Received January 10, 1995[⊗]

Rhenium and manganese complexes of the 3,5-di-*tert*-butyl-1,2-benzosemiquinone (DBSQ) ligand, $[M(CO)_{4-n}(DBSQ)_n]$, *fac*- $[M(CO)_3(L)(DBSQ)]$, and *cis,trans*- $[M(CO)_2(L)_2(DBSQ)]$, with a widely varied nature of co-ligand(s) ($L = THF, Me_2CO, MeC(O)Ph, py, NEt_3, Ph_3PO, SbPh_3, AsPh_3, PCy_3, P(OPh)_3, PPh_3, dppe-p, PPh_2Et, P(OEt)_3, PEt_3$) were generated in solution and characterized as valence-localized molecules containing the radical-anionic DBSQ ligand bound to Re^I or Mn^I metal atoms. This is evidenced by the following. (i) Carbonyl stretching frequencies $\nu(C=O)$ and average force constants k_{av} are typical for Mn^I or Re^I carbonyls. (ii) Frequencies of the intra-dioxolene C=O bond stretching vibration, $\nu(C=O)$, lie within the 1400–1450 cm^{-1} range which is diagnostic for coordinated semiquinones. (iii) EPR spectra indicate a very small spin density on the metal atom ($0.2\% < a_M/A_{iso} > 2.6\%$). (iv) Absorption spectra show $Re^I \rightarrow DBSQ$ MLCT electronic transitions characterized by a resonant enhancement of the Raman peaks due to the $\nu(C=O)$ and intra-DBSQ $\nu(C=O)$ vibrations. (iv) Finally, the electrochemical pattern consists of DBSQ/DBQ and DBSQ/DBCat ligand-localized redox couples. All these properties are, in a limited range, dependent on the nature and, especially, the number of co-ligands L, indicating a small delocalization of the singly occupied MO of the DBSQ ligand over the metal atom. The extent of this delocalization may be finely tuned by changing the co-ligands, although in absolute terms, it remains rather limited, and the DBSQ ligand behaves toward Re^I and Mn^I as a very weak π -acceptor only. The changes of the electronic properties of the metal center induced by the co-ligands are mostly compensated by more flexible $M \rightarrow CO$ π back-bonding as is manifested by large variations of the average C=O stretching force constant.

Introduction

o-Semiquinone radical-anions¹ are very remarkable ligands, able to form stable radical complexes with both transition^{2,3} and nontransition^{4,5} metals. When bound to a metal atom that does not possess unpaired electrons and that is difficult both to reduce and to oxidize, semiquinones (SQ) often behave as organic radicals stabilized by the coordination. Some SQ complexes of Co^{III} ^{6–9} or of nontransition metals like Zn^{II} ¹⁰ are typical examples. Such complexes pose a unique opportunity to investigate the properties of a radical-anionic ligand and to study

Scheme 1

how the unpaired electron on the ligand interacts with the metal, thus affecting the behavior of the complex molecule. Semiquinones are redox-active ligands, see Scheme 1, which may easily be reduced to catecholates (Cat) and oxidized to quinones¹ (Q) while remaining bound to the metal.^{2,3,11} Therefore, an ambiguity in the assignment of the oxidation states to the metal atom and to the dioxolene¹ ligand arises whenever a semiquinone is coordinated to a redox-active metal.^{2,3,11} Thus, a complex molecule that contains a $[M^{n+}(SQ)]$ unit may, in principle, have two other valence isomers,¹¹ which differ only in the distribution of the electrons between the metal and the dioxolene ligand, $[M^{(n+1)+}(Cat)]$ and $[M^{(n-1)+}(Q)]$. Some dioxolene complexes are known to exist in two such different valence forms, depending on factors such as the nature of the co-ligands, environment, or temperature.^{2,3,11} For example, copper–dioxolene complexes occur as Cu^I –semiquinone, $[Cu^I(L)_2(DBSQ)]$, when “soft” co-ligands such as phosphines, phosphites, CO, isonitriles, alkynes, alkenes, and thioethers are pres-

[⊗] Abstract published in *Advance ACS Abstracts*, January 15, 1996.

- (1) The term “dioxolene” (Diox) is used for ligands derived from 1,2-dioxobenzene, irrespective of their oxidation state, i.e. for catechol dianion (Cat), *o*-semiquinone radical-anion (SQ), or *o*-quinone (Q), without specifying the substituents on the benzene ring. The individual oxidation states of the 3,5-di-*tert*-butyl-1,2-dioxobenzene (DBDiox) are denoted DBCat, DBSQ, and DBQ.

ent in their coordination spheres.^{12–15} When the ligand L is substituted for a harder ligand, *e.g.*, 2,2'-bipyridine, a complete switchover to the [Cu^{II}(bpy)(DBCat)] isomer occurs.^{12–15} Subtle co-ligand control of the electron distribution within the [M(Diox)] unit was found also for [Co^{II}(L₂)(DBSQ)₂]/[Co^{III}(L₂)(DBCat)(DBSQ)] or [Mn^{II}(L₂)(DBSQ)₂]/[Mn^{III}(L₂)(DBCat)(DBSQ)]/[Mn^{IV}(L₂)(DBCat)₂] groups of bistable complexes^{16–18} and for some dioxolene complexes of Mn, Rh, etc.^{2,3,11} Such switching of the electron localization between two sharply defined valence forms, induced by a co-ligand change, indicates very little electronic delocalization within the metal–dioxolene chelate rings [M(SQ)] and [M(Cat)]. However, although most semiquinone complexes appear to be valence-localized¹¹ with well-defined metal and ligand (*i.e.* SQ) oxidation states, an occurrence of a delocalized structure [M(Diox)]ⁿ⁺ cannot be *a priori* excluded.

