JACC: CARDIOVASCULAR INTERVENTIONS CME/MOC/ECME

This article has been selected as this issue's CME/MOC/ECME activity, available online at <http://www.acc.org/jacc-journals-cme> by selecting the JACC Journals CME/MOC/ECME tab.

Accreditation and Designation Statement

The American College of Cardiology Foundation (ACCF) is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians.

The ACCF designates this Journal-based CME activity for a maximum of 1 AMA PRA Category 1 Credit(s)[™]. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

Successful completion of this CME activity, which includes participation in the evaluation component, enables the participant to earn up to 1 Medical Knowledge MOC point in the American Board of Internal Medicine's (ABIM) Maintenance of Certification (MOC) program. Participants will earn MOC points equivalent to the amount of CME credits claimed for the activity. It is the CME activity provider's responsibility to submit participant completion information to ACCME for the purpose of granting ABIM MOC credit.

Update on Cardiac Catheterization in Patients With Prior Coronary Artery Bypass Graft Surgery will be accredited by the European Board for Accreditation in Cardiology (EBAC) for 1 hour of External CME credits. Each participant should claim only those hours of credit that have actually been spent in the educational activity. The Accreditation Council for Continuing Medical Education (ACCME) and the European Board for Accreditation in Cardiology (EBAC) have recognized each other's accreditation systems as substantially equivalent. Apply for credit through the post-course evaluation. While offering the credits noted above, this program is not intended to provide extensive training or certification in the field.

Method of Participation and Receipt of CME/MOC/ECME Certificate

To obtain credit for this CME/MOC/ECME, you must:

1. Be an ACC member or JACC: *Cardiovascular Interventions* subscriber.
2. Carefully read the CME/MOC/ECME-designated article available online and in this issue of the journal.
3. Answer the post-test questions. A passing score of at least 70% must be achieved to obtain credit.
4. Complete a brief evaluation.
5. Claim your CME/MOC/ECME credit and receive your certificate electronically by following the instructions given at the conclusion of the activity.

CME/MOC/ECME Objective for This Article: Upon completion, the reader should be able to: 1) select optimal vascular access for patients with prior CABG; 2) evaluate strategies to prevent and treat distal embolization; 3) compare the outcomes of DES versus BMS in SVG PCI; 4) identify the optimal treatment strategy for acute graft failure; 5) select the optimal method of revascularization in patients with prior CABG; and 6) decide between native vessel versus graft PCI in prior CABG patients.

CME/MOC/ECME Editor Disclosure: JACC: *Cardiovascular Interventions* CME/MOC/ECME Editor Michael C. McDaniel, MD, has reported that he is a Penumbra-Investigator on the EXTACT-PE trial.

Author Disclosures: Dr. Alaswad has received consulting fees from Terumo and Boston Scientific; and has been an unpaid consultant for Abbott Laboratories. Dr. Rinfret has received speaker and proctorship honoraria from Boston Scientific, Abbott Vascular Canada, Medtronic Canada, SoundBite, and Terumo US. Dr. Nicholson has been a proctor, consultant, and advisory board member for Abbott Vascular, Boston Scientific, and Medtronic. Dr. Karpaliotis has received speaker honoraria from Abbott Vascular and Boston Scientific. Dr. Mashayekhi has received consulting/speaker fees from Ashai Intecc, AstraZeneca, Biotronik, Boston Scientific, Cardinal Health, Daiichi-Sankyo, Medtronic, Teleflex, and Terumo. Dr. Cavalcante has received research grants from Medtronic and Abbott; and has been a consultant/speaker for Medtronic, Circle Cardiovascular Imaging, and Siemens Inc. Dr. Burke has received consulting and speaker honoraria from Abbott Vascular and Boston Scientific. Dr. Brilakis has received consulting/speaker honoraria from Abbott Vascular, American Heart Association (associate editor: *Circulation*), Boston Scientific, Cardiovascular Innovations Foundation (board of directors), CSI, Elsevier, GE Healthcare, InfraRedx, and Medtronic; has received research support from Regeneron and Siemens; is a shareholder in MHI Ventures; and has served on the board of trustees for the Society of Cardiovascular Angiography and Interventions. All other authors have reported that they have no relationships relevant to the contents of this paper to disclose.

Medium of Participation: Print (article only); online (article and quiz).

Update on Cardiac Catheterization in Patients With Prior Coronary Artery Bypass Graft Surgery

Ioşif Xenogiannis, MD,^{a,b} Peter Tajti, MD,^{a,b,c} Allison B. Hall, MD,^a Khaldoon Alaswad, MD,^d Stéphane Rinfret, MD,^e William Nicholson, MD,^f Dimitri Karpaliotis, MD,^g Kambis Mashayekhi, MD,^h Sergey Furkalo, MD,ⁱ João L. Cavalcante, MD,^a M. Nicholas Burke, MD,^a Emmanouil S. Brilakis, MD, PhD^{a,b}

ABSTRACT

Patients who undergo coronary bypass graft surgery often require subsequent cardiac catheterization and repeat coronary revascularization. Saphenous vein graft lesions have high rates for distal embolization that can be reduced with use of embolic protection devices. They also have high restenosis rates, which are similar with drug-eluting and bare-metal stents. Percutaneous coronary interventions of native coronary arteries is generally preferred over saphenous vein graft interventions, but can often be complex, requiring expertise and specialized equipment. Prolonged dual-antiplatelet therapy and close monitoring can help optimize subsequent clinical outcomes. (J Am Coll Cardiol Intv 2019;12:1635-49)

