27 **Abstract**

28           The occurrence of cylindrospermopsin (CYN) in toxic blooms of cyanobacteria  
29 is increasing in both frequency and distribution over the world. CYN persistence in  
30 water potentiates its accumulation in a wide range of aquatic animals destined to human  
31 consumption representing a serious problem. The aim of this work was to study for the  
32 first time the influence of cooking (boiling and steaming) for 1 or 2 min, on the stability  
33 of CYN in muscle of fish (*Oreochromis niloticus*) contaminated under laboratory  
34 conditions, also analyzing the waters in which samples were cooked. CYN was  
35 extracted and quantification was carried out by a developed and validated UPLC-  
36 MS/MS method. The results show that concentrations of CYN in fish are dependent on  
37 the cooking method, being the steaming for 2 min the most effective in reducing CYN  
38 levels (26%), followed by boiling for 2 min (18%), and significant differences have  
39 been found between the two periods assayed (1 min vs. 2 min). CYN was also detected  
40 in waters in which fish muscles were cooked in the range 0.10-0.28 µg/L. Moreover,  
41 characteristic decomposition products depending on the type of cooking were detected  
42 for the first time among the results of these treatments. The present findings emphasize  
43 the need for further studies to evaluate the influence of cooking in the presence of CYN  
44 in fish for a more realistic risk evaluation for the human health.

45 **Keywords:** Cylindrospermopsin, Fish, Steaming, Boiling, decomposition products.

46

## 48 1. Introduction

49 Cyanotoxins, produced by cyanobacteria, are increasingly perceived as a global  
50 water-quality issue growing in scope and persistence (Loftin et al., 2016). Potential  
51 human illness and mortality may occur following direct consumption or indirect  
52 exposure to contaminated organisms or toxins in the environment (Jasim and  
53 Saththasivam, 2016). In this group, an important emergent toxin is Cylindrospermopsis  
54 (CYN), produced by several cyanobacteria such as *Cylindrospermopsis raciborskii*  
55 (Ohtani, Moore, & Runnegar, 1992), *Umezakia natans* (Harada et al., 1994), *Anabaena*  
56 *bergii*, *Aphanizomenon ovalisporum*, *Aphanizomenon flos-aquae* and *Raphidiopsis*  
57 *curvata* (Falconer, 2006). Structurally, CYN (C<sub>15</sub>H<sub>21</sub>N<sub>5</sub>O<sub>7</sub>S, M=415.43) is an alkaloid  
58 consisting of a tricyclic guanidine moiety combined with hydroxymethyluracil (Ohtani  
59 et al., 1992). It has hepatotoxic, general cytotoxic and neurotoxic effects, affecting  
60 plants, several aquatic organisms and mammals with different degrees of damage  
61 (Prieto, Campos, Cameán & Vasconcelos, 2011; Puerto et al., 2011; Gutiérrez-Praena et  
62 al., 2014; Guzmán-Guillén et al., 2015a; He et al., 2016). In the normal pH range of  
63 natural waters, it is a zwitterion, making it highly water-soluble, as much as 90% of  
64 total CYN is found outside the cells (He et al., 2016). The relatively high stability of  
65 CYN to light and over a wide range of pH and temperature (21-100°C), although  
66 decomposition of CYN occurs after incubation at high temperatures combined with  
67 alkaline pH, might have significant consequences for aquatic environments, (Chiswell  
68 et al., 1999; Adamski et al, 2016a).

69 The high levels and persistence of CYN in waters can potentiate its  
70 accumulation in a wide range of aquatic animals (Gutiérrez-Praena, Jos, Pichardo,  
71 Moreno & Cameán, 2013; Freitas et al., 2016). CYN has been detected in lake samples  
72 showing extracellular superficial values ranging from 2.6 to 126 µg/L, exceeding the  
73 recommended safety value of 1 µg/L in drinking water, and in tissues from *Salmo trutta*  
74 trouts (up to 2.7 ng/g) (Messineo, Melchiorre, Di Corcia, Gallo & Bruno, 2010). CYN  
75 was also found to contaminate crayfish (*Cherax quadricarinatus*, up to 4.3 µg/g) and  
76 fish (*Melanotaenia eachamensis*, up to 1.2 µg/g) from a small Australian aquaculture  
77 pond (Saker & Eaglesham, 1999), as well as freshwater mussels (*Anodonta cygnea*, up  
78 to 2.52 µg/g) in a 16-day exposure study (Saker, Metcalf, Codd, & Vasconcelos, 2004).

79 Berry, Jaja-Chimedza, Dávalos-Lind, & Lind (2012) showed accumulation of CYN  
80 (0.09-1.26 µg/kg) in several species of finfish (*Oreochromis aureus*, *Dorosoma*  
81 *mexicana*, *Bramocharax cabelleri*, *Heterandria jonesii*, *Vieja* sp., *Cichlasoma* sp. and  
82 *Rhamidia* sp.) caught and consumed locally in the Catemaco Lake. Therefore, this fact  
83 constitutes a serious concern, especially if the organisms can be destined to human  
84 consumption (Messineo et al., 2010).

85         Based on the potential risks for human health, a provisional tolerable daily  
86 intake (TDI) of 0.03 µg CYN/kg of body weight has been proposed by Humpage &  
87 Falconer (2003). Most evaluations of the risk associated with ingestion of seafood  
88 products are performed on the product uncooked, as sold or captured (Domingo, 2011;  
89 Chiocchetti, Piedra, Vélez, & Devesa, 2016). However, fish is normally processed  
90 and/or cooked before consumption, and these practices can alter the concentration of  
91 CYN available in food (Freitas et al., 2016). In addition, one important concern for  
92 public health is that cyanotoxins-contaminated fish, either raw or cooked, look normal  
93 and undetectable by taste, appearance and smell (Wong, Hung, Lee, Mokb, & Kam,  
94 2009). In this sense, studies of the influence of cooking on food are required to achieve  
95 a more accurate knowledge of the actual intake and reducing the risk for the consumer  
96 in the last step of the food chain.