Mixed-ligand carbonyl–semiquinone complexes of Re and Mn, [M(CO)_{4–n}(L)_n(DBSQ)] (*n* = 0, 1, 2) are very suitable systems to investigate the co-ligand influence on the electron distribution and (de)localization between the metal and the semiquinone ligand. Although the radical character of these complexes was recognized earlier,^{19–31} no such systematic study has been undertaken so far. Hence, to better understand the bonding properties of the DBSQ ligand, we have generated a series of complexes [M(CO)_{4–n}(L)_n(DBSQ)] (M = Re, Mn; *n* = 0, 1, 2) (see Figure 1) with the co-ligands L of widely varied bonding properties and studied their IR, resonance Raman, electronic absorption, and EPR spectra, as well as the electrochemical redox potentials. When the information obtained was combined, it was possible to address the question of how increasing electron density on the metal atom influences the extent of electronic delocalization within the [M^I(SQ)] chelate ring.

Experimental Section

Materials. 3,5-Di-*tert*-butyl-1,2-benzoquinone, DBQ (Aldrich), was recrystallized from *n*-heptane. Re₂(CO)₁₀ and Mn₂(CO)₁₀ (Strem) were used without further purification. Purity of the ligands (L = THF, Me₂CO, MeC(O)Ph, py, NEt₃, Ph₃PO, SbPh₃, AsPh₃, P(Cy)₃, P(OPh)₃, PPh₃, dppe-*p*, PPh₂Et, P(OEt)₃, PEt₃ obtained commercially (Fluka, Aldrich, BDH, Merck) was checked by melting points and by NMR. If necessary, they were purified by recrystallization or distillation

Figure 1. Structures of the [M(CO)_{4–n}(L)_n(DBSQ)] complexes (M = Re or Mn, *n* = 0, 1, 2). M = Re: *n* = 0, 1, L = THF, Me₂CO, MeC(O)Ph, py, NEt₃, Ph₃PO, SbPh₃, AsPh₃, P(OPh)₃, PPh₃, dppe-*p*, PPh₂Et, PCy₃; *n* = 2, L = PPh₃, P(OPh)₃, AsPh₃. M = Mn: *n* = 0, 1, L = THF, CH₃CN, PPh₃, py, H₂O; *n* = 2, L = P(OPh)₃, P(OEt)₃, PPh₃, PEt₃.

under reduced pressure. Bu₄NPF₆ (Fluka) was dried *in vacuo* at 80 °C for 10 h. [Cp₂Fe]BF₄ was synthesized by a published method.³² [Bu₄N][Mn(CO)₃(DBCat)] was prepared according to ref 33. Solvents (spectroscopic grade) were freshly distilled under argon or nitrogen atmosphere. THF and CH₂Cl₂ (Fluka) were distilled from a sodium–benzophenone mixture or from P₂O₅, respectively. Pyridine (Merck) was dried by refluxing with KOH followed by a fractional distillation. Benzene was distilled from a Na wire or from LiAlH₄. Solutions for photolyses were freeze–pump–thaw degassed and handled under vacuum. Electrochemical and spectroscopic studies were carried out using argon or nitrogen atmosphere.

Generation of Semiquinone Complexes. [Re(CO)₄(DBSQ)] was generated by irradiation of a stirred solution (10 mL) of 5 × 10^{–3} M Re₂(CO)₁₀ and 10^{–2} M DBQ in degassed benzene or CH₂Cl₂ with a 125 W medium-pressure or a 200 W high-pressure mercury lamp overnight. The 300–370 nm irradiation spectral region was selected by a combination of the Pyrex glass of the reaction vessel and a UG11 Oriol band-pass filter. Nearly complete (>95%) conversion to [Re(CO)₄(DBSQ)] was accomplished, as was determined by IR spectra. [Re(CO)₃(L)(DBSQ)] complexes were generated by an addition of a 10-fold molar excess of the ligand L to the solutions of [Re(CO)₄(DBSQ)] under vacuum or inert atmosphere. [Re(CO)₂(L)₂(DBSQ)] complexes, L = PPh₃, P(OPh)₃, or AsPh₃, were produced by photolysis of [Re(CO)₃(L)(DBSQ)] solutions with a 10-fold excess of L overnight.

[Mn(CO)₃(THF)(DBSQ)] was generated by an oxidation²⁸ of degassed THF solutions of [Bu₄N][Mn(CO)₃(DBCat)] with solid [Cp₂Fe]BF₄. Subsequent addition of an excess of L = phosphines or phosphites to the solutions of [Mn(CO)₃(THF)(DBSQ)] cleanly formed [Mn(CO)₂(L)₂(DBSQ)] complexes while the reaction with pyridine led to [Mn(CO)₃(py)(DBSQ)]. [Mn(CO)₃(PPh₃)(DBSQ)] was prepared according to ref 31. The [Mn(CO)₄(DBSQ)] complex was produced by an oxidation of the CH₂Cl₂ solution [Bu₄N][Mn(CO)₃(DBCat)] with a small excess of [Cp₂Fe]BF₄ under CO atmosphere. Alternatively, the manganese–semiquinone complexes were generated by electrochemical oxidation of THF or CH₂Cl₂ solutions of [Bu₄N][Mn(CO)₃(DBCat)] and the ligand L on a Pt-mesh electrode within a multipurpose optically transparent thin layer electrochemical (OTTLE) cell,³⁴ and their spectroscopic properties were studied *in situ*. [Mn(CO)₂(PPh₃)₂(DBSQ)] was also produced by mixing [Bu₄N][Mn(CO)₃(DBCat)] with 2 equiv of PPh₃ and 1 equiv of [Mn(CO)₂(PPh₃)₂(DBQ)](PF₆)³¹ in THF or CH₂Cl₂ solutions.