Patients who undergo coronary artery bypass graft surgery (CABG) often require additional revascularization because of bypass graft failure or progression of native coronary artery disease (**Figure 1**) (1,2). Due to the high risk of redo CABG, coronary revascularization is performed by percutaneous coronary intervention (PCI) in nearly all prior CABG patients, but is associated with several challenges, both clinical (high-risk patient characteristics) and technical (such as treatment of failing bypass grafts, chronic total occlusions [CTOs], and severe calcification). We sought to

provide an overview of novel developments in cardiac catheterization and PCI in prior CABG patients, as well as practical recommendations (**Central Illustration**).

ACCESS SITE SELECTION

Engagement of arterial grafts and saphenous vein grafts (SVGs) for angiography and/or PCI can be performed using either femoral or radial approach, however femoral access is associated with lower contrast and radiation dose (3). Although systematic

HIGHLIGHTS

- Additional revascularization is often needed after coronary artery bypass graft surgery and carries increased risk.
- Optimal saphenous vein graft percutaneous coronary intervention requires embolic protection devices and vasodilators.
- If feasible, recanalization of the native coronary artery is preferred over bypass graft recanalization.
- Novel technical developments and pharmacotherapy are needed to improve outcomes after coronary bypass graft surgery.

reviews of mainly observational studies have suggested similar success with radial and femoral access, in the RADIAL CABG (RADIAL Versus Femoral Access for Coronary Artery Bypass Graft Angiography and Intervention) trial, diagnostic coronary angiography via radial access was associated with a higher mean contrast volume (142 ± 39 ml vs. 171 ± 72 ml; $p < 0.01$), longer procedure time (21.9 ± 6.8 min vs. 34.2 ± 14.7 min; $p < 0.01$), greater patient air kerma radiation exposure (1.08 ± 0.54 Gray vs. 1.29 ± 0.67 Gray; $p = 0.06$), and higher operator radiation dose (first operator 1.3 ± 1.0 mrem vs. 2.6 ± 1.7 mrem; $p < 0.01$) but higher patient satisfaction as compared with femoral access (4). In observational studies, however, radial access was associated with fewer vascular complications, and reduced hospital stay (4-6). If radial access is selected, the left radial artery should be used in most cases to facilitate engagement of the left internal mammary artery (LIMA) and the other bypass grafts. When graft engagement is challenging using radial access, early conversion to femoral access should be considered (7).

PHYSIOLOGICAL ASSESSMENT OF SVGs

Although fractional flow reserve (FFR) measurement is the standard of care for assessing intermediate native coronary artery lesions, its use in SVG lesions has been controversial (Table 1) (8-10) and is subject to important limitations. First, FFR of a SVG is the result of SVG flow, flow through the native coronary artery (unless the latter is occluded), and flow via collateral vessels; hence, FFR may be normal, even when a SVG has severe stenosis. Second, the variable

rate of progression of SVG lesions affects the utility of physiological assessment in deciding to defer revascularization, and more data are warranted to determine the utility of physiological assessment (11-14).

INTERMEDIATE SVG LESIONS

As mentioned in the preceding text, in contrast to native coronary artery lesions, intermediate SVG lesions have high rates of progression, which limits the value of physiological assessment in this lesion subgroup. Despite promising early results with prophylactic stenting of such lesions in the VELETI (Moderate VEin Graft LEsion Stenting With the Taxus Stent and Intravascular Ultrasound) trial, the larger VELETI II trial did not show any improvement of clinical outcomes with stenting of intermediate SVG lesions as compared with medical therapy alone during 3-year follow-up (12-14). In addition to the 2 currently proven treatments to prevent SVG failure (aspirin and statins [15-18]), intensive low-density cholesterol lowering with Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors holds promise for preventing progression of SVG atherosclerosis and is currently being investigated for slowing the progression of intermediate SVG lesions (Alirocumab for Stopping Atherosclerosis Progression in Saphenous Vein Grafts [ASAP-SVG]; NCT03542110).

PREVENTION AND TREATMENT OF DISTAL EMBOLIZATION DURING SVG PCI

SVG PCIs represent approximately 6% of all PCIs performed in the United States (2,19). The 2 key limitations of SVG PCI are: 1) distal embolization and no reflow in the acute phase; and 2) high rates of restenosis and/or SVG disease progression during follow-up.

SVG PCI has high risk for no reflow, likely due to embolization of atheromatous material to the distal vasculature and intense vasospasm caused by microembolization of platelet-rich thrombi that release vasoactive agents resulting in microvascular obstruction (1,20). No reflow during SVG PCI has been associated with high risk of subsequent adverse cardiac events. Hong et al. (21) demonstrated that compared with patients who did not develop no reflow, those who did had higher risk for myocardial infarction (MI) (14.36% vs. 55.2%; $p = 0.036$) and death (13.33% vs. 52.19%; $p = 0.039$) during 5-year follow-up.