97         With respect to the effects of cooking on the increase or decrease of  
98 contaminants in food (especially fish and meat), the studies are mainly focused on a  
99 number of chemical pollutants, such as metals (Laparra, Vélez, Montoro, Barberá, &  
100 Farré, 2003), polychlorinated biphenyls, polycyclic aromatic hydrocarbons -PAHs-,  
101 hexachlororobenzene (HCB) (Perelló, Martí-Cid, Llobet, Castell, & Domingo, 2009),  
102 dioxins (Hori et al., 2005), as has been reviewed by Domingo (2011) and Chiocchetti et  
103 al. (2016). It seems that these changes depend mainly on the cooking conditions  
104 including time, temperature, and medium of cooking, with a clear general tendency to  
105 increase metal concentrations after cooking (Domingo, 2011). Concerning cyanotoxins,  
106 studies are scarce, and they have shown different patterns of variation for microcystins  
107 (MCs), nodularin (NOD), paralytic shellfish toxins (PSP-toxins) and CYN in clams,  
108 mussels, scallops, prawns and fish (Van Buynder et al., 2001; Morais, Augusto,  
109 Carvalho, Vale, & Vasconcelos, 2008; Bruno et al., 2009; Wong et al., 2009; Zhang,  
110 Xie, & Chen, 2010; Guzmán-Guillén, Prieto, Moreno, Soria, & Cameán, 2011; Freitas,  
111 Azevedo, Carvalho, Campos, & Vasconcelos, 2014; Freitas et al., 2016).

112 It has been previously demonstrated that boiling fish muscle was able to reduce  
113 levels of unconjugated MCs (MC-LR, -RR and -YR) in cooked tilapia fish in a range  
114 between 34% and 59% (Guzmán-Guillén et al., 2011). On the contrary, MCs mean  
115 concentrations were significantly higher in muscle of bighead carp after boiling, and in  
116 clams boiled for 5 and 15 min, compared to unboiled controls (Zhang et al., 2010;  
117 Freitas et al., 2014). Concerning CYN, only Freitas et al. (2016) carried out a recent  
118 study on changes on CYN concentration in edible mussels after boiling or steaming,  
119 showing no significant alterations in toxin concentration due to the cooking processes,  
120 although the toxin was found in the cooking water. Therefore, the exact incidence of  
121 different cooking and eating practices on cyanotoxin levels and exposure remain  
122 uncertain (Testai et al., 2016).

123 Previous studies concerning cooking processes of aquatic organisms have  
124 determined MCs by ELISA (Morais et al., 2008; Bruno et al., 2009), High Performance  
125 Liquid Chromatography-Diode-Array (HPLC-DAD) (Metcalf & Codd, 2000), or Liquid  
126 Chromatography-Mass Spectrometry (LC-MS) (Zhang et al., 2010; Guzmán-Guillén et  
127 al., 2011; Freitas et al., 2014), as LC-MS has been proved suitable for determination of  
128 MCs in natural blooms, cyanobacterial strain cultures and biological samples (Cameán,  
129 Moreno, Ruíz, & Picó, 2004; Ruíz, Cameán, Moreno, & Picó, 2005). PSP-toxins have  
130 been analyzed by HPLC-fluorescence (Wong et al., 2009), and NOD and CYN by LC-  
131 tandem Mass Spectrometry (LC-MS/MS) (Van Buynder et al., 2001; Freitas et al.,  
132 2016). However, these have not been conducted by Ultra-performance liquid  
133 chromatography tandem mass spectrometry (UPLC-MS/MS), which has become the  
134 technique of choice for analysis of different cyanotoxins (several variants of MCs,  
135 NOD, CYN, anatoxin-a, homo-anatoxin and domoic acid) in water and complex  
136 matrices, and offers excellent specificity and sensitivity for their detection and  
137 quantification (Oehrle, Southwell, & Westrick, 2010; Adamski et al., 2016a,b; Greer et  
138 al., 2016; Pekar et al., 2016).

139 Besides, in most of the above-mentioned studies, the structure and properties of  
140 the toxin decomposition products have not been described. Only Adamski et al. (2016a,  
141 b) have investigated the stability of CYN from a *C. raciborskii* culture under the  
142 influence of pH, temperature and irradiation, characterizing its forming products by  
143 UPLC-MS/MS. Considering the relevant toxic properties of CYN, it would be of  
144 interest to investigate the mechanism of its decomposition in intoxicated fish after

145 cooking. For this purpose, orbitrap can provide a much higher mass resolution and mass  
146 precision compared to triple quadrupole mass analyzers (MS/MS) (Gerssen, Mulder, &  
147 Boer, 2011).

148 In view of these reports, the aim of the present study was to investigate for the  
149 first time the influence of common practices for cooking of fish meat and obtention of  
150 fish soups around the world, such as boiling and steaming, on CYN concentration in  
151 muscle of fish (*Oreochromis niloticus*) contaminated under laboratory conditions,  
152 assaying two different periods of time (1 and 2 min). Moreover, a precise  
153 characterization of CYN by-products in fish samples under the influence of cooking  
154 was conducted.

## 155 **2. Materials and Methods**

### 156 *2.1 Chemicals and reagents*

157 Cyindrospermopsin standard (purity 95%) was supplied by Alexis Corporation  
158 (Lausen, Switzerland). Standard solutions of CYN were prepared in Milli-Q water  
159 (100 µg/mL) and diluted as required for their use as working solutions (1-100 µg/L). All  
160 chemicals and reagents used in this study were analytical grade materials. HPLC-grade  
161 methanol, dichloromethane, acetonitrile, and trifluoroaceticacid (TFA) were purchased  
162 from Merck (Darmstadt, Germany). Deionized water (418 MΩ/cm resistivity) was  
163 obtained from a Milli-Q water purification system (Millipore, Bedford, USA). BOND  
164 ELUT<sup>®</sup> Carbon cartridges (PGC column) (500 mg, 6 mL) and Bakerbond<sup>®</sup> C18  
165 cartridges (500 mg, 6 mL) were supplied by Agilent Technologies (The Netherlands,  
166 Europe) and Dicsa (Andalucía, Spain), respectively. For UHPLC-MS/MS analyses  
167 reagents were of LC-MS grade. Water and acetonitrile were purchased from VWR  
168 International (Fontenay-sous-Bois, France) and formic acid was purchased from Fluka  
169 (Stainheim, Germany).

