gives rise to a unique optimal message.<sup>11</sup>

If we take this observation to define GRICE as a strategy for production,  $\sigma_G(s) \stackrel{\text{def}}{=} f_s$ , then it is easy to see that  $\text{GRICE} = \langle \sigma_G, \rho_G \rangle$  is its own best response:

$$\begin{aligned} \rho_{\text{BR}(\sigma)}(f) &= \{s; \sigma(s) = f\} \\ \rho_{\text{BR}(G)}(f) &= \{s; \sigma_G(s) = f\} \\ &= \{s; f_s = f\} \\ &= \{s; \min_Q(s) = \min_Q(\llbracket f \rrbracket)\} \\ &= \rho_G(f) \end{aligned}$$

(by the rephrased definition of  $\text{GRICE}(f, Q)$ , (4) from Lemma 14).

That is, GRICE interpreted in this way as strategies  $\langle \sigma_G, \rho_G \rangle$  is its own unique best reply, a strict Nash equilibrium. □

The second clause of Theorem 23 is easy to see. Let  $\sigma$  be a strategy for which  $\rho_E$  is a putative best reply; since  $\sigma$  is total, a best receiver response  $\rho_{\text{BR}(\sigma)}$  should include every information state in the interpretation of some message. But  $\rho_E$  does not do this (some information states are UNINDUCABLE, i.e., there are information states  $s$  for which there is no  $f \in F_Q$  such that  $s \in \rho_E(f) = \text{EXPERT}(f, Q)$ ), so the payoff according to  $\rho_E$  falls short of that given by  $\rho_{\text{BR}(\sigma)}$  according to the penalty.

**Definition 24** (*Expert speaker*) Take  $\epsilon \in [0, 1]$  a value ‘reasonably close’ to zero. The distribution  $P$  represents an EXPERT SPEAKER (with respect to  $\epsilon$ ) if for all  $s \subseteq W$ ,  $P(s) < \epsilon$  just in case  $\exists w, w' \in s : V_w(Q) \subset V_{w'}(Q)$ .

(Note that this definition is a rough parallel to Definition 6, in that the observations receiving low probability are each less expert than some other observation that receives high probability.)

**Definition 25** (*Game with expert speaker*) A game  $G_n^P$  is a “game with expert speaker” if there exists a positive probability  $\epsilon$  such that:

1. For any receiver strategy  $\rho$ , if for any  $s, s' \subseteq W$  and  $f \in F$  we have  $\{s, s'\} \subseteq \rho(f)$  and  $P(s) < \epsilon \leq P(s')$ , then  $\rho$  is not a best response to any sender strategy in  $G_n^P$ ; and
2.  $P$  represents an expert speaker with respect to  $\epsilon$ .

Intuitively the triple  $\langle \delta, n, \epsilon \rangle$  as a whole represents a ‘cultural parameter’ of language use, corresponding roughly to the notion of how much evidence is ‘enough’ to justify stating something with conviction. It has been suggested, on the basis of data from Malagasy, that quantity implicature is not in fact universal Keenan (1977);

---

<sup>11</sup> Compare for instance mention-some questions (“Where can I buy a newspaper?”), in which for many information states several answers are intuitively equally optimal; these require a different payoff function, and will not be treated further in this paper.

an alternative interpretation of the data seems to be that the “required degree of conviction” parameter is in this case turned extremely high. It is interesting to speculate whether this representation could also be applied to languages requiring explicit evidential markers (see for example [Ifantidou 2001](#)).

**Theorem 26** *Let  $G$  be a game with expert speaker. Then in  $G$ ,*

1. *for no sender strategy  $\sigma$  is  $\rho_G$  a best response; and*
2. *there is at least one  $\sigma$  which is a best sender response to  $\rho_E$ , and for every such  $\sigma$ ,  $\rho_E$  is in turn the unique best receiver response.*<sup>12</sup>

The first clause follows immediately from the construction of the game with expert speaker. The second clause is a generalisation of the notion of Nash equilibrium, which is necessary in the signalling games setting when (as in this case) some information states are uninducible.<sup>13</sup> We cannot (as in [Theorem 23](#)) simply find a sender strategy forming a strict Nash equilibrium: how such a strategy behaves on the uninducible—low probability—information states will not affect the payoff, so there will be many non-strict best responses. What is ensured by the construction, however, is that all of these sender strategies will behave the same way on the high-probability information states, and thus that  $\rho_E$  will be the unique best receiver response to each of them.