Instrumentation. Electronic absorption spectra were obtained on a Hewlett-Packard 8452A diode array or a Perkin-Elmer Lambda 5 spectrophotometer. Varian E4 and Bruker 300 X-band spectrometers were used to measure the EPR spectra. The *g* factors were determined against the DPPH standard (*g* = 2.0037). IR spectra were obtained

on the following FTIR instruments, detectors and spectral resolutions being specified in parentheses: Philips PU9800 (DTGS, 4 cm⁻¹), Nicolet 7199B (liquid N₂ cooled MCT, 1 cm⁻¹), and Bio-Rad FTS-7 (DTGS, 2 cm⁻¹). Resonance Raman spectra were measured on a Dilor XY Raman spectrometer that employs a backscattering geometry. Sample solutions were placed in demountable IR cells equipped with NaCl windows and excited either by a SP 2016 Ar⁺ laser or by a CR-590 dye laser employing Coumarine 6 or Rhodamine 6G dyes pumped by the Ar⁺ laser. Cyclic voltammetry measurements were performed in 10⁻³ M sample solutions containing 10⁻¹ M Bu₄NPF₆ using a PA4 polarographic analyzer (EKOM, Czech Republic) or PAR Model 173 potentiostat. Potentials were measured on a Pt disk working electrode against a Ag wire pseudoreference electrode and are referenced to the ferrocene/ferrocenium (Fc/Fc⁺) redox couple used as an internal standard.³⁵ Spectroelectrochemical generation and investigation of the Mn—semiquinone complexes were carried out in an IR-OTTLE cell³⁴ equipped with a Pt minigrid working electrode (6 × 5 mm rectangle, 32 wires/cm). The same OTTLE cell³⁴ was used to obtain Raman, FTIR, and UV—vis absorption spectra using NaCl, KBr, and CaF₂ windows, respectively. Usual sample concentrations for the spectroelectrochemical studies were in the range 5 × 10⁻³ to 10⁻² M with 3 × 10⁻¹ M Bu₄NPF₆ added.

Results and Discussion

The complexes studied were characterized in solution by their FTIR and EPR spectra which confirmed their compositions and structures shown in Figure 1. No radical- or carbonyl-containing impurities have been detected.

IR Spectra in the ν(C≡O) Region. IR ν(C≡O) stretching frequencies of the complexes under study are summarized in Table 1. Typical^{36–39} spectral patterns observed are consistent with the configurations indicated in Figure 1, *i.e.* *cis*-[M(CO)₄(DBSQ)], *fac*-[M(CO)₃(DBSQ)], and *cis,trans*-[M(CO)₂(L)₂(DBSQ)] with the two ligands in the axial positions. Individual C≡O stretching force constants were not obtained as no unequivocal assignment of the IR bands of the tetra- and tricarbonyls is possible^{36–39} without the isotopic substitution. Instead, an average force constant,³⁷ *k*_{av}, has been calculated (Table 1) and used as an indication of the extent of the M → CO π-back-donation. The *k*_{av} values decrease rapidly with decreasing number of CO ligands present in the coordination sphere. For the substituted species, *k*_{av} decreases in the order L = P(OPh)₃ > P(OMe)₃ > PPh₃ > PPh₂Et > PR₃, *i.e.* with decreasing π-acceptor and increasing σ-donor capacity of the phosphorus ligand. Among the tricarbonyls, the lowest *k*_{av} values were found for hard σ-donors without any prominent π-bonding properties: L = THF, MeC(O)Ph, NEt₃, py, Me₂CO, and Ph₃PO.

EPR Spectra. All the semiquinone complexes investigated exhibit intense EPR signals (see Table 2 for parameters) centered at *g* values that are only slightly lower than the *g* factor of the free DBSQ radical-anion (*g* = 2.0051 in 10⁻¹ M Bu₄NPF₆/THF),²³ indicating that the unpaired electron is dominantly localized on the DBSQ radical ligand. Small, but definite, deviation of the *g*-factors below the free DBSQ value points to the presence of a low-lying unoccupied MO that is mixed with the singly occupied MO (SOMO), both MO's involved containing small contributions from the metal *d* orbitals.^{40,41}

^a Compounds are listed in the order of increasing metal hyperfine splitting constant a_M . Splitting constants in Gauss = 0.1 mT. ^b 1:4 (v/v) C₆H₆:Me₂CO mixture. ^c 1:4 (v/v) C₆H₆:py mixture. ^d 1:4 (v/v) P(OPh)₃:C₆H₆ mixture. ^e From ref 21. ^f g value from ref 22. ^g Hyperfine splitting due to the 5-Bu^t protons = 0.26 G. ^h From ref 31. ⁱ Measured at 230 K, from ref 31; a_L corresponds to H₂O protons.

patterns of [M(CO)₂(L)₂(DBSQ)] show that the two ligands L are equivalent in agreement with the *cis,trans* configuration. The hyperfine splitting from the ¹H(*I* = 1/2) nucleus of the H atom bound at the C4 position⁴ of the DBSQ ligand was observed only for Mn complexes and [Re(CO)₄(DBSQ)]. The a_H values are close to that of free DBSQ (3.2 G),²³ consistent with the predominant localization of the unpaired electron on the DBSQ ligand. In other cases, the ¹H splitting was not resolved because of relatively large line widths (1.5–1.8 G for Mn and 7.5–8 G for Re). For the same reason, no ¹⁴N hyperfine coupling was found for [Re(CO)₃(py)(DBSQ)] and [Re(CO)₃(NEt₃)(DBSQ)].

Magnitudes of the metal splitting constants show that the spin density on the metal atom is, in all complexes studied, rather small. Thus, the a_M values are comparable with those of “spin-adducts” of Mn(CO)₅[•] and Re(CO)₅[•] radicals with nitroso compounds^{42,43} which were formulated as Mn^I and Re^I complexes of radical-anionic ligands. The a_{Mn} values are much smaller than those observed for a related Mn⁰ complex [Mn(CO)₃(DBCat)]²⁻, 53.4 G,²⁸ and for Mn^{II} complexes.⁴⁴ The ratio between a_M and the theoretical splitting constant A_{iso} , calculated^{44,45} for an unpaired electron localized in the outer

Figure 2. Correlation between the Re hyperfine splitting constants, a_{Re} , and g-factors of the [Re(CO)_{4-n}(L)_n(DBSQ)] complexes. The linear correlation ($R = 0.996$) is based on the data measured for following co-ligands L (●, from left to right): $n = 2$, PPh₃, P(OPh)₃; $n = 1$, PPh₂Et, PPh₃, dppe-*p*, P(OPh)₃, CO, py. Data for $n = 2$ (L = AsPh₃) and for $n = 1$ (L = AsPh₃, PCy₃, NEt₃, Me₂CO) (◇, from left to right) are slightly off the line but follow an identical trend.