### 170 *2.2 Experimental setup*

171 Tilapia fish (*Oreochromis niloticus*) were supplied by Valenciana de Acuicultura  
172 (fish hatchery of Valencia, Spain) and were transferred to the laboratory where they  
173 were acclimatized and were kept during 15 days in two aquariums (8  
174 individuals/aquarium) with 96 L of tap-water, and the temperature was kept constant  
175 (21 ± 2°C). Fish were fed daily (0.3 g/day) only with commercial fish food (Dibaq S.L.,

176 Segovia, Spain). After acclimation, they were sacrificed, dissected and each muscle  
177 sample was cut into approximately 4 g portions. Five fish muscle samples per cooking  
178 method (n=5) were spiked with 500  $\mu$ L of a stock solution containing 100  $\mu$ g CYN/L  
179 (equivalent to 50 ng CYN/g dry weight -d.w.-), directly injecting the toxin into the  
180 muscle. This concentration was considered relevant from a naturally environmental  
181 point of view and considering the accumulation of CYN found in aquatic organisms in  
182 other studies (Seifert, McGregor, Eaglesham, Wickramasinghe, & Shaw, 2007; Kinnear,  
183 2010; Freitas et al., 2016).

### 184 *2.3 Cooking of fish samples*

185         Following spiking of samples with the toxin, they were cooked by boiling and  
186 steaming, for 1 and 2 min. The experimental control group was CYN-fortified fish  
187 muscle which was not processed, being directly extracted for toxin quantification. The  
188 assays were always carried out by quintuplicate (n=5).

189         To test the boiling method, the fish muscle sample was introduced into pots of  
190 stainless steel with cool tap water (50 mL). In the case of steaming, the sample was put  
191 into a metal food steamer where the food is kept separate from the boiling water but has  
192 direct contact with the steam. Both for boiling and steaming, the fish muscle was  
193 introduced into the pot or onto the food steamer, respectively, with cool water, heated to  
194 boiling (100°C) and then continued to boil for 1 and 2 min. The remaining water in  
195 which fish muscle was cooked was also analyzed. Water evaporation was prevented in  
196 this study, by the use of a top cover, in order to simulate the usual household cooking  
197 procedure. No salt, spices or any other additional ingredients were added to the samples.  
198 Values are expressed as ng CYN/g dw or  $\mu$ g CYN/L, representing the unconjugated  
199 fraction of CYN.

200         Muscle fish weights were recorded before (approximately 4 g) and after  
201 cooking. The final mean weights of fish muscle after boiling were  $3.78 \pm 0.21$  g (1 min)  
202 and  $3.68 \pm 0.14$  g (2 min), and after steaming, means were  $3.85 \pm 0.12$  g (1 min) and  
203  $3.91 \pm 0.19$  g (2 min). All samples were frozen at -80°C and lyophilized (Cryodos 80  
204 model, Telstar, Tarrasa, Spain) before CYN was extracted. Once the lyophilization  
205 process was finished, the samples were weighed, and the final mean lyophilized weight  
206 was  $0.86 \pm 0.08$  g dw. Thus, the mean loss of weight due to the cooking and  
207 lyophilization processes was approximately 78.5 %.

#### 208 2.4 Extraction of CYN from tissues and waters and clean up

209 After cooking and lyophilization of the samples, CYN was extracted from fish  
210 muscles and from water samples used for boiling and steaming. Extraction and clean up  
211 procedures were performed according to the validated methods of Guzmán-Guillén et  
212 al. (2015b) in muscle samples, and Guzmán-Guillén, Prieto, González, Soria-Díaz, &  
213 Caméan (2012) in water samples, with some modifications, applying a UPLC-MS/MS  
214 method in the present study, instead of the former LC-MS/MS system, reducing costs  
215 and time of analysis (5 min vs. 20 min run, with a retention time of 1.30 min vs. 9.55  
216 min) (Guzmán-Guillén et al., 2015b). Regression equations were obtained for this  
217 method by linear regression of two 7-point calibration curves calculated from CYN  
218 standards prepared in blank extracts from lyophilized muscle (2; 10; 15; 20; 40; 60 and  
219 100 ng/g dw) and from blank boiling water (processed water) (1; 5; 7.5; 10; 20; 30 and  
220 50 µg/L). Limits of detection (LOD) and quantitation (LOQ) were estimated according  
221 to the equation  $Y_{LOD \text{ or } LOQ} = Y_{blank} + nS_{blank}$ , where  $Y_{blank}$  and  $S_{blank}$  are the average value  
222 of 10 blank signals and its corresponding standard deviation, and  $n$  is a constant (3 for  
223 LOD and 10 for LOQ). These values are then converted into concentration by using the  
224 calibration functions obtained before. Recoveries and precision (within-day and  
225 between-day) were also assessed by calculating the relative standard deviation (RSD).  
226 This was carried out by spiking before extraction, in triplicate (n=3) within the same  
227 day, and on three different days, blank extracts from lyophilized muscle or from  
228 processed waters at three levels of CYN concentration (5, 20 and 50 µg/L, equivalent to  
229 10, 40 and 100 ng CYN/g dry muscle).