ABBREVIATIONS AND ACRONYMS

- BMS** = bare-metal stents
- CABG** = coronary artery bypass graft surgery
- CI** = confidence interval
- CTO** = chronic total occlusion
- DAPT** = dual-antiplatelet therapy
- DES** = drug-eluting stents
- EPD** = embolic protection device
- FFR** = fractional flow reserve
- IMA** = internal mammary artery
- LIMA** = left internal mammary artery
- MACE** = major adverse cardiac events
- MI** = myocardial infarction
- OR** = odds ratio
- PCI** = percutaneous coronary intervention
- SVG** = saphenous vein grafts

FIGURE 1 Progression of Coronary Artery Disease in Patients With Prior CABG

(2). CABG = coronary artery bypass graft surgery; NCDR = National Cardiovascular Data Registry; PCI = percutaneous coronary intervention; pts = patients; SVG = saphenous vein grafts.

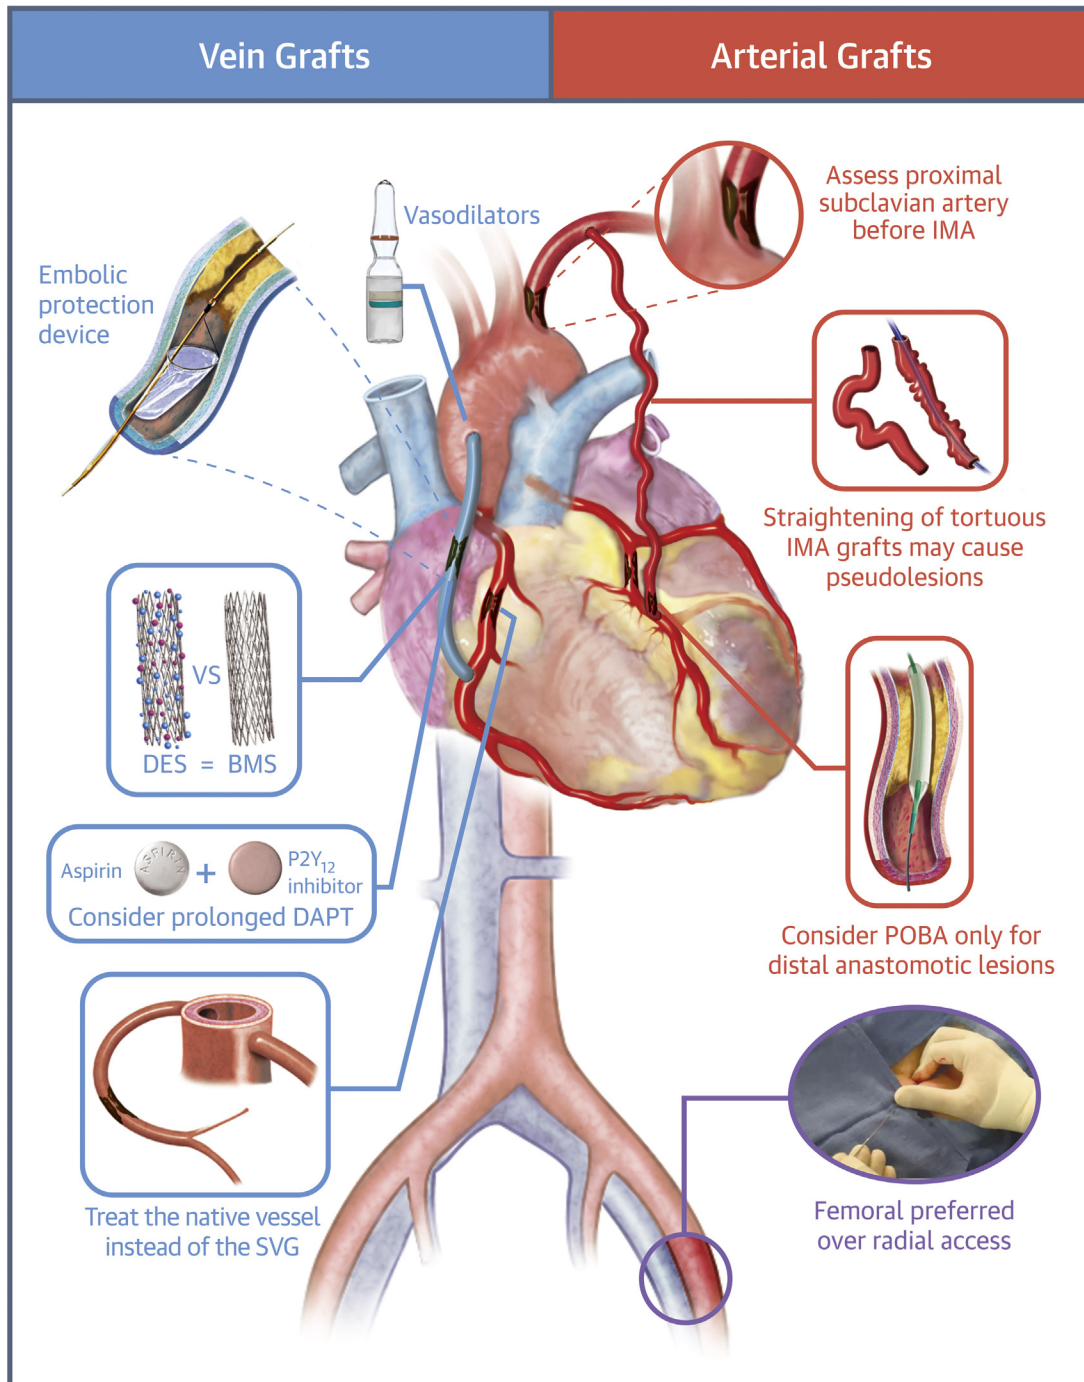

Several strategies can be used to reduce the risk of distal embolization and no reflow (Figure 2). The only strategy that has been tested in randomized controlled trials is use of embolic protection devices. Other strategies include vasodilator administration, direct stenting (22), and use of undersized stents (23). Nicardipine is often preferred due to prolonged duration of action and less hypotensive effect and is often administered both before and after PCI. Other pharmacological agents such as adenosine, nitroprusside, and verapamil have also shown to prevent or improve no reflow events after intragraft administration (24-31). By contrast, platelet glycoprotein IIb/IIIa receptor inhibitors can cause harm during SVG intervention and should not be used routinely in SVG PCI (32). Laser may result in “vaporization” of thrombus and plaque components, potentially reducing the risk for distal embolization; however, it may lead to perforation, especially in highly angulated SVGs (33).

The only currently available embolic protection devices (EPDs) are filters: the FilterWire (Boston Scientific, Natick, Massachusetts) and the Spider (Medtronic, Santa Rosa, California) (Table 2) (34-40). Both require a distal landing zone for deployment; hence, they cannot be used in distal anastomotic lesions (unless the filter is deployed in the native coronary artery). The FilterWire is directly advanced through the target SVG lesion, whereas the Spider can be delivered over any guidewire advanced through the

SVG lesion. A proximal occlusion device (Proxis, St. Jude Medical, Saint Paul, Minnesota) was discontinued in 2012, and a distal occlusion device (Guardwire, Medtronic) was discontinued in 2017.