metal s orbital, ranges from 0.2% to 1.8% for Re–semiquinones and from 0.3% to 2.6% for Mn. Similar low a_M/A_{iso} values were reported^{46–49} for complexes of diimine radical-anions bound to metal atoms with a spin-paired d⁶ configuration, e.g. Cr⁰, Mo⁰, W⁰, Mn^I, and Re^I. From the data in Table 2, it follows that the a_M splitting constants increase with decreasing number of the CO ligands and, for P ligands, in the order P(OPh)₃ < P(OMe)₃ < PPh₃ < PPh₂Et < PR₃ that reflects their decreasing π -acceptor and increasing σ -donor ability. Increasing electron density on the Re atom raises the energy of the M d(π) orbital, whose interaction with the DBSQ-localized SOMO strengthens. Hence, the changes of a_M splitting constant may be correlated with the changes of the metal-localized spin density transmitted through the d(π)– π^* (SOMO) delocalization. This conclusion is fully supported⁴⁴ by the observed linear correlation between a_{Re} and the g-factor shown in Figure 2, since the increasing participation of the d(π) orbital in SOMO also increases the contribution from the large spin–orbit coupling of the Re atom, thus diminishing the g-factor. Small deviations from the a_{Re} –g correlation observed for complexes with co-ligands like AsPh₃, SbPh₃, and bulky PCy₃ or hard N and O donors probably reflect^{44,45} variations in the radial wave functions of the Re s and d orbitals caused by changes in the Re–L σ -bonding, instead of a different extent of the Re–DBSQ π -bonding.

Rather large a_L values are fully consistent⁴¹ with the ligand L occupying the axial, *i.e. cis*, position with respect to the DBSQ radical ligand. The hyperfine coupling to the co-ligand donor atom originates mainly in the π^*/σ_{ML} hyperconjugation^{41,44–47} that is efficient only when the co-ligand is in a position *cis* to the radical ligand with the M–L bond(s) perpendicular to the DBSQ plane. Accordingly, the a_L values observed are rather large, especially in comparison with pseudotetrahedral [Cu^I(L)₂(DBSQ)] complexes¹² where the M–L bonds are bent away from the DBSQ ligand. In addition to the π^*/σ_{ML} mechanism, some spin density is also transmitted to the P atom from the DBSQ ligand through the metal d(π) orbital as is indicated by a_P values found for phosphites (stronger π -acceptors) which are somewhat larger than those for phosphines.

Electronic Absorption Spectra. All the Re–semiquinone complexes studied exhibit a single broad absorption band in

^a Compounds are listed in the order of decreasing energy of the visible absorption band. ^b 1:4 (v/v) C₆H₆:P(OPh)₃. ^c 1:4 (v:v) C₆H₆:Me₂CO. ^d 1:2 (v:v) C₆H₆:Me₂CO. ^e 1:6 (v/v) C₆H₆:THF. ^f 1:4 (v/v) C₆H₆:py. ^g 5:1 (v/v) C₆H₆:py. ^h From ref 31, at 228 K.

the visible spectral region ($\epsilon = 4300\text{--}6500\text{ M}^{-1}\text{ cm}^{-1}$) with a long weak ($\epsilon \leq 500\text{ M}^{-1}\text{ cm}^{-1}$) tail extending into the near infrared spectral region. For [Re(CO)₄(DBSQ)], shoulders were detected at 825 and 980 nm. Band parameters are listed in Table 3.

The maximum of the visible absorption band of [Re(CO)₄(L)_n(DBSQ)] shifts to lower energies with a decreasing number of CO ligands. Among both the tri- and dicarbonyl series, the absorption energy decreases with decreasing π -acceptor and increasing σ -donor strength of the co-ligand(s) L, *i.e.* with increasing electron density on the Re atom. This co-ligand effect points to the $d(\pi) \rightarrow \pi^*$ (DBSQ) MLCT character of the electronic transition(s) involved. The absorption maxima shift slightly to lower energies with decreasing solvent polarity, in agreement with their MLCT assignment. The $d(\pi) \rightarrow \pi^*$ (DBSQ) transitions are directed into the 3b₁ SOMO^{10,50} of the DBSQ ligand (b₁ refers to the idealized C_{2v} local ligand point group). The 3b₁ SOMO overlaps with the d_{yz} metal orbital (see Figure 1 for axes orientation). Therefore, the d_{yz} \rightarrow 3b₁ transition is expected to be the most intense of the three $d(\pi) \rightarrow$ 3b₁ MLCT transitions possible and, hence, responsible for the main visible absorption band. This assignment is also in line with earlier^{6,9,10,51,52} studies on electronic spectra of other semiquinone complexes. Further weak transitions that might contribute to the absorption band and to its low-energy tail may

belong either to the less intense d_{x²-y²} \rightarrow 3b₁ and d_{xz} \rightarrow 3b₁ MLCT or to the DBSQ-localized intraligand transitions. The latter have been observed to occur below 15 000 cm⁻¹ with extinction coefficients lower than 500 M⁻¹ cm⁻¹ for free DBSQ⁵³ as well as for many of its complexes.^{10,51} These intraligand transitions were described^{10,51} as $n \rightarrow \pi^*$ (3b₁ – SOMO), the n orbital being the symmetrical (9a₁) combination of the lone electron pairs of the two DBSQ oxygen donor atoms. This assignment was based on CNDO/2 and Fenske–Hall calculations^{10,50} of the 1,2-benzosemiquinone molecule which indicated that the n(9a₁) orbital is the HOMO of the free ligand. However, these calculations take into account neither the ligand open-shell nature nor the strong involvement of the 9a₁ orbital in the σ -bonding to the metal. Therefore, we expect the n(9a₁) $\rightarrow \pi^*$ (3b₁) transition to occur at higher energies and to be rather dependent on the nature of the metal atom. Hence, we prefer to assign the weak low-energy absorption to π^* (SOMO) $\rightarrow \pi^{**}$ transitions of the DBSQ ligand. Analogous transitions were found in many other organic radical-anions.^{54,55}

Spectra of the Mn complexes usually show two broad bands in the visible region tailing into NIR. One band with a shoulder on its high-energy side was found³¹ for [Mn(CO)₄(DBSQ)], [Mn(CO)₃(PPh₃)(DBSQ)], and [Mn(CO)₂(PPh₃)₂(DBSQ)]. Their extinction coefficients are lower than those for Re. Except for [Mn(CO)₃(H₂O)(DBSQ)] and [Mn(CO)₃(THF)(DBSQ)], the main absorption band shifts to lower energy with increasing σ -donor and decreasing π -acceptor properties of the co-ligand(s). This trend is most obvious in the [Mn(CO)₂(L)₂(DBSQ)] series and supports the assignment of the main absorption maximum to the d_{yz} \rightarrow 3b₁ MLCT transition. The less intense absorption band present in the spectra of some of the Mn^I complexes studied, see Table 3, may be assigned to other $d(\pi) \rightarrow$ 3b₁ MLCT transition(s). Intraligand DBSQ-localized transitions contribute again to the low-energy weak absorption that extends into the NIR.