#### 230 2.5 Analytical determination

231 Chromatographic separation was performed using a UPLC Acquity (Waters)  
232 coupled to Xevo TQS-micro (Waters) consisting of a triple quadrupole mass  
233 spectrometer equipped with an electrospray ion source operated in positive mode.  
234 UPLC analyses were performed on a 50 x 2.1 mm Acquity BEH C18 1.7 µm column.  
235 The flow rate was 0.45 mL min<sup>-1</sup>. Chromatographic separation was performed using a  
236 binary gradient consisting of (A) water, and (B) methanol. Both eluents contained 0.1%  
237 formic acid (v/v). Injection volume was 5 µL. The elution profile was: 0 % B (0.8 min),  
238 linear gradient to 90% B (2.2 min), 90 %B (1 min) and finally 100 % B (1 min).  
239 Multiple Reaction Monitoring (MRM) experiment was applied where the parent ions

240 and fragments ions were monitored at Q1 and Q3, respectively. The transitions for the  
241 analyte CYN are: 416.2/194.0, and 416.2/176.0. The transition 416.2/194.0 was chosen  
242 for quantitation of CYN and the transition 416.2/176.0 as confirmatory. For UPLC-ESI-  
243 MS/MS analyses, the mass spectrometer was set to the following optimised tune  
244 parameters: Capillary voltage: 3.0 kV, Source Temperature: 500°C and source Gas  
245 flow: 1000 L/h.

#### 246 *2.6 Characterization of CYN decomposition products after boiling and steaming by* 247 *UHPLC-MS/MS Orbitrap*

248 In order to characterize the possible decomposition products of unconjugated  
249 CYN by the effects of cooking, the same cooking procedures were reproduced for 2  
250 min, with two fish muscle samples per cooking method by injecting into the muscle 500  
251 µL containing 80 µg CYN/mL (equivalent to 40 µg CYN/g d.w.), as unconjugated CYN  
252 contents detected after spiking with 50 ng CYN/g d.w. were too low to be analyzed by  
253 Orbitrap. This quantity was the same that Adamski et al. (2016b) used in their  
254 experiment to identify CYN by-products in a *C. raciborskii* culture. Afterwards,  
255 cooking of samples and extraction of CYN from them were carried out as described in  
256 sections 2.3 and 2.4, respectively.

257 All analysis were performed using a Thermo Scientific liquid chromatography  
258 system consisting of a binary UHPLC Dionex Ultimate 3000 RS, connected to a  
259 quadrupole-orbitrap Qexactive hybrid mass spectrometer (Thermo Fisher Scientific,  
260 Bremen, Germany), which was equipped with a heated-electrospray ionization probe  
261 (HESI-II). Xcalibur software was used for instrument control, data acquisition and data  
262 analysis. Trace Finder 3.3 software was used for data analysis also. Chromatographic  
263 separations were performed using an Acquity UPLC BEH (bridged ethyl hybrid) C18  
264 column (2.1 × 100 mm, 1.7 µm) (Waters). The column was maintained at 40°C and  
265 eluted under the following conditions: 100% of eluent A over 2 min and gradient  
266 elution from 100% to 30% of eluent A over 10 min at a flow rate of 0.3 mL min<sup>-1</sup>.  
267 Eluent A was water/formic acid (0.1%, v/v), and eluent B was acetonitrile/formic acid  
268 (0.1%, v/v). Injection volume was 5µL.

269 MS detection of the CYN decomposition products observed by Adamski et al.  
270 (2016a, b) by the influence of pH, temperature and irradiation was performed in the  
271 present study with the Q-Exactive Orbitrap mass spectrometer through the accurate *m/z*

272 measurement of each molecule, by scanning from 100 to 1000  $m/z$ , in positive and full  
273 scan (FS) mode at a resolution of 70000 (full width half maximum, FWHM at  $m/z$  200).  
274 Each compound observed was associated with a chemical formula hypothesis. Then, a  
275 relative mass error expressed in ppm was calculated, a result lower than 5 ppm being  
276 considered as an acceptable value (Makarov, Denisov, Lange, & Horning, 2006). The  
277 Q-Exactive Orbitrap was also used to sustain the identity of CYN decomposition  
278 products performing tandem mass spectrometry (MS<sup>2</sup>) experiments using the parallel  
279 reaction monitoring (PRM) method, which was acquired in positive mode and a  
280 resolution of 17500, with an isolation window of 1  $m/z$ , and normalized collision energy  
281 was set at 35 eV. The selected  $[M+H]^+$  were 214.15500, 290.08052, 292.09617,  
282 336.16663, 338.18228, 414.10780, 416.12345 and 434.13401. The identity of the  
283 compounds was then sustained by the agreement between theoretical and experimental  
284 isotopic patterns, and by the consistency with the resulting product ions formed during  
285 MS<sup>2</sup> analysis. HESI source parameters were as follows: spray voltage 3.5 kV, capillary  
286 temperature 320°C, sheath, auxiliary and sweep gas flow rate (N<sub>2</sub>) 45, 15 and 2  
287 (arbitrary units) respectively, probe heater temperature 350°C and S-Lens RF level 50.  
288 Considering the areas of the corresponding chromatographic peaks, a relative  
289 comparison among different cooking treatments and the control was carried out by  
290 selecting the following fragments:  $m/z$  194.12879 for the molecular ions  $[M+H]^+$   
291 416.12345 and 336.16663;  $m/z$  178.13387 for the molecular ions  $[M+H]^+$  338.18228  
292 and 214.15500;  $m/z$  292.09617 for the molecular ion  $[M+H]^+$  434.13401;  $m/z$  210.12427  
293 for the molecular ion  $[M+H]^+$  290.08052;  $m/z$  212.13935 for the molecular ion  $[M+H]^+$   
294 292.09617, and the fragment ion at  $m/z$  192.11314 for the molecular ion  $[M+H]^+$   
295 414.10780.

## 296 2.7 Statistical Analysis

297 Results were subjected to one-way analysis of variance (ANOVA) with the  
298 statistical package INSTAT, Graph Pad<sup>TM</sup>, and represent mean  $\pm$  standard deviation  
299 (SD) of 5 samples per group. Differences in mean values between groups were assessed  
300 by the Tukey's test and were considered statistically significant at  $p < 0.05$  level.