In the first randomized controlled trial of EPD versus no EPD for SVG (SAFER [Saphenous vein graft Angioplasty Free of Emboli Randomized] trial) that randomized 801 patients, use of the Guardwire was associated with lower incidence of MI (8.6% vs. 14.7%; p = 0.008) and “no reflow” (3% vs. 9%; p = 0.02) (36). Given the results of the SAFER trial, subsequent EPD trials in SVG PCI compared one device with another. The FIRE (FilterWire EX Randomized Evaluation) trial compared the FilterWire with the GuardWire in 651 patients undergoing SVG-PCI. Thirty-day major adverse cardiac events (MACE) rates were similar between the 2 groups (9.9% of FilterWire EX group vs. 11.6% of GuardWire group; p = 0.0008 for noninferiority) (35). In the SPIDER (Saphenous vein graft Protection In a Distal Embolic protection Randomized) trial, the SpiderRX filter was compared with FilterWire and GuardWire in 700 patients and was shown to be noninferior with comparable 30-day MACE rates (9.1% vs. 8.4%; p = 0.01 for noninferiority) (34). In a pooled analysis of 5 controlled trials and 1 registry evaluating EPDs in SVG-PCI, Coolong et al. (41) showed that the benefit of EPDs for reducing 30-day MACE was consistent across various degrees of SVG degeneration scores.

CENTRAL ILLUSTRATION Cardiac Catheterization in Patients With Prior CABG: A Systematic Approach

Xenogiannis, I. et al. *J Am Coll Cardiol Interv.* 2019;12(17):1635-49.

BMS = bare-metal stents; CABG = coronary artery bypass graft surgery; DAPT = dual-antiplatelet therapy; DES = drug-eluting stents; IMA = internal mammary artery; POBA = plain old balloon angioplasty; SVG = saphenous vein grafts.

TABLE 1 Published Studies on Bypass Graft Physiological Assessment

First Author (Year) (Ref. #)	Number of Patients	Objective	Major Findings
Aqel et al. (2008) (9)	10 patients with 10 SVG lesions with >50% stenosis	Access the physiological significance of SVG lesions with FFR	The sensitivity, specificity, PPV, NPV, and accuracy of FFR <0.75 for the detection of ischemia on stress MPI were 50%, 75%, 33%, 85%, and 70%, respectively
Di Serafino et al. (2013) (10)	233 patients with CABG and intermediate graft lesions (venous and arterial)	Compare the outcomes between FFR-guided and angiography-guided PCI	Patients with arterial graft stenosis had lower rates of MACE and TVF in the FFR-guided group. Patients with SVG stenosis had no significant difference for both MACE and TVF between the 2 groups
Almomani et al. (2018) (8)	33 patients with SVG lesions vs. 532 patients with native vessel disease	Compare the prognostic value of deferring intervention in lesions with FFR >0.8 in native coronary artery lesions vs. aortocoronary bypass grafts	MACE and TVF rates were significantly higher in the SVG group vs. the native vessel group (36% vs. 21%; p = 0.01 and 27% vs. 14%; p = 0.01)

CABG = coronary artery bypass surgery; FFR = fractional flow reserve; MACE= major adverse cardiac events; MPI = myocardial perfusion imaging; NPV = negative predictive value; PCI = percutaneous intervention; PPV = positive predictive value; SVG = saphenous vein graft; TVF = target vessel failure.