All the Re– and Mn–semiquinone complexes have very strong absorptions in the UV region which belong to the DBSQ intraligand transitions. This is manifested by the narrow band at 310 nm ($\epsilon = 9380\text{ M}^{-1}\text{ cm}^{-1}$) for [Mn(CO)₃(THF)(DBSQ)] which is very similar to the absorption band⁵³ of free DBSQ. Analogously, both [Re(CO)₄(DBSQ)] and [Re(CO)₃(PPh₃)(DBSQ)] show a band at 282 nm, $\epsilon \approx 10^4\text{ M}^{-1}\text{ cm}^{-1}$. The spectral transitions in the UV region were not studied further.

Resonance Raman Spectra. Resonance Raman (rR) spectra of [Re(CO)₄(DBSQ)], [Re(CO)₃(PPh₃)(DBSQ)], and [Re(CO)₂(PPh₃)₂(DBSQ)] are shown in Figure 3, and selected data are presented in Table 5. Intensities of all the Raman bands decrease when the excitation was tuned to shorter wavelengths, out of the visible absorption band, thus proving their (pre)-resonance intensity enhancement. The rR spectra are dominated by a strong peak in the 1400–1450 cm⁻¹ range, *i.e.* in the region characteristic^{2,3,6,11} of the $\nu(\text{C}=\text{O})$ stretching vibration of coordinated semiquinones. Raman bands at 1524 and 1528 cm⁻¹ found for [Re(CO)₄(DBSQ)] and [Re(CO)₃(PPh₃)(DBSQ)], respectively, as well as a group of weaker bands between 1240 and 1400 cm⁻¹ may be assigned to the intraligand C–C vibrations. Raman band due to the highest-frequency A₁

(55) Photostability of the Re complexes might be used as an argument against a contribution from the $n \rightarrow \pi^*$ intraligand transition to the visible absorption band. Such a transition would be expected to strongly labilize the M–DBSQ bonding. The same is true for a weak (π^* -SOMO) 3b₁ \rightarrow M LMCT transition which could also occur in the visible region.

Figure 3. Resonance Raman spectra of [Re(CO)₄(DBSQ)] (A) [Re(CO)₃(PPh₃)(DBSQ)] (B), and [Re(CO)₂(PPh₃)₂(DBSQ)] (C). Excitation wavelengths: 514.5, 579, and 621 nm, respectively. An asterisk (*) denotes Raman peaks of the CH₂Cl₂ solvent.

$\nu(\text{C}\equiv\text{O})$ mode occurs at 2111, 2023, and 1919 cm^{-1} for the tetra-, tri-, and dicarbonyls, respectively. Another important group of three Raman peaks occurs in the range 480–550 cm^{-1} . By analogy with five-membered chelate rings involving oxygen donor atoms, e.g. oxalates, and with [Ru(bpy)₂(SQ)]⁺, these peaks may be assigned^{36,56,57} to skeletal vibrations of the Re-(DBSQ) chelate ring. The central most prominent peak of [Re(CO)₃(PPh₃)(DBSQ)] and [Re(CO)₂(PPh₃)₂(DBSQ)] probably corresponds to the symmetrical Re–O stretching vibration that is partly coupled to the C₁–C₂ stretch,^{36,56,57} $\nu(\text{Re}–\text{O})$. For [Re(CO)₄(DBSQ)], this group of peaks looks like one peak at 492 cm^{-1} with two shoulders at 502 and 510 cm^{-1} . We tentatively assign the central shoulder at 502 cm^{-1} to $\nu(\text{Re}–\text{O})$. (Alternative $\nu(\text{Re}–\text{O})$ assignment to the main peak at 492 cm^{-1} is less probable as this band is exhibited by all three complexes.) Other weak Raman peaks observed at frequencies below 700 cm^{-1} correspond to bending vibrations of the Re-(DBSQ) ring, $\delta(\text{M}–\text{C}\equiv\text{O})$, and $\nu(\text{M}–\text{C})$ vibrations.^{36,56,57}

The enhancement of the Raman bands due to the intra-DBSQ $\nu(\text{C}=\text{O})$ and $\nu(\text{C}\equiv\text{O})$ vibration is in full agreement^{58–60} with the $d(\pi) \rightarrow 3b_1$ MLCT character of the resonant electronic transition which affects the DBSQ C=O bonds through the population of the C=O π -antibonding^{10,51} $3b_1$ orbital. The C–C bonds are affected to a much lesser extent as $3b_1$ is only weakly antibonding to the C(3)–C(4) and C(5)–C(6) bonds and weakly bonding with respect to the C(1)–C(2) and C(2)–C(3), C(4)–C(5), and C(6)–C(1) bonds.^{10,50} Hence, the peaks due to C–C vibrations exhibit much smaller enhancement. The Raman peak due to the $\nu(\text{C}\equiv\text{O})$ vibration is enhanced because of the

depopulation of the $d(\pi)$ orbital(s), involved in the Re–CO back-bonding, upon the MLCT excitation.⁵⁸