## 301 3. Results

302 Concerning UPLC-MS/MS, the LOD and LOQ obtained for the muscle were 1.6  
303 and 3.4 ng/g dw, respectively, compared to the former 2.5 and 7.3 ng/g dw obtained by

304 LC-MS/MS (Guzmán-Guillén et al., 2015b). In the case of waters, LOD and LOQ were  
305 0.36 and 0.40  $\mu\text{g/L}$ , respectively, compared to the former 0.5 and 0.9  $\mu\text{g/L}$  obtained by  
306 LC-MS/MS (Guzmán-Guillén et al., 2012). This contributes to a better sensitivity of the  
307 analysis by UPLC-MS/MS compared to LC-MS/MS. The linear ranges were within 2-  
308 100 ng CYN/g dw for the muscle (regression equation  $y = 97.826x - 33.396$ ;  $r^2 =$   
309  $0.9962$ ), and within 0.4-50  $\mu\text{g/L}$  for waters (regression equation  $y = 165.43x + 5.0475$ ;  
310  $r^2 = 0.9989$ ). Recoveries were 90, 100 and 100% for muscle, and 96, 94 and 106% for  
311 waters, for the CYN spiked levels of 5, 20 and 50  $\mu\text{g/L}$ , respectively, and RSDs were  
312 below 20% in all cases. All these values are acceptable in comparison to the recovery  
313 and RSD ranges depending on the analyte level (González & Herrador, 2007).

314 Both cooking treatments applied in the present study produced a significant  
315 decrease in unconjugated CYN concentration in fish muscles (Fig. 1). Cooking the fish  
316 reduced unconjugated CYN levels by 9 % ( $p < 0.05$ ) and 8 % ( $p < 0.05$ ) by boiling and  
317 steaming for 1 min, respectively, compared to control fish. Reductions found by  
318 cooking for 2 min were of 18% ( $p < 0.001$ ) and 26% ( $p < 0.001$ ) for boiling and  
319 steaming, respectively, compared to control fish. Moreover, significant differences have  
320 been found between the two periods assayed (1 and 2 min) for boiling ( $p < 0.05$ ) and  
321 steaming ( $p < 0.001$ ). Unconjugated CYN was also detected in waters in which fish  
322 muscles were cooked, showing values of 0.27 and 0.28 ng/mL in case of boiling for 1  
323 and 2 min, and 0.10 and 0.12 ng/mL in case of steaming for 1 and 2 min, respectively  
324 (Fig. 2). CYN was not detected in blank boiling water samples for non-cooked fish. It is  
325 important to emphasize that CYN concentration detected in the fish muscles refers to  
326 un-bound, free toxin, once the method applied to analyze these samples does not detect  
327 CYN bound to proteins.

328 The mass spectra of control, boiled and steamed samples, and of the cooking  
329 waters, revealed the presence of seven similar decomposition products. Their retention  
330 times (RT), putative chemical formula, observed  $m/z$  (experimental,  $[\text{M}+\text{H}]^+$  ions),  
331 calculated  $m/z$  (theoretical,  $[\text{M}+\text{H}]^+$  ions), mass error (ppm) and fragmentation ions with  
332 their respective information are presented in Tables 1-3. The decomposition product  
333 with  $m/z$  290.08052 was detected with  $\text{RT} \approx 1.51$  min (named as C-1). As can be  
334 observed, two of the compounds (C-2 and C-3) were detected at two different RT  
335 having the same molecular ion  $[\text{M}+\text{H}]^+$ , indicating that they may be diastereoisomers  
336 (thus named as A and B). The parent ions with  $m/z$  292.09617 were detected at  $\approx 2.42$

337 and  $\approx 3.19$  min (C-2A and C-2B, respectively.). At  $\approx 2.86$  min, slightly before CYN, its  
338 epimer 7-epi-CYN was eluted. Moreover, as seen in Fig. 4, a peak was observed at  
339  $\approx 3.25$  min, with the putative chemical formula  $C_{30}H_{42}N_{10}O_{14}S_2$  and an  $m/z$  831.24005  
340 ( $m/z$  calculated 831.23961; mass error: 0.53 ppm); this is the CYN dimer which was  
341 observed in all samples. Besides, the fragment with  $m/z$  336.16663 is observed in the  
342 mass spectrum of CYN, corresponding to the loss of  $SO_3$  from the CYN molecule due to  
343 in-source fragmentation (see Fig. 6). Then, two different peaks with the same  $m/z$   
344 336.16663 were observed at  $\approx 3.45$  min (C-3A) and  $\approx 5.15$  min (C-3B), possibly  
345 diastereoisomers. Whereas C-3B is observed in all samples, C-3A is only observed in  
346 cooked samples, but not in control uncooked samples. Finally, the decomposition  
347 product at  $m/z$  414.10780 was detected from 4.94 to 5.04 min (C-4). The decomposition  
348 products C-1, C-2A, C-2B, 7-epi-CYN, C-3B and C-4 are observed in all samples  
349 assayed, non-cooked and cooked fish and waters (Tables 1-3). Figs. 4 and 5 show the  
350 MS and  $MS^2$  spectra in FS and PRM, respectively, for characteristic decomposition  
351 products detected in control uncooked samples and in the water used for steaming. The  
352 extracted ion chromatogram for full MS experiments of CYN and its decomposition  
353 products in control and steamed fish are shown in Fig. 6.

#### 354 **4. Discussion**

355 Generally, estimations of exposure to cyanotoxins as food contaminants have  
356 assumed that the available toxin concentrations in raw and cooked food is similar,  
357 which is not true (Freitas et al., 2014). Ibelings & Chorus (2007) suggest that in  
358 industrially processed seafood, the removal of parts in which cyanotoxins can  
359 accumulate prior to processing could be effective in avoiding hazards. But this is  
360 impracticable in case of CYN accumulation in muscle of fish, as this is the edible  
361 fraction, or in cases where fish are eaten whole. Analysis of the available data by the  
362 European Food Safety Authority (EFSA) indicates that additional efforts should be put  
363 into elucidating the levels of human exposure to cyanotoxins under different scenarios.  
364 In this sense, new research should be conducted to explore the effect of cooking on the  
365 concentration of cyanotoxins in seafood (Testai et al., 2016), because these studies are  
366 few in the case of MCs (Morais et al., 2008; Bruno et al., 2009; Zhang et al., 2010;  
367 Guzmán-Guillén et al., 2011; Freitas et al., 2014) and even scarcer with CYN (Freitas et  
368 al., 2016). To our knowledge, this is the first report presenting the influence of some

369 domestic cooking treatments such as boiling and steaming on unconjugated CYN  
370 concentration in fish, characterizing its possible decomposition products.