Despite the aforementioned trials and the American College of Cardiology/American Heart Association guideline recommendation to use EPDs in SVG PCI when technically feasible (Class I, Level of Evidence: B), EPDs remain underused: they were used in only 22% of patients undergoing SVG PCI in the United States (42-44) and in an even lower proportion in other countries, likely due to concerns over cost,

prolongation of the procedure, and lack of expertise in use of those devices. The 2018 European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS) changed the EPD recommendation to Class IIa (Level of Evidence: B) from Class I (Level of Evidence: B) (45), referencing observational studies that did not find an association between EPD use and improved clinical outcomes (46,47). However, observational studies comparing EPD use versus no EPD use are subject to significant selection bias (higher risk lesions are more likely to be treated with an EPD), therefore their impact on clinical practice should be limited. Prospective, randomized trials of EPDs in SVG PCI would be optimal, but are unlikely to be performed. EPDs may not be required for in-stent restenotic lesions that have low risk for distal embolization (48). Recurrent SVG in-stent restenosis may respond to brachytherapy (49).

STENT SELECTION IN SVG PCI

Saphenous vein graft lesions have high rates of in-stent restenosis, which often presents as an acute coronary syndrome (50-52). Whether drug-eluting stents (DES) improve outcomes compared with bare-metal stents (BMS) in SVG lesions has been examined in 6 prospective randomized trials (Table 3) (50-59). During long-term follow-up, the 2 larger studies showed no difference between DES and BMS (54,56), and another showed worse outcomes with DES (59). In a meta-analysis of the 6 previously mentioned randomized trials by Kheiri et al. (60), there were no significant differences between DES and BMS in the long-term incidence of MACE, target lesion revascularization, target vessel revascularization, stent thrombosis, and all-cause mortality.

TABLE 2 Published Trials of EPDs in SVG Interventions

Study (Ref. #)	Year	Number of Cases	Primary Endpoint	EPD Event Rate (%)	Control Group Event Rate (%)	p Value Superiority
EPD vs. No EPD						
SAFER (37)	2002	801	30-day composite of death, MI, emergency CABG, or TLR	(Guardwire) 9.6	16.5	0.004
EPD vs. Another EPD

Because BMS and DES provide similar outcomes in SVGs, BMS should be preferred in countries with significant difference in the prices of DES and BMS.

There are several potential explanations for the failure of DES to improve outcomes as compared with BMS. First, the pathophysiology and physical history of SVG disease differs from that of native