Observation of the resonant enhancement of the $\nu(\text{Re}–\text{O})$ peak shows that the bonding within the Re(DBSQ) chelate ring is also affected by the MLCT excitation. Generally, we may expect^{59,60} that the enhancement of this peak will increase with increasing mixing between the d_{yz} and $3b_1$ orbitals, which is equivalent to a partial π -bonding between Re and DBSQ. The MLCT excitation then gains, in part, a character of a $\pi(\text{Re}–\text{O}) \rightarrow \pi^*(\text{Re}–\text{O})$ transition. The effect of the electronic excitation on the Re–O and semiquinone C=O bonds may be compared using the ratio between the intensities of the Raman bands due to corresponding stretching vibrations. It may be approximately expressed as⁶¹

$$\frac{I_a}{I_b} = \frac{\omega_a^2 \Delta_a^2}{\omega_b^2 \Delta_b^2} \quad (1)$$

where ω is the vibration frequency and Δ is the displacement of corresponding normal coordinates upon the resonant electronic excitation. Calculated $\Delta(\text{Re}–\text{O})/\Delta(\text{C}=\text{O})$ ratios of the $\nu(\text{Re}–\text{O})$ and $\nu(\text{C}=\text{O})$ normal mode displacements, shown in Table 5, indicate rather strong relative excited state distortion of the skeletal normal modes of the Re(DBSQ) ring which increases with decreasing number of CO ligands.

Electrochemistry. Table 4 summarizes the reduction and oxidation potentials of the complexes investigated. Unless stated otherwise, the redox couples listed in Table 4 are electrochemi-

Figure 4. Correlation between the oxidation and reduction potentials of the $[\text{Re}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$ complexes. Members of the $[\text{Re}(\text{CO})_{4-n}(\text{PPh}_3)_n(\text{DBSQ})]$ series (●) are connected by a full line, members of the $[\text{Re}(\text{CO})_{4-n}(\text{P}(\text{OPh})_3)_n(\text{DBSQ})]$ series (◆) by a short-dashed (---) line, and members of the $[\text{Re}(\text{CO})_{4-n}(\text{AsPh}_3)_n(\text{DBSQ})]$ series (▼) by a long-dashed line (---). Unconnected points (○) correspond to $[\text{Re}(\text{CO})_3(\text{L})(\text{DBSQ})]$ complexes. From left to right: L = PPh₂Et, dppe-*p*, py, Ph₃PO, NEt₃, THF, SbPh₃, Me₂CO.

cally reversible or quasireversible. As we have shown previously,^{28–31} both the oxidation and reduction are localized on the DBSQ ligand, producing quinone and catecholate complexes, respectively. Complicated chemistry that follows the reduction of some Re complexes³⁰ (Table 4, footnote *c*) was suppressed by using low temperatures. Reduction potentials of the Mn complexes were measured in the presence of an excess of free L to minimize the effects of the dissociation of the co-ligand L upon the reduction.^{28,29} Even so, related structural change renders the reduction couples quasireversible or, for $[\text{Mn}(\text{CO})_4(\text{DBSQ})]$ and $[\text{Mn}(\text{CO})_2(\text{PPh}_3)_2(\text{DBSQ})]$, even irreversible.

Neglecting the changes in the entropy and solvation energy, and assuming that neither the energies nor the (de)localization of the redox orbitals are dependent on the number of electrons in the molecule, the reduction potential of spin-doublet semiquinone complexes may be expressed^{62,63} by the SOMO orbital energy, ϵ_i , and the Coulombic integral J_{ii} : $E_{1/2}(\text{red}) = -\epsilon_i - J_{ii} + \text{constant}$. The oxidation potential is related to ϵ_i only,^{62,63} $E_{1/2}(\text{ox}) = -\epsilon_i + \text{constant}$. The difference between the oxidation and reduction potentials ($\Delta E_{1/2}$, Table 4) is then approximately equal to the value of J_{ii} (positive). If both the oxidation and reduction were indeed fully DBSQ-localized, the redox potentials were expected to be nearly independent of the composition of the coordination sphere and $\Delta E_{1/2}$ expected to be constant and close to the free ligand value, 0.61 V. A linear correlation between $E_{1/2}(\text{ox})$ and $E_{1/2}(\text{red})$ would then be predicted. Data in Table 4 clearly show that $\Delta E_{1/2}$ is much larger than expected, around 1 V. The general trend of decreasing oxidation potential with decreasing reduction potential was observed, although the linear correlation predicted by the simple model was not found (see Figure 4). The largest deviations occur for $[\text{Re}(\text{CO})_2(\text{L})_2(\text{DBSQ})]$ whose oxidation potentials appear to be smaller than expected. The same effect occurs in the Mn series, see Table 4.

Dependence of the ligand-localized redox potentials on the co-ligands may also be discussed in terms of the ligand-specific electrochemical parameters $E_L(\text{L})$ ^{64,65} whose sum, $\sum E_L(\text{L})$, should correlate linearly with the redox potentials. Reduction potentials of all the $[\text{Re}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$ complexes studied,

regardless of the number ($n = 0, 1, 2$) and nature of the co-ligands L, follow the same linear correlation with the $\sum E_L(\text{L})$ parameter: slope = 0.5, intercept = $-2.4 \text{ V vs Fc/Fc}^+$. For the oxidation potentials, two distinct correlations were found, one for the $[\text{Re}(\text{CO})_4(\text{DBSQ})]$ and $[\text{Re}(\text{CO})_3(\text{L})(\text{DBSQ})]$ complexes (slope = 0.3, intercept = -0.7 V) and another for the $[\text{Re}(\text{CO})_2(\text{L})_2(\text{DBSQ})]$ species (slope = 0.8, intercept = -2.4 V). Both the much larger slope and much more negative intercept found for the oxidation of the dicarbonyls indicate a much larger influence of the Re–DBDiox electronic coupling on the potential of the $[\text{Re}(\text{CO})_2(\text{L})_2(\text{DBQ})]^+ / [\text{Re}(\text{CO})_2(\text{L})_2(\text{DBSQ})]$ redox couple than on the oxidation of the tri- and tetracarbonyl semiquinones. However, these differences in the electronic delocalization have to be much larger in the oxidized products, $[\text{Re}(\text{CO})_{4-n}(\text{L})_n(\text{DBQ})]^+$, than in the parent semiquinones, since the discontinuity between the tri- and dicarbonyls was not found for the reduction potentials.