371 In the present work, the effectiveness in reducing unconjugated CYN levels in  
372 cooked fish followed this descending order, with statistical differences: steaming 2 min  
373 > boiling 2 min > boiling 1 min  $\approx$  steaming 1 min, achieving the major reduction in  
374 CYN concentration with the longer period assayed (2 min) (Figs. 1 and 3). In this sense,  
375 boiling and steaming were able to decrease unconjugated CYN levels in fish muscle up  
376 to 18 and 26 % of the initial concentration, respectively. By contrast, in most of the  
377 cited studies carried out with the cyanotoxins MCs or CYN (only one study with the  
378 latter), boiling or steaming the food containing them (fish or shellfish), results have  
379 shown that these cooking treatments did not produce any significant reduction in toxin  
380 concentration in the tissues, even causing an increase. Our results could be explained by  
381 the high water-solubility of CYN, in direct and continuous contact with the high  
382 temperatures of the boiling water and steam, as heat processing seemed to enhance  
383 CYN extraction from fish muscles, phenomenon also observed with MCs in fish  
384 (Guzmán-Guillén et al., 2011) and with CYN in mussels (Freitas et al., 2016). This fact  
385 is reinforced by the results of the analysis of the waters in which fish were cooked,  
386 showing a small but sufficient concentration of unconjugated CYN (Fig. 2). Similarly to  
387 domestic cooking, in this study evaporation of water was prevented, and therefore lower  
388 CYN levels may have been detected in the cooking waters, compared to a situation  
389 where water is evaporated and the toxin could be more concentrated. In any case, the  
390 risks of consumption could be reduced by discarding the waters in which CYN-  
391 contaminated fish is cooked. Generally, the variation in the content of toxic agents  
392 during cooking is related to some extent to product weight losses or to a possible  
393 solubilisation of the toxicant to the liquid used for cooking (Chiocchetti et al., 2016). In  
394 this sense, some authors have observed increased toxicants concentrations in food due  
395 to weight changes after the heating process (Hori et al., 2005). In the present work the  
396 original sample weights have been taken into account, so decreases found in CYN  
397 concentrations can be associated with the cooking process itself. Moreover, it has been  
398 suggested that a decrease in CYN detection in samples could be due to the binding to  
399 enzymes (Freitas et al., 2016). Recently, varying percentages of unbound CYN were  
400 detected with incubation with different animal and plant proteins (Esterhuizen-Londt  
401 and Pflugmacher, 2016). In the present work, the decrease found in CYN levels could

402 be attributed to the cooking process itself, and this could not be explained as an increase  
403 of the conjugated fraction of the toxin, as no binding is expected in samples.

404 CYN is stable at temperatures ranging from 4-50 °C for up to 5 weeks in the  
405 dark; after 4 weeks at 50 °C, 83% of initial (1 mg/L) toxin concentration remained  
406 (Chiswell et al., 1999). Moreover, Adamski et al. (2016a) demonstrated that boiling  
407 (100°C) does not result in decomposition of CYN in acidic and neutral conditions (pH  
408 3, 5 and 7), whereas under alkaline conditions (pH 10 and 12) it reduces CYN  
409 concentration within 4 h to 47% and 18% of the initial value, respectively. In our  
410 experiment, the water boiling temperatures were higher than 100°C, which could  
411 explain the decrease in CYN concentration for the cooking processes. Besides,  
412 significantly higher pH values for steamed samples (7.9-8.9) were recorded than for the  
413 boiled ones (6.7-6.8). According to the results from Adamski et al. (2016a), this may be  
414 also the reason why higher decreases in CYN concentration were found in steamed  
415 samples, compared to the boiled ones.

416 Although a reduction in unconjugated CYN concentration up to 26% in cooked  
417 samples was observed in the present study, Freitas et al. (2016) showed in cooked  
418 mussels that boiling and steaming did not produce significant differences in CYN  
419 concentration. Differences could be attributed to the matrix (fish vs. mussels), as  
420 previously suggested by Domingo (2011). Nevertheless, in agreement with our results,  
421 they found CYN in the cooking water, with higher values for boiled than for steamed  
422 samples, suggesting that heat processing can be used to reduce the availability of this  
423 toxin in the flesh if water is discarded.

424 In the present study, a total of seven decomposition products were detected in  
425 control and cooked fish samples, six of them in all samples and one only in cooked  
426 samples, apart from the dimer observed in all samples. The dimer could be  
427 characteristic of the matrix studied (fish muscle), as Adamski et al. (2016 a, b) did not  
428 mention this compound. The decomposition products with  $m/z$  292.09617, 416.12345  
429 and 336.16663 agree with that previously observed by Adamski et al. (2016a) under  
430 high temperature. However, as a novelty, diastereoisomers for two of those three  
431 decomposition products were detected, thus naming them as C-2A, C-2B, 7-epi-CYN,  
432 C-3A and C-3B. Moreover, two more compounds were observed, agreeing with two  
433 decomposition products observed by Adamski et al., (2016b) under irradiation

434 conditions ( $m/z$  290.08052 and 414.10780, C-1 and C-4, respectively). Therefore, our  
435 results suggest that boiling and steaming could also yield some fragments that Adamski  
436 et al. (2016b) observed after irradiation of CYN.