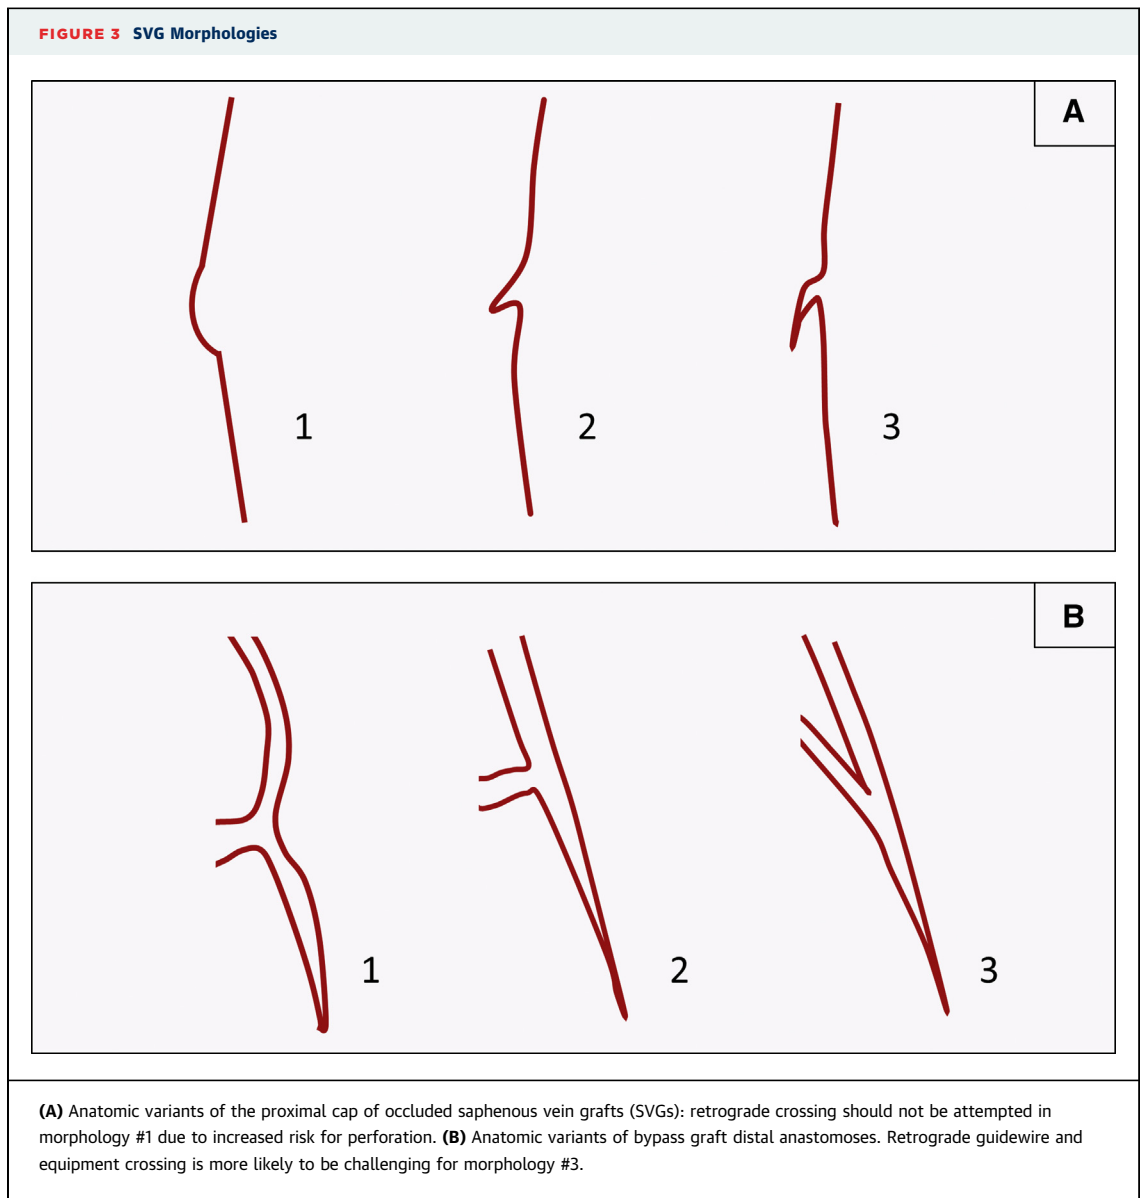

coronary arteries. Whereas atherosclerosis in coronary arteries takes decades to develop, accelerated atherosclerosis is observed in SVGs within months to years, often in a more concentric and diffuse pattern with less well-defined fibrous cap that likely responds differently to DES. Second, neo-atherosclerosis occurs earlier in DES compared with

TABLE 3 Randomized Controlled Trials of DES Versus BMS in SVG Lesions

ADEPT = Comparison between the STENTYS self-apposing bare metal and paclitaxel-eluting coronary stents for the treatment of saphenous vein grafts; BASKET-SAVAGE = Basel Kosten Effektivitäts Trial-Saphenous Venous Graft Angioplasty Using Glycoprotein 2b/3a Receptor Inhibitors and Drug-Eluting Stents trial; BMS = bare-metal stents; DES = drug-eluting stents; DIVA = Drug-Eluting Stents vs. Bare Metal Stents In Saphenous Vein graft Angioplasty; ISAR-CABG = Is Drug-Eluting-Stenting Associated with Improved Results in Coronary Artery Bypass Grafts? trial; RRISC = Reduction of Restenosis In Saphenous vein grafts with Cypher™ sirolimus-eluting stent trial; SOS = Stenting Of Saphenous vein grafts trial; other abbreviations as in Tables 1 and 2.

BMS, which may lead to a catch-up phenomenon (61,62). Third, thin-strut BMS may have lower risk for restenosis in SVGs than thicker strut stents that were used in most prior studies. Fourth, most DES versus BMS studies had mandatory angiography follow-up and were not blinded (50,52,53,57), which may bias outcomes in favor of DES (oculostenotic reflex). The DIVA (Drug-Eluting Stents vs. Bare Metal Stents In Saphenous Vein Graft Angioplasty) trial, the more recent randomized controlled trial that demonstrated no benefit of DES over BMS used blinding and did not mandate routine angiographic follow-up (54).

EARLY POST-OPERATIVE GRAFT FAILURE, ACUTE AND CHRONIC TOTAL SVG OCCLUSIONS

Graft failure during the early post-operative period occurs in up to 12% of the grafts, with approximately 3% of the patients developing symptoms (63). Graft occlusion rates are higher for vein grafts (3% to 12% before discharge) compared with radial artery (3% to 4%) and internal mammary artery (IMA) (1% to 2.5%) grafts (64). Potential causes include conduit defects, suboptimal anastomosis technique, poor native vessel runoff, and competitive flow with the native vessel.

Graft patency is higher when anastomosed to highly stenosed native coronary arteries: in a study of 164 patients who underwent pre-CABG FFR, graft occlusion at coronary angiography after 1 year was 8.9% for bypass grafts on functionally significant lesions (FFR <0.75) versus 21.4% for bypass grafts on lesions with FFR ≥0.75 (65). Conversely, there is an accelerated rate of disease progression in bypassed native coronary vessels, especially for non-left anterior descending artery vessels and when SVGs are used as compared with arterial grafts (66).

Unless the diagnosis of acute graft failure is made in the operating room, PCI is preferred for symptomatic graft failure. PCI is best performed in the corresponding native coronary artery instead of the bypass graft, if possible, in part because PCI of the graft anastomosis may lead to suture dehiscence and perforation (45). Redo CABG is recommended when coronary anatomy is not suitable for PCI, a large territory of myocardium is under jeopardy, multiple significant grafts are occluded, or in case of anastomotic lesions (46,67).

Acute SVG occlusions carry a high risk for short- and long-term adverse outcomes. Welsh et al. (68) demonstrated that prior CABG patients presenting

with an ST-segment elevation myocardial infarction had similar outcomes compared with patients without prior CABG when the infarct-related artery was a native coronary artery; however, 90-day mortality was much higher in prior CABG patients whose culprit vessel was a SVG (19% vs. 5.7%; p = 0.05). Thrombosed SVGs often have large thrombotic burden which can be approached with thrombectomy and use of embolic protection devices (69). Aspiration thrombectomy is preferred over rheolytic thrombectomy to minimize the risk for distal embolization and adverse outcomes (70). Suction should be maintained until removal of the aspiration thrombectomy catheter from the guide catheter for optimal thrombus retrieval and reduction of the systemic thromboembolism risk. Occasionally, aspiration through a deeply intubated guide catheter or guide catheter extension (balloon-assisted deep intubation–BADI) may be required for retrieval of very large thrombi. Use of laser is another option for such patients, whereas thrombolytic administration has been associated with poor outcomes and is generally avoided (71).