## 5 GRICE Characterised

In the previous section we showed that playing according to GRICE is rational when the speaker is inexpert, and according to EXPERT when she is expert. However the question still remains, what of other possible strategies? In the case of an inexpert speaker, the game also admits of a multitude of alternative solutions, some decidedly pathological-looking. We would like to do more than show that GRICE is rational, we would like to show that it is the *only* rational strategy given an inexpert speaker. The following characterisation result comes much closer to achieving this desideratum:

**Theorem 27** *Let  $G$  be a game with inexpert speaker. Let  $\rho$  be a receiver strategy with the following properties:*

1.  $\forall f \in F : \llbracket f \rrbracket \in \rho(f)$  (“Faithfulness”), and
2.  $\forall s, s', s'' \subseteq W : \forall f \in F : s \subseteq s' \subseteq s'' \ \& \ s, s'' \in \rho(f) \Rightarrow s' \in \rho(f)$  (“Convexity”).

*Then there exists a sender strategy  $\sigma$  (obeying Quality) such that  $\langle \sigma, \rho \rangle$  is a strict Nash equilibrium in  $G$  if and only if  $\rho(f) = \text{GRICE}(f, Q)$ .*

Clearly these conditions alone are not sufficient to characterise GRICE. The requirement of rational play in a game with inexpert speaker ensures that  $\min_Q(\llbracket f \rrbracket) \in \rho(f)$

<sup>12</sup> The formulation is a special case of the notion of an EVOLUTIONARILY STABLE SET of languages: it is—roughly speaking—a maximal closed set of neutrally stable (mixed) strategies surrounded by a region of strategies that earn lower payoff, in this case with the additional property that each language appearing in the set has the same sender strategy.

<sup>13</sup> In more general terms: when there are more states than messages, and when mixed strategies are disallowed.

for each message  $f$ ; this provides a minimal element for each interpretation. Faithfulness provides a maximal element, and Convexity fills in the information states between to match GRICE.

*Proof* First, let  $\rho(f) = \text{GRICE}(f, Q)$  for all  $f \in F$ . By Lemma 14 (4),  $\llbracket f \rrbracket \in \text{GRICE}(f, Q)$  for all  $f$ , so Faithfulness is fulfilled. Now take  $s, s', s'' \subseteq W$  and  $f \in F$  such that  $s, s'' \in \text{GRICE}(f, Q)$ . Then by Lemma 14 (3),

$$\begin{aligned} \min_Q(\llbracket f \rrbracket) \subseteq s \subseteq s' \subseteq s'' \subseteq \llbracket f \rrbracket \\ \Rightarrow \min_Q(\llbracket f \rrbracket) \subseteq s' \subseteq \llbracket f \rrbracket \\ \Rightarrow s' \in \text{GRICE}(f, Q), \end{aligned}$$

so the Convexity condition is also satisfied.

The converse is a little more involved. Suppose that  $\rho$  is both faithful and convex (in the sense of Theorem 27). It is sufficient to show that if  $\rho$  occurs in a Nash equilibrium language, then for all  $f$ ,  $\min_Q(\llbracket f \rrbracket) \in \rho(f)$ . [In that case by faithfulness  $\llbracket f \rrbracket \in \rho(f)$  and by the convexity condition all  $s \subseteq \llbracket f \rrbracket$  such that  $\min_Q(f) \subseteq s \subseteq \llbracket f \rrbracket$  also occur in  $\rho(f)$ ; that is,  $\rho(f) \supseteq \text{GRICE}(f, Q)$ . If  $\rho(f) \neq \text{GRICE}(f, Q)$ , then some information state  $s'$  outside  $\text{GRICE}(f, Q)$  is also in  $\rho(f)$ ; then  $s'$  will also appear in  $\rho(f')$  for some  $f' \neq f$ , so  $\rho$  is not the best response to any sender strategy, a contradiction.]