437         Based on the fragmentation spectra by PRM obtained for all samples in the  
438 present study, every characteristic fragment from the coincident parent ions with  
439 Adamski et al. (2016a, b) have been confirmed in the present work, enabling a correct  
440 identification of the parent ions. The fragmentation pathways for these compounds have  
441 been proposed by Adamski et al. (2016a, b). The decomposition product C-1 with an  
442  $m/z$  of 290.08052 ( $RT \approx 1.51$  min) could derive from the cleavage of the uracil ring, with  
443 insertion of an oxygen atom. Its fragmentation spectra showed two fragments in all  
444 samples: one with  $m/z$  of 210.12370, another with  $m/z$  of 192.11314, by the loss of  $SO_3$   
445 and  $H_2O$ . For this parent ion, the relation among areas in the control (uncooked) sample  
446 and in the cooked ones is similar, so this would not be the main fragmentation pathway  
447 under the influence of the cooking methods assayed. The parent ions C-2A and C-2B,  
448 both with  $m/z$  292.09617 and different  $RT$ , are a reduced form of C-1, and follow a  
449 similar fragmentation pathway (Adamski et al., 2016b), giving the fragments at  $m/z$   
450 212.13935, 194.12879 and 176.11822 in all samples, although there are cases where,  
451 after cooking, the last fragment is not observed, maybe because of its low intensity in  
452 relation to the fragment at  $m/z$  194.12879. In any case, among all the decomposition  
453 products observed in steamed samples, C-2 has been the less detected, indicating that  
454 the decrease found in CYN concentration in this study by steaming does not seem to be  
455 related to the formation of this ion. 7-epi-CYN, an epimer of CYN, was eluted with a  
456  $RT \approx 2.86$  min, slightly before CYN ( $RT \approx 3.25$  min), and its five fragmentation ions were  
457 observed in all samples. This product has an S configuration for its hydroxyl group at  
458 C-7, in contrast to an R configuration in CYN (Adamski et al., 2016b). Two different  
459 peaks, possibly diastereoisomers, with the same  $m/z$  (336.16663) were observed at  
460  $\approx 3.45$  min (C-3A) and  $\approx 5.15$  min (C-3B). In this case, the sulphate group of the CYN  
461 molecule is substituted by a hydroxyl group; the subsequent loss of the uracil group and  
462  $H_2O$  yield the characteristic fragments at  $m/z$  194.12879 and 176.11822 (Adamski et al.,  
463 2016a). Since C-3A is not present in uncooked control samples, it can be assumed that it  
464 is characteristic of the cooking procedure itself (Table 1). By comparing the relative  
465 areas of this fragment in steamed and boiled muscle, a steamed/boiled ratio of 1.3 is  
466 obtained, agreeing with the higher degradation of CYN shown by the steaming process

467 compared to boiling. However, C-3B is observed in all samples, but it is not increased  
468 in the cooked samples compared to the uncooked control samples. Again, in some  
469 cases, the fragment with  $m/z$  176.11822 might not have been detected because of its low  
470 intensity in relation to the fragment at  $m/z$  194.12879. Finally, the decomposition  
471 product at  $m/z$  414.10780 (C-4, RT from 4.94 to 5.04 min) may come from the  
472 hydroxylation with dehydration of the tricyclic guanidine moiety (Adamski et al.,  
473 2016b). Loss of the uracil ring from this parent ion results in the ion at  $m/z$  272.06995,  
474 whereas loss of the sulphate group and H<sub>2</sub>O result in the ions at  $m/z$  334.15098 and  
475 192.11314, all of them detected in the present study. Of all the decomposition products  
476 observed by steaming, C-4 is the most detected, based on its relative abundance,  
477 suggesting that this might be one of the decomposition pathways when CYN  
478 degradation occurs (Fig. 5).

479 Concerning other cyanotoxins, cooking (e.g. boiling) may alter MCs  
480 concentration in aquatic edible organisms, although very contrasting results are  
481 available (Testai et al., 2016), showing various degrees of decrease (Bruno et al., 2009;  
482 Guzmán-Guillén et al., 2011), no effects (Morais et al., 2008), or even an increase  
483 (Zhang et al., 2010; Freitas et al., 2014). Bruno et al. (2009) showed that baking had no  
484 effect on MCs concentration, but stir-frying and braising resulted in 36 and 82%  
485 decrease, respectively, measured by ELISA. Moreover, 25-50% reductions in  
486 unconjugated MCs levels in cooked tilapia (by boiling and microwaving) were detected  
487 by LC-MS, being more effective boiling than microwaving (Guzmán-Guillén et al.,  
488 2011). Morais et al. (2008) reported no effect on MCs availability in mussels after  
489 boiling for 5 or 30 min. On the other hand, other authors showed an increase after  
490 boiling in MCs concentration up to 300% in fish (Zhang et al., 2010) and by 57-213%  
491 in clams (Freitas et al., 2014). Freitas et al. (2014) suggested that boiling was the most  
492 effective method for a better MC-LR extraction from clams. However, it is worth noting  
493 that they analyzed boiled clams together with the boiling water, so MC-LR levels reflect  
494 the combination of the contents in both matrices. It cannot be assumed a certain effect  
495 of the boiling treatment in their study and, therefore, their results may be not  
496 comparable to ours in this point. Besides, the chemical differences between MCs and  
497 CYN may be taken into account, as CYN is highly hydrophilic, thus a higher transfer of  
498 this toxin to water may be expected in our study.

499 Van Buynder et al. (2001) suggested that NOD is not destroyed by boiling, but  
500 simply redistributes between prawn viscera, flesh and water used for cooking. Similar to  
501 our results, steaming induced significant losses (11-24%) of PSP-toxins from several  
502 organs of scallops contributing to obtention of PSP-toxins-contaminated soups (Wong  
503 et al., 2009). Some uncertainties are related to the saxitoxins stability during cooking,  
504 since the toxins are only partially destroyed by high temperatures of cooking and are, at  
505 least in part, poured into the cooking fluids, which may still be ingested, for example  
506 when eating soups (Testai et al., 2016). A similar process may be occurring with CYN,  
507 with a possible solubilisation of the toxin into the liquid used for cooking or exuded by  
508 the cooked fish muscle.