To account for these observations, it should be noted that both the wave function and energy of the $3b_1$ frontier orbital and, hence, the extent of the metal–dioxolene delocalization depend strongly on the oxidation state of the dioxolene ligand.¹¹ From the electrochemical data alone, it is thus difficult to distinguish whether the co-ligand dependence of the redox potentials arises from a strong electronic delocalization in the semiquinone complexes themselves or in their redox products, *i.e.* quinone and catecholate complexes. The redox potentials may then be expressed as

$$E_{1/2}(\text{red}) = -\epsilon_i - J_{ii} - E_r(\text{red}) + \text{constant} \quad (2)$$

$$E_{1/2}(\text{ox}) = -\epsilon_i + E_r(\text{ox}) + \text{constant} \quad (3)$$

where $E_r(\text{red})$ and $E_r(\text{ox})$ stand for the relaxation energies (negative) which correspond to an extra stabilization of the reduced and oxidized product, respectively, by changes of the orbital and correlation energies upon the electron transfer. For dioxolene complexes, these quantities might be the dominant contributions to the redox potentials. The spectroscopic studies of the Mn^I and Re^I quinone and catecholate complexes suggest that $E_r(\text{ox})$ is the most important term, especially for the $[\text{M}(\text{CO})_2(\text{L})_2(\text{DBSQ})]$ which are oxidized to exceptionally stable quinone complexes with a delocalized $\text{M}(\text{DBQ})^+$ bonding.^{28–31} Consequently, the oxidation potentials of $[\text{Re}(\text{CO})_2(\text{PPh}_3)_2(\text{DBSQ})]$ and $[\text{Re}(\text{CO})_2(\text{AsPh}_3)_2(\text{DBSQ})]$, and, to a lesser extent, also of $[\text{Re}(\text{CO})_2\{\text{P}(\text{OPh})_3\}_2(\text{DBSQ})]$, are more negative than expected either from the general trend between the oxidation and reduction potentials (Figure 4) or from the $\sum E_L(\text{L})$ electrochemical parameters.

Oxidation States and the Co-ligand Effects. Compounds investigated in this study have three electrons in two frontier orbitals, the metal $d(\pi)$ and dioxolene $3b_1$, whose interaction is symmetry allowed. Therefore, we should distinguish between $[\text{M}^I(\text{DBSQ})]$ and $[\text{M}^{II}(\text{DBCat})]$ valence isomers characterized by $[(d(\pi))^2(3b_1)^1]$ and $[(3b_1)^2(d(\pi))^1]$ electron configurations, respectively. Alternatively, very strong $\text{M} \rightarrow \text{DBSQ} \pi$ -back-donation could result in a delocalized $\text{M}(\text{DBDiox})$ bonding characterized by a $[(d(\pi) + 3b_1)^2(d(\pi) - 3b_1)^1]$ configuration.

The spectroscopic and electrochemical data discussed in the preceding sections provide compelling evidence that all the $[\text{M}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$, $n = 0, 1, 2$, complexes investigated may best be formulated as containing a radical-anionic DBSQ ligand bound to a formally M^I central atom with a spin-paired d^6 configuration, regardless the number of the CO ligands and the nature of the co-ligand(s) L. This conclusion is also in full agreement with the molecular structure⁶⁶ of $[\text{Re}(\text{CO})_3(\text{PPh}_3)(\text{DBSQ})]$ which meets all the usual structural criteria^{2,3,11,67} for a coordinated semiquinone ligand.

The influence of the nature of the co-ligands on the properties of the $[\text{M}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$, $n = 0, 1, 2$, complexes may be interpreted by competitive $\text{M} \rightarrow \text{DBSQ}$ and $\text{M} \rightarrow \text{CO}$ π -back-bonding. From this point of view, comparison of the data obtained for the $[\text{Re}(\text{CO})_{4-n}(\text{PPh}_3)_n(\text{DBSQ})]$ ($n = 0, 1, 2$) series, summarized in Table 5, is especially revealing. Data obtained on other $[\text{M}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$ ($n = 0, 1, 2$; $\text{M} = \text{Re}, \text{Mn}$) series follow identical trends, see Tables 1–4. Increasing electron donation to the metal atom from the co-ligand(s) L along the $n = 0, 1, 2$ series or by using a more basic L raises the metal $d(\pi)$ orbital energy. This is manifested by the shift of the $\text{Re} \rightarrow \text{DBSQ}$ MLCT absorption band to lower energies. The metal atom becomes a stronger π -donor, and both the $\text{M} \rightarrow \text{DBSQ}$ and $\text{M} \rightarrow \text{CO}$ π -back-bonding are strengthened. This is accompanied by a large decrease of the average $\text{C}=\text{O}$ stretching force constants k_{av} . For example, going from $[\text{Re}(\text{CO})_4(\text{DBSQ})]$ to $[\text{Re}(\text{CO})_3(\text{PPh}_3)(\text{DBSQ})]$, the k_{av} value drops by 101 N m^{-1} . The replacement of another CO ligand in $[\text{Re}(\text{CO})_3(\text{PPh}_3)(\text{DBSQ})]$ to $[\text{Re}(\text{CO})_2(\text{PPh}_3)_2(\text{DBSQ})]$ results in the k_{av} decrease by another 108 N m^{-1} . For comparison, the same sequential CO substitutions in the $[\text{Re}(\text{CO})_4(\text{bpy})]^+$ complex are accompanied⁶⁸ by a k_{av} decrease by 90 and 60 N m^{-1} only, see Table 1, suggesting that the π -acceptor capacity of the DBSQ ligand is significantly smaller than that of 2,2'-bipyridine. IR data thus show that the changes in the electron density on the metal atom induced by the co-ligand(s) are compensated mostly by the π -back-bonding to the CO-ligands.