Let  $\rho$  occur in a Nash equilibrium language. Suppose towards a contradiction that for some  $f' \neq f$  that  $\min_Q(\llbracket f \rrbracket) \in \rho(f')$ . Let  $\sigma$  be a best response to  $\rho$ ; then  $\sigma(\min_Q(\llbracket f \rrbracket)) = f'$ . If  $\sigma$  obeys Quality, since message denotations are upwards monotonic we have  $\min_Q(\llbracket f \rrbracket) \subseteq \llbracket f \rrbracket \subseteq \llbracket f' \rrbracket$ . But since  $\{*\}; \min_Q(\llbracket f \rrbracket), \llbracket f' \rrbracket\} \subseteq \rho(f')$  (by faithfulness and our hypothesis), by the convexity condition we have also  $\llbracket f \rrbracket \in \rho(f')$ . But now by faithfulness we have also  $\llbracket f \rrbracket \in \rho(f)$ , and this means, for games with inexpert speakers, that  $\rho$  is not a best reply to  $\sigma$ , or indeed to any sender strategy.

That is, if  $\rho$  satisfies the conditions of Theorem 27 and occurs in a Nash equilibrium language, then for all  $f$ ,  $\min_Q(\llbracket f \rrbracket)$  occurs only in  $\rho(f)$ ; this in turn implies that  $\rho(f) = \text{GRICE}(f, Q)$ , and the equivalence is complete. □

The names of the conditions in Theorem 27 are deliberately suggestive. These are not arbitrary properties, they are in fact very natural constraints on the structure of an interpretative principle.

The first, Faithfulness, is perhaps even stronger: it can be read as a requirement on the relation between semantics and pragmatics in the model. Recall that we began by simply stipulating a conventionalised semantic meaning for each of our messages. If the “semantic meaning” of some message is *never* in the interpretation by a receiver, it could be described as somewhat disengenuous to continue to call it “semantic meaning”; the faithfulness requirement then ensures that our terminology remains honest.

The convexity condition is a closure property on sets; like any such, it helps enormously for describing, learning, and remembering the interpretations these sets represent, since we can compactly describe a set in terms of just a few of its elements. In our case, we can describe the pragmatic interpretation of  $f$  in terms of just  $\min_Q(\llbracket f \rrbracket)$ , once the two constraints are given. Convexity constraints in particular play an important role in describing linguistic universals in generalised quantifier theory (Thijsse

1983; Benthem van Benthem 1986) and cognitive semantics (Gärdenfors 2000), and are given an independent game-theoretic motivation in Jäger (2007).

## 6 Conclusion

We have given a game-theoretic implementation of the interpretative principles GRICE (Quantity implicature) and EXPERT (exhaustive interpretation) defined by van Rooij and Schulz (2004), Schulz and van Rooij (2006) and Spector (2003). In a signalling games framework we specified what it means to have an expert speaker by means of the penalty value and ‘degree of conviction’ parameter bundle  $\langle \delta, n, \epsilon \rangle$ . Under these definitions, we found that *interpretation* according to GRICE and EXPERT is rational in exactly the cases we would expect; GRICE induces a strict Nash equilibrium in the inexpert case and thus fixes the sender strategy, while EXPERT in the expert case leaves some details of the sender strategy unspecified but is nonetheless stable in a natural extended sense.

These models did not achieve the desideratum of singling out a unique pragmatic interpretation rule. To do this we require in addition *structural* constraints on the form of an interpretative strategy: Faithfulness (that pragmatic interpretation should not discard the semantic meaning) and Convexity (that the interpretation of a message should be a convex set, under the set inclusion partial order). With these constraints, and with an inexpert speaker, the uniquely rational interpretative strategy is Gricean Quantity implicature.

Note also that all these results have an interpretation in *evolutionary* game theory: strict Nash equilibrium corresponds to evolutionary stability, while the extended equilibrium notion required for the expert speaker is closely related to neutral stability and the notion of an evolutionarily stable set of strategies. In particular, the characterisation result implies that GRICE is the unique evolutionarily stable strategy for the game with inexpert speaker.

This perspective suggests a different way of looking at the relationship between GRICE and EXPERT. If we consider speaker strategies instead of interpretative strategies, Theorem 26 shows that EXPERT is nothing but GRICE restricted to the information states of an expert speaker. Combined with the characterisation result of Theorem 27 we are left with a picture of GRICE as a fundamental pragmatic rule and EXPERT as an application of that rule in the common case of a speaker we trust to know what she is talking about.