509 Although data for CYN safety limits in tissues are scarce, a maximum allowable  
510 intake of 18  $\mu\text{g}$  CYN/day can be calculated from the TDI of 0.03  $\mu\text{g}/\text{kg}/\text{d}$  proposed by  
511 Humpage & Falconer (2003) for a 60 kg adult. Therefore, a derived health alert level in  
512 fish flesh of approximately 158  $\mu\text{g}/\text{kg}$  wet weight is obtained based upon consumption  
513 over a 14-d period of 1600 g of fish (Ibelings & Chorus, 2007). Considering these  
514 values, none of the concentrations of CYN found in fish muscle after cooking in the  
515 present study would exceed the maximum allowable values indicated, thus suggesting  
516 there would be no potential human risk.

517 In general, in view of these results, the potential human exposure to CYN due to  
518 consumption of contaminated fish based on the amount of toxin in raw fish could be  
519 over-estimated. However, transference of CYN from the tissue to the cooking waters  
520 might be taken into account, and this water should be removed to avoid its  
521 consumption. Further studies are necessary in this regard in order to not under- or  
522 overestimate the potential threat of aquatic food contaminated with cyanotoxins to  
523 human health. These studies could confirm first if the reported reductions in the levels  
524 of CYN are correlated basically with the specific cooking process and, second, with the  
525 different cooking conditions (such as time, temperature, and medium of cooking).  
526 Furthermore, some authors reported that the influence of cooking on the levels of  
527 diverse contaminants depends not only on the particular cooking process, but even more  
528 on the specific food item, probably due to the variable lipid content of the foodstuffs or  
529 to the efficient lipid removal (Domingo, 2011). Therefore, new studies carried out with  
530 different fish species would help to elucidate if the variations found in CYN  
531 concentration in the present work are species-specific too.

## 532 **5. Conclusions**

533 In conclusion, this study sheds new light on the issue of the influence of some  
534 cooking practices (boiling and steaming) on the levels of unconjugated CYN in edible  
535 organisms, being the first one conducted in fish. The results show that concentrations of  
536 CYN in fish are dependent on the cooking method, being the steaming for 2 min the  
537 most suitable, followed by boiling for 2 min, for a significant reduction of CYN levels  
538 in the fish muscles. Moreover, the decrease in CYN levels in cooked samples leads to  
539 changes in several and characteristic decomposition products depending on the type of  
540 cooking, observed for the first time under their influence. Thus, C-3A ( $m/z$  336.16663)  
541 was exclusive in cooked samples, and C-4 ( $m/z$  414.10780) is the most relevant  
542 compound found in steamed fish muscles. Therefore, for estimating real intakes of  
543 CYN, it is necessary to take into consideration levels in both the cooked and uncooked  
544 food. These findings emphasize the need for further studies to evaluate the influence of  
545 cooking in the presence of CYN in several fish species for a more realistic risk  
546 evaluation for the human health, and to investigate the possible decomposition products  
547 obtained when CYN degradation occurs under cooking conditions.

## 548 **Acknowledgements**

549 The authors would like to acknowledge the Ministerio de Economía y  
550 Competitividad of Spain (AGL2015-64558-R, MINECO/FEDER, UE) for its financial  
551 support.

## 720 **Figure Legends**

721 **Fig. 1.** Concentration of CYN (ng CYN/g dry weight-d.w.-) in fish muscles  
722 (*Oreochromis niloticus*) spiked with 500  $\mu$ L of a CYN standard solution containing 100  
723  $\mu$ g CYN/L (equivalent to 50 ng CYN/g dw) and submitted to either no treatment or to  
724 different cooking treatments for 1 and 2 min (boiling and steaming). Values are  
725 expressed as the mean  $\pm$  SD ( $n = 5$ ). The significant levels observed are  $^*p < 0.05$  or  $^{***}p$   
726  $< 0.001$  in comparison to control group (spiked and non-cooked fish),  $^{\#}p < 0.05$  or  $^{\#\#\#}p$   
727  $< 0.001$  when comparing 1 min vs 2 min within the same cooking method,  $^{\alpha}p < 0.05$   
728 when comparing steaming vs boiling within the same period,  $^{\&\&\&}p < 0.001$  in  
729 comparison to boiling for 1 min,  $^{\pm}p < 0.05$  in comparison to steaming for 1 min.

730 **Fig. 2.** Concentration of CYN (ng CYN/mL) detected in collected water samples from  
731 the boiling and steaming treatments assayed. Values are expressed as the mean  $\pm$  SD ( $n$   
732  $= 5$ ). The significant levels observed are  $^*p < 0.05$  or  $^{**}p < 0.01$  between waters for  
733 boiling and steaming within the same period of time.

734 **Fig. 3.** UPLC-MS/MS chromatograms showing CYN retention time and peak areas of a  
735 CYN-spiked control muscle sample (50 ng CYN/g dw) and not cooked (A), a CYN-

736 spiked (50 ng CYN/g dw) muscle sample submitted to steaming for 1 min (B) and a  
737 CYN-spiked (50 ng CYN/g dw) muscle sample submitted to steaming for 2 min (C).  
738 Chromatograms are presented from 0-3 min.

739 **Fig. 4.** Mass spectra of CYN ( $C_{15}H_{21}N_5O_7S$ ) and the CYN dimer ( $C_{30}H_{42}N_{10}O_{14}S_2$ ) in  
740 control (uncooked) muscle of tilapia fish (*Oreochromis niloticus*), eluting at 3.25 min,  
741 recorded (a) without fragmentation, in FS mode and (b) with fragmentation in PRM  
742 mode at 35 eV.

743 **Fig. 5.** Mass spectra of the ion 414.10780 with the chemical formula  $C_{15}H_{19}N_5O_7S$  in  
744 the water used for steaming muscle of tilapia fish (*Oreochromis niloticus*), eluting at  
745 5.03 min, recorded (a) without fragmentation, in FS mode and (b) with fragmentation in  
746 PRM mode at 35 eV.

747 **Fig. 6.** Extracted ion chromatogram (XIC) for full MS experiments of CYN and its  
748 decomposition products in control (uncooked) muscle of tilapia fish (*Oreochromis*  
749 *niloticus*) (a) and in steamed muscle of tilapia fish (*Oreochromis niloticus*) for 2 min  
750 (b).