ST-segment elevation myocardial infarction due to SVG obstruction can be very challenging to treat. Given the suboptimal results of thrombolytic therapy

TABLE 4 Major Studies Comparing Bypass Graft Versus Native Coronary Artery PCI

First Author (Year) (Ref. #)	N	Endpoint	Bypass Graft PCI	Native Coronary Artery PCI	p Value	Comments

in occluded SVGs, PCI is the preferred reperfusion modality (71). Sometimes, identifying and engaging the grafts can be challenging, often requiring multiple catheters or aortography that may delay reperfusion (72). Use of embolic protection may be useful in such cases, although irreversible injury may have already occurred. SVG lesions are highly friable and rich in thrombus, and carry high risk for no reflow. Thrombolysis In Myocardial Infarction (TIMI) flow grade 3 post-PCI is achieved less frequently in patients who had SVG as the culprit vessel compared with patients who had a native coronary artery as the culprit vessel, and such patients had higher in-hospital and 30-day mortality and 1-year MACE rates (73,74).

Because of high risk for restenosis, SVG CTOs should generally not be recanalized (Class III indication, Level of Evidence: C) (42), unless no other treatment options exist. Occluded SVGs can be used, however, for retrograde crossing of the corresponding native coronary artery if the occlusion morphology is favorable (Figure 3).

LEFT INTERNAL MAMMARY ARTERY AND ARTERIAL GRAFT PERCUTANEOUS CORONARY INTERVENTION

PCI of arterial grafts and especially of the LIMA is much less common than SVG PCI. The 2 main reasons are the better rates of LIMA patency over SVGs and

possibly performance of redo CABG in cases of LIMA failure (Figure 4). Redo CABG is generally avoided in patients with a patent IMA graft to the left anterior descending coronary artery (75).

There should be high threshold for performing PCI through IMA grafts, given the high risk for ischemia and complications. Straightening of a tortuous LIMA during the advancement of guidewires and microcatheters may lead to pseudolesions (the so-called “accordioning effect”), that can lead to flow compromise and ischemia. Pseudolesions must be differentiated from vasospasm and dissection. Administration of intravenous vasodilators will be ineffective in the presence of the pseudolesions, which should correct with guidewire withdrawal (76). Deep guide intubation and use of guide catheter extensions may lead to IMA dissection and/or perforation (77,78). Despite the aforementioned limitations, PCI to IMA lesions has been associated with higher rates of restoration of TIMI flow grade 3 and lower rates of periprocedural complications compared with SVG PCI (79). IMA anastomotic lesions may be best treated with balloon angioplasty, whereas proximal and mid-segment lesions are stented in most cases (80). Gruberg et al. (81) analyzed 174 patients who underwent PCI of 128 IMA anastomotic lesions and found a higher need for repeat revascularization after stenting (33%) as compared with balloon angioplasty only (4.3%). Sharma et al. (82) also reported worse

outcomes with stenting compared with angioplasty alone at the anastomotic site (25% vs. 4.2%; $p = 0.006$) in 288 patients with 311 IMA lesions.

In patients with IMA grafts, the proximal subclavian artery should be evaluated, because severe lesions in this location could lead to coronary ischemia and even acute coronary syndromes (83). Subclavian artery stenting can be an effective treatment in such cases.

NATIVE CORONARY ARTERY PCI IN PRIOR CABG PATIENTS

Most PCIs (approximately two-thirds) performed in prior CABG patients are in native coronary artery lesions (2,84). Native coronary artery lesions in prior CABG patients are often complex, with high rates of calcification, tortuosity, and CTOs. The bypass grafts can often be used for retrograde crossing in such patients, although wiring upstream from the distal anastomosis can be challenging (Figure 3). Shortened guiding catheters are especially recommended for PCI of the distal native vessels through the IMA and also retrograde techniques. Advanced PCI techniques, such as use of atherectomy and CTO PCI are, therefore, often needed (85). Nevertheless, outcomes after native coronary artery PCI are better than outcomes post-SVG PCI in multiple series (Table 4) (1,2,84,86-90).

In patients presenting with SVG lesions, several operators advocate treating the native coronary artery instead, given the high short- and long-term risks of SVG PCI. The 2018 ESC/EACTS guidelines on myocardial revascularization state that PCI to a native vessel should be preferred over PCI of the bypass graft (Class IIa, Level of Evidence: C) (45). Decision making can be challenging, however, as the corresponding native coronary artery lesions are often complex to treat or even totally occluded (often CTOs). One approach is to treat the native coronary artery when it is simple or when both SVG PCI and native coronary PCI are complex, and there is local expertise in treating such lesions (Figure 4). This could also be done in a staged manner: the culprit SVG lesion is initially treated (especially for patients presenting with acute coronary syndromes who have complex native coronary artery lesions), followed by PCI of the native coronary artery weeks or months later (91). If the thrombosed SVG cannot be recanalized, PCI of the native coronary artery can sometimes be performed (92). Because SVGs that become occluded due to thrombus have very high rates of reocclusion, staged PCI of the corresponding native

coronary artery should be considered after the initial procedure. In such cases, stenting the distal SVG anastomosis should be avoided, if possible, as it could hinder subsequent treatment of the native coronary vessel. This conceptually appealing approach will need to be validated in clinical studies.