Nevertheless, the properties of the $[\text{M}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$ complexes studied are strongly influenced by the $\text{M} \rightarrow \text{DBSQ}$ π -back-bonding whose extent depends on the co-ligands. This is shown by coherent trends of all relevant parameters listed in Table 5. The decrease of the intra-DBSQ $\nu(\text{C}=\text{O})$ frequency and of the g factor and parallel increase of the Re hyperfine splitting constant a_{Re} with decreasing number of CO ligands along the $[\text{Re}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$, $n = 0, 1, 2$, series point to an increasing donation of the $d(\pi)$ electron density from Re to the $3b_1$ (*i.e.* $\text{C}=\text{O}$ antibonding) orbital. Correlations between these parameters (see Figures 2 and 5) indeed show that they reflect the same structural factor, namely the $\text{Re}-\text{DBSQ}$ π -delocalization that results from the $d(\pi) - 3b_1$ mixing. Parallel evidence for increasing $\text{Re}-\text{DBSQ}$ π -interaction along this series is provided by the electronic transition which changes in character along the $[\text{Re}(\text{CO})_{4-n}(\text{PPh}_3)_n(\text{DBSQ})]$, $n = 0, 1, 2$, series from $d(\pi) \rightarrow 3b_1$ MLCT to partly delocalized ($d(\pi) + 3b_1$) \rightarrow ($d(\pi) - 3b_1$). This is manifested by increasing excited

Figure 5. Correlation of the intra-DBSQ $\nu(\text{C}=\text{O})$ stretching frequency (●) and of the oxidation potential $E_{1/2}(\text{ox})$ (■) with the Re hyperfine splitting constants, a_{Re} , in the $[\text{Re}(\text{CO})_{4-n}(\text{PPh}_3)_n(\text{DBSQ})]$ series.

state distortion of the bonds involved in the $\nu(\text{Re}-\text{O})$ vibrational mode relative to the distortion of the DBSQ $\text{C}=\text{O}$ bonds (see Table 5, $\Delta(\text{Re}-\text{O})/\Delta(\text{C}=\text{O})$). Increasing $\text{Re} \rightarrow \text{DBSQ}$ π -back-bonding also results in strengthening of the $\text{Re}-\text{O}$ bond and, possibly, of the electronic and vibrational coupling within the

$\text{Re}-\text{O}-\text{C}_1-\text{C}_2-\text{O}$ chelate ring, as is shown by increasing $\nu(\text{Re}-\text{O})$ frequency with decreasing number of CO ligands. The negative shift of redox potentials with increasing electron donation from the co-ligand(s) reflects an increase in the energy of the DBSQ $3b_1$ redox orbital caused by increasing mixing with the metal $d(\pi)$ orbital. In addition, extra stabilization of $[\text{M}(\text{CO})_2(\text{L})_2(\text{DBQ})]^+$ oxidation products^{28–31} contributes to the drop in oxidation potentials between tricarbonyls and dicarbonyls. Interestingly, a correlation was found between $E_{1/2}(\text{ox})$ and the parameters that reflect the strength of the $\text{Re}-\text{DBSQ}$ π -interaction, namely a_{Re} and the intra-DBSQ $\nu(\text{C}=\text{O})$ frequency (see Figure 5). Apparently, the increase of the delocalization energy upon the oxidation depends on the composition of the coordination sphere in the same way as the π -interaction within the $\text{Re}(\text{DBSQ})$ chelate ring itself. Interestingly, the sensitivity of the spectroscopic and electrochemical parameters to the co-ligand and even solvent nature is higher in the dicarbonyl than tricarbonyl series, apparently because of lower π -acceptor capacity of the $\text{M}(\text{CO})_2$ fragment compared with that of $\text{M}(\text{CO})_3$.

The spectroscopic and electrochemical data thus provide definite evidence for a limited π -donation from Re^I or Mn^I to the DBSQ ligand whose extent may be finely tuned by the co-ligands. The absolute magnitude of the $\text{M} \rightarrow \text{DBSQ}$ π -back-donation remains, however, rather low. Importantly, all the spectroscopic parameters change gradually with changing composition of the coordination sphere, ruling out any switch-over to a valence isomer other than $[\text{M}^I(\text{DBSQ})]$ within the $[\text{M}(\text{CO})_{4-n}(\text{L})_n(\text{DBSQ})]$ ($n = 0, 1, 2$) series, regardless of the nature of the co-ligands. The carbonyl–semiquinone complexes

 (68) Stor, G. J.; Hartl, F.; van Outersterp, J. W. M.; Stufkens, D. J. *Organometallics* **1995**, 14, 1115.

of Re^{I} and Mn^{I} thus behave differently from some other semiquinone complexes, *e.g.* of Cu or Co, that exhibit a co-ligand-controlled $[\text{Cu}^{\text{I}}(\text{L}_2)(\text{DBSQ})]/[\text{Cu}^{\text{II}}(\text{L}_2)(\text{DBCat})]$, $[\text{Mn}^{\text{II}}(\text{L}_2)(\text{DBSQ})_2]/[\text{Mn}^{\text{III}}(\text{L}_2)(\text{DBCat})(\text{DBSQ})]/[\text{Mn}^{\text{IV}}(\text{L}_2)(\text{DBCat})_2]$, or $[\text{Co}^{\text{II}}(\text{DBSQ})]/[\text{Co}^{\text{III}}(\text{DBCat})]$ switching.^{12–18} Noteworthy, the metal $d(\sigma)$ and dioxolene $3b_1(\pi^*)$ frontier orbitals of the bistable Cu and Co semiquinone complexes are orthogonal, not interacting with each other. It thus appears that the bistability of the Re^{I} — and Mn^{I} —semiquinones is prevented by the direct π -interaction between the $d(\pi)$ metal-HOMO and the $3b_1$ DBSQ-SOMO and by the presence of CO ligands which very effectively compensate for the changes in the electron density on the metal atom. Although the $\text{M} \rightarrow \text{DBSQ} \pi$ -bonding becomes more important upon raising the electron density on the metal atom, the CO ligands are far better π -acceptors, thus

“shielding” the semiquinone ligand from the metal-localized electronic effects induced by the co-ligands and keeping the $d(\pi)$ electrons energetically well below the $3b_1$ SOMO of the DBSQ ligand. The amount of electron density transferred from the metal to the semiquinone ligand is then not sufficient to induce the structural changes necessary¹¹ for a switchover to the $[\text{M}^{\text{II}}(\text{DBCat})]$ valence isomer.