Remaining flow in the SVG after successful native vessel PCI has been a source of concern because competitive flow from the SVG can lead to native stent thrombosis (93,94). Some operators advocate routine SVG coiling after treating the native coronary artery although robust data are missing (95).

COMPLICATIONS

Due to the need to engage and visualize the bypass grafts (and the often high complexity of treated lesions) angiography and PCI in prior CABG patients requires longer procedural and fluoroscopy time, higher radiation dose, and larger volume of contrast (96-98). As a result (and also because of worse baseline renal function), the risk for contrast nephropathy and possibly hemodialysis is increased in those patients who have had prior CABG compared with those who have not (93,97,99).

Even though coronary perforations were previously considered to be “innocent” complications in prior CABG patients due to pericardial adhesions preventing formation of a pericardial effusion and tamponade, it is now appreciated that they can be lethal events. Coronary perforation in prior CABG patients can lead to loculated hematomas resulting in cardiac chamber compromise and hemodynamic collapse (dry tamponade). In the OPEN-CTO (Outcomes, Patient Health Status, and Efficiency in Chronic Total Occlusion Hybrid Procedures) database, the perforation rate in post-CABG patients was approximately 7%. Four perforations that led to death occurred in the 365 patients with prior CABG (1.1%) (100). Such loculated effusions may require surgery or computed tomography-guided drainage for treatment. Prompt identification and treatment of coronary or graft perforation is, therefore, critical in prior CABG patients (101,102).

POST-PROCEDURAL ANTITHROMBOTIC THERAPY

Long-term dual-antiplatelet therapy (DAPT) is conceptually appealing in prior CABG patients, as they often have extensive, multilevel atherosclerotic disease and high risk for subsequent adverse cardiovascular events. In a meta-analysis of 22 studies comparing DAPT to aspirin alone following CABG,

DAPT was associated with lower cardiovascular mortality (odds ratio [OR]: 0.67; $p = 0.02$) and a trend toward lower all-cause mortality (OR: 0.78; $p = 0.08$), although there was no difference when the analysis was confined to randomized controlled trials. SVG occlusion up to 1 year after CABG was significantly lower with DAPT overall (OR: 0.64; $p < 0.01$) and in the subset of randomized controlled trials (OR: 0.58; $p < 0.01$). Importantly, patients who were treated with DAPT for >6 months had lower stroke rates (OR: 0.47; $p = 0.04$) but higher incidence of major bleeding (OR: 1.31; $p = 0.03$) (103).

In another meta-analysis of 9 randomized controlled trials, patients who received ticagrelor or prasugrel in addition to aspirin had lower mortality compared with patients taking clopidogrel and aspirin (relative risk: 0.49; 95% confidence interval [CI]: 0.33 to 0.71; $p = 0.0002$), whereas there was no significant difference when clopidogrel plus aspirin was compared with aspirin monotherapy (104). In a subanalysis of the PLATO (Platelet Inhibition and Patient Outcomes) trial, the reduction of the primary endpoint of cardiovascular death, MI, and stroke was not statistically significant in post-CABG patients (19.6% vs. 21.4%; adjusted hazard ratio: 0.91 [interquartile range: 0.67 to 1.24]) (105). Large, randomized trials are needed in order to clarify the usefulness of DAPT in different clinical settings (acute coronary syndromes vs. stable coronary artery disease) and the optimal antiplatelet combination.

In a study of 603 patients who underwent SVG PCI, those taking clopidogrel in addition to aspirin for more than 2 years had lower rates of MI or death during a 5-year follow-up after the cessation of clopidogrel, compared with patients who were taking clopidogrel for a shorter time period (106). In the

DAPT (Dual Antiplatelet Therapy) study, patients who underwent SVG PCI had better outcomes with 30-month versus 12-month DAPT (107,108). Administration of DAPT for a longer duration than is usually recommended after native vessel PCI (generally 6 months for stable coronary disease and 1 year for acute coronary events) in patients undergoing SVG PCI, therefore, may be beneficial.

Whether anticoagulation can reduce bypass graft failure and improve clinical outcomes after CABG remains controversial. In a substudy of COMPASS (Cardiovascular Outcomes for People Using Anti-coagulation StrategieS) trial, the combination of 2.5 mg of rivaroxaban twice per day with aspirin did not reduce the incidence of graft failure in patients with prior CABG compared with aspirin administration alone (113 [9.1%] vs. 91 [8.0%]; OR: 1.13; 95% CI: 0.82 to 1.57; $p = 0.45$). It also did not reduce the composite endpoint of cardiovascular death, MI, and stroke (12 [2.4%] vs. 16 [3.5%], hazard ratio: 0.69; 95% CI: 0.33 to 1.47; $p = 0.34$) (109).

CONCLUSIONS

Prior CABG patients undergoing cardiac catheterization have increased risk for complications and often require complex procedures. Several new studies have advanced our understanding of the optimal approach to cardiac catheterization and PCI in these high-risk patients.
